Managing body reserves is critical for successful cow management and requires an accurate assessment of the cow's 'condition'. Body condition scoring is an important aspect of metabolic diseases of farm animals. Body weight alone is not a valid indicator of body reserves, as cows of a specific weight may be tall and thin or short and fat. The energy stores may vary by as much as 40% in cows of similar body weight, which emphasizes the futility and inaccuracy of relying on body weight alone as an index of cow condition. In addition, because tissue mobilization in early lactation occurs as feed intake is increasing, decreases in body tissue weight can be masked by enhanced fill of the gastrointestinal tract, so that body weight changes do not reflect changes in adipose tissue and lean tissue weight. There is a strong positive relationship ($r^2 = 0.86$) between body condition score (BCS) and the proportion of physically dissected fat in Friesian cows. Therefore, the visual or tactile (palpation) appraisal of the cow's body condition score provides a good assessment of body fat reserves, ignoring, or minimizing the effect of, frame size and intestinal contents. Most animal and dairy scientists acknowledge successfully manipulating BCS as an important management factor, influencing or having a relationship to animal health, milk production, and reproduction in the modern dairy cow. For example, cows which lost 0.5–1.0 point in BCS between parturition and first service achieved pregnancy rate to first service of 53%, while those losing >1.0 point achieved a rate of 17%. In a seasonal pasture-based system for Holstein–Friesian cows, it is necessary to maintain a BCS at $\geq 2.75$ during the breeding season. Body condition score is important in achieving good reproductive performance. Loss of body condition between calving and first service should be restricted to 0.5 BCS to avoid a detrimental effect on reproductive performance.

BCS is a subjective method of assessing the amount of metabolizable energy stored in fat and muscle (body reserves) on a live animal. BCS in dairy cows is done using a variety of scales and systems. This method involves palpating the cow to assess the amount of tissue under the skin. Scoring body condition and assessing changes in the body condition of dairy cattle have become strategic tools in both farm management and research. BCS is being researched worldwide. But international sharing, comparing, and use of data generated are limited because different BCS systems are used. There is difficulty in interpreting the literature because of variability in the way authors apply scoring methods. In the USA, Canada, and Ireland a 5-point BCS system is used for dairy cows, whereas Australia and New Zealand use 8- and 10-point scales, respectively. The following scoring method is recommended for the 0–5 scale. The BCS chart adapted from Edmonson et al. appears in Figure 29.1.

Score: 0
- Condition: Very poor
- Tailhead area: Deep cavity under tail and around tailhead. Skin drawn tight over pelvis with no tissue detectable inbetween
- Loin area: No fatty tissue felt. Shapes of transverse processes clearly visible
- Animal appears emaciated

Score: 1
- Condition: Poor
- Tailhead area: Cavity present around tailhead. No fatty tissue felt between skin and pelvis, but skin is supple
Fig. 29.1 Body condition scoring chart adopted from Edmonson et al. (1989).

- Loin area: Ends of transverse processes sharp to touch and dorsal surfaces can be easily felt. Deep depression in loin.

Score: 2
- Condition: Moderate
- Tailhead area: Shallow cavity lined with fatty tissue apparent at tailhead. Some fatty tissue felt under the skin. Pelvis easily felt.
- Loin area: Ends of transverse processes feel rounded but dorsal surfaces felt only with pressure. Depression visible in loin.

Score: 3
- Condition: Good
- Tailhead area: Fatty tissue easily felt over the whole area. Skin appears smooth but pelvis can be felt
- Loin area: Ends of transverse processes can be felt with pressure but thick layer of tissue dorsum. Slight depression visible in loin.

Score: 4
- Condition: Fat
- Tailhead area: Folds of soft fatty tissue present
- Patches of fat apparent under skin. Pelvis felt only with firm pressure
- Loin area: Transverse processes cannot be felt even with firm pressure. No depression visible in loin between backbone and hip bones.

Score: 5
- Condition: Grossly fat
- Tailhead area: Tailhead buried in fatty tissue. Skin distended. No part of pelvis felt even with firm pressure
- Loin area: Folds of fatty tissue over transverse processes. Bone structure cannot be felt.

Relationships among international body condition scoring
The New Zealand 10-point scale was compared with the scoring systems in the USA, Ireland, and Australia by trained assessors. Cows were assessed visually in the USA and Australia and in Ireland, cows were assessed by palpating key areas of the cow's body. Significant positive linear relationships were found between the New Zealand 10-point scale and the other scoring systems. The relationship between the 10-point BCS scale used in New Zealand and Ireland and the USA are summarized in Table 29.4.
Table 29.4 Relationship between the 10-point BCS scale used in New Zealand and the 5-point BCS scale used in Ireland and the USA, and the 8-point scale used in Australia.

**REFERENCES**

**ETIOLOGY**
A depression of the levels of ionized calcium in tissue fluids is the basic biochemical defect in milk fever. A transient period of subclinical hypocalcemia (total plasma calcium <1.9 mmol/L) occurs at the onset of lactation caused by an imbalance between calcium output in the colostrum and influx of calcium to the extracellular pool from intestine and bone. The onset of lactation results in a sudden large demand on the calcium homeostasis. A cow producing 10 kg of colostrum (2.3 g of Ca/kg) will lose 23 g of calcium in a single milking. This is about nine times as much calcium as that present in the entire plasma calcium pool of the cow. Calcium lost from the plasma pool must be replaced by increasing intestinal absorption and bone resorption of calcium. During the dry period, calcium requirements are minimal at about 10–12 g/d. At parturition, the cow must mobilize about 30 g or more of calcium into the calcium pool per day. Hypocalcemia occurs in spite of apparently adequate function of the parathyroid and vitamin D endocrine system and most cows adapt within 48 h after calving by increases in plasma concentrations of parathyroid hormone and 1,25-(OH)2D vitamin at the onset of the hypocalcemia and mobilize calcium by increasing intestinal absorption and bone resorption.

About 5–20% of adult cows are unable to maintain plasma calcium and consequently develop severe hypocalcemia (total plasma calcium, 1.0–1.4 mmol/L) or clinical milk fever which requires treatment.

**TIME OF OCCURRENCE**
In cattle, milk fever occurs at three main stages in the lactation cycle. Most prepartum cases occur in the last few days of pregnancy and during parturition but rare cases occur several weeks before calving. Some cases will occur a few hours before parturition or at the time of parturition when the attendant expects the cow to calve and the second stage of parturition does not occur because of uterine inertia due to hypocalcemia. Most cases occur within the first 48 h after calving and the danger period extends up to about the 10th postpartum day. Up to 20% of cases can occur subsequent to the 8th day after calving. In such cases the declines in serum calcium and phosphorous levels are smaller and the increases in serum magnesium levels are greater than in parturient cows. The clinical signs are also less severe and there are fewer relapses after treatment. Occasional cases occur 6–8 weeks after parturition (mid-lactation). Such cases are most often recurrences of the disease in highly susceptible cows which were affected at calving. Undue fatigue and excitement may precipitate such attacks and there is a special susceptibility at estrus. In the latter case, the depression of appetite by the elevation of blood estrogen levels may be a significant factor.

The plasma levels of phosphorus also decrease and the plasma levels of magnesium increase as cows at the time of parturition. Hypocalcemic episodes lasting 1–2 days may occur two or three times with a periodicity of about 9 days. These cows are referred to as ‘calcium cyclers’ and the magnitude of the cycling was increased by feeding cows 200 g/d of 1,25-dihydroxyvitamin D for 5 days around the time of parturition. Fluctuations in the intestinal absorption of calcium during this period may be the cause of calcium cycling. Subclinical hypocalcemia is of major significance because it inhibits reticuloosmer motility, which affects appetite and exacerbates the negative energy balance already existing in the cow in 1st month of lactation.

Episodes of subclinical hypocalcemia occur in up to 50% of adult cows during the first few weeks of lactation. It is suggested that these calcium cyclers are...
animals whose calcium homeostatic mechanisms have not adapted well enough.

**Stressors.** Starvation for 48 h also causes severe depression of serum calcium levels and this may be of importance in the production of hypocalcemic paresis in this species at times other than in the postparturient period. Pregnant beef cattle may develop hypocalcemic paresis during the winter months when they are fed on poor-quality roughage; within a group of such cows the less aggressive ones may suffer selective malnutrition. The disease has also occurred in beef cows affected with diarrhea of undetermined etiology. As another explanation of the heightened susceptibility of cows at estrus, a possible depression of the degree of ionization of calcium under the influence of increased serum estrogens is suggested. However, there were no significant differences in total serum calcium or plasma ionized calcium values in cows from 48 h before and after estrus.

Hypocalcemic syndromes in ruminants are also observed at times other than related to parturition. Thus, it can be part of an early or mild overeating of fermentable carbohydrate. The IV administration of certain aminoglycosides, especially neomycin, ethidrostreptomycin and gentamicin, may cause a reduction in the degree of ionization of serum calcium and a syndrome similar to milk fever. Oral dosing with zinc oxide (40 or 120 mg Zn/kg BW) as a prophylaxis against facial eczema in ewes causes a serious fall in serum calcium levels 24 h later. Caution is recommended with the use of these drugs in parturient cows.

**Sheep and goats**

In sheep, the disease commonly occurs in outbreaks in groups of ewes exposed to forced exercise, long-distance transport, sudden deprivation of food and grazing on oxalate-containing plants or green cereal crops. These circumstances commonly precipitate outbreaks of hypocalcemic paresis in sheep, mature ewes are the most susceptible, particularly in the period from 6 weeks before to 10 weeks after lambing. Up to 25% of the flock may be affected at one time. The disease also occurs in young sheep up to about 1 year old, especially when they graze green oats, but also when pasture is short in winter and spring, as in southeast Australia. The disease is manifested by paresis but in the rest of the flock poor growth, lameness and bone fragility can be detected. A sudden deprivation of feed or forced exercise of ewes can cause marked depression of the serum calcium levels. However, ewes are in a susceptible state in early lactation because they are in negative calcium balance. In late lactation a state of positive balance is due to a low rate of bone resorption. There is an unexplained occurrence of hypocalcemia in sheep fed on hay when they are supplemented with an energy-rich concentrate which increases their calcium intake. Some of the concentrates fed to ewes in feedlots contain supplementary magnesium as a prevention against hypomagnesemia, which may affect calcium absorption and precipitate hypocalcemia in susceptible ewes. Another occurrence in ewes is at the end of a drought when the pasture growth is lush and very low in calcium content. The incidence may be as high as 10% and the case-fatality rate 20% in ewe flocks in late pregnancy or early lactation.

Hypocalcemia in sheep depresses endogenous glucose production and in late pregnancy in combination with hyperketonemia, facilitates the development of pregnancy toxemia.4

In goats, a depression in serum levels of calcium and phosphorus occurs similar to that in cows but in ewes no such depression occurs at lambing and the intervention of a precipitating factor appears to be necessary to further reduce the serum calcium level below a critical point.

Milk ing goats become affected mostly during the 4-6-year age group. Cases occur before and after kidding, some later than 3 weeks after parturition. Clinical syndromes are identical to those in cows, including the two stages of ataxia and recumbency. Serum calcium levels are reduced from normal levels for parturient does of 9.4–3.6 mg/dL (2.35–0.9 mmol/L).

**Morbidity and case fatality**

Several epidemiological studies of milk fever have shown an incidence risk of 5–10%, calculated either as the lactational incidence or incidence per cow year.2 Generally the disease is sporadic but on individual farms the incidence may rarely reach 25–30% of high-risk cows. In Victoria, Australia, 85% of dairy herds calve in the spring and the incidence of milk fever ranges from 2% to 5%.3 With early treatment relatively few deaths occur in uncomplicated cases but incidental losses due to aspiration pneumonia, mastitis, and limb injuries may occur. From 75% to 85% of uncomplicated cases respond to calcium therapy alone. A proportion of these animals require more than one treatment, either because complete recovery is delayed, or because relapse occurs. The remaining 15–25% are either complicated by other conditions or incorrectly diagnosed.

**Subclinical hypocalcemia.** Subclinical hypocalcemia (total plasma calcium <1.9 mmol/L) occurs in dairy cattle during the first few weeks of lactation. The incidence of subclinical hypocalcemia based on measurement of blood calcium around the time of calving and later in lactation ranges from 23% to 39%.2 Up to 50% of aged cows may be unable to maintain plasma calcium above the lower normal limit (2.18 mmol/L) as defined by the 99% confidence interval of plasma calcium concentrations in cows outside the first month of lactation. In New Zealand, up to 40% of apparently normal cows may have subclinical hypocalcemia during the first 12 days of lactation.4 Up to 33% of cows grazing pasture in New Zealand may have subclinical hypocalcemia on the day of calving.

In the USDA National Animal Health Monitoring System Dairy study of 2002, 1446 cows from 480 dairy herds in 21 states were sampled within 48 h of parturition. Subclinical hypocalcemia increased with advancing age and represented 25.3%, 43.9%, and 57.8% of first, second, and third lactation cows, respectively.6 Of the groups studied, 38.7% were on a DCAD program and the incidence of hypocalcemia was significantly less in those animals on the DCAD program. Also, with normal calcium levels had lower serum NEFAs indicating that their energy status was better than those with hypocalcemia.

**Risk factors**

The literature on the risk factors associated with milk fever has been reviewed.7

**Animal risk factors**

Serum calcium levels decline in all adult cows at calving due to the onset of lactation. Serum calcium levels decline to lower levels in some cows than in others and it is this difference which results in the varying susceptibility of animals to parturient paresis.8 First-calf heifers rarely develop milk fever because while some degree of hypocalcemia occurs during the first few days of lactation, they are able to adapt rapidly to the high demands of calcium for lactation. With increasing age, this adaptation process is decreased and results in moderate-to-severe hypocalcemia in most adult cows. The adaptation mechanism is directly related to the efficiency of intestinal absorption of calcium, which decreases with increasing age.

**Calcium homeostasis.** Three factors affect calcium homeostasis and variations in one or more of them may be important in causing the disease in any individual:

1. Excessive loss of calcium in the colostrum beyond the capacity of absorption from the intestines and mobilization from the bones to replace Variations in susceptibility between cows could be due to variations in the concentration of calcium in the milk and the volume of milk secreted.
2. Impairment of absorption of calcium from the intestine at parturition.
3. Mobilization of calcium from storage in the skeleton may not be sufficiently rapid to maintain normal serum levels. The calcium mobilization rate and the immediately available calcium reserves are sufficiently reduced in cows in later pregnancy to render them incapable of withstanding the expected loss of calcium in the milk.

In older cows, bone resorption makes only a minor contribution to the total rate of calcium mobilization at parturition and is therefore of minor importance for the prevention of periparturient hypocalcemia. Osteoblasts are the only type of bone cell to express the 1,25-(OH)_{2}D receptor protein and the decrease in the numbers of osteoblasts with increasing age could delay the ability of bone to contribute calcium to the plasma calcium pool. It was once postulated that failure to secrete sufficient levels of parathyroid hormone or 1,25-dihydroxyvitamin D was the primary defect in cows which developed milk fever. While it is accepted that the calcium homeostatic mechanisms, regulated by parathyroid hormone and 1,25-dihydroxyvitamin D, fail to maintain normal blood calcium concentrations resulting in severe hypocalcemia, the nature of the endocrine defect is not well understood. It was also once thought that calcitonin, a hormone which inhibits bone calcium resorption was a cause of milk fever but this has not been demonstrated in cows with milk fever. Recent studies have shown that the secretion of parathyroid hormone and the production of 1,25-dihydroxyvitamin D is similar in most cows with or without milk fever. However, about 20% of cows treated for parturient paresis experience relapsing episodes of hypocalcemia which require further treatment. These cows fail to produce adequate levels of 1,25-dihydroxyvitamin D at the onset of lactation. Both relapsing and non-relapsing cows develop the same degree of hypocalcemia and secondary hyperparathyroidism, but production of 1,25-dihydroxyvitamin D is about two-fold greater in non-relapsing cows than relapsing cows. Following treatment of parturient hypocalcemia with calcium salts IV and restoration of ruminal and intestinal motility, non-relapsing cows establish calcium homeostasis over the next 3–4 days by increasing intestinal absorption of calcium which is activated by a sufficient level of 1,25-dihydroxyvitamin D. In relapsing cows, even when rumen and intestinal motility are restored after treatment, hypocalcemia and paresis are likely to occur because of insufficient plasma 1,25-dihydroxyvitamin D. These cows may remain in this stage of prolonged hypocalcemia for several days and only after a few days and several repeated treatments with calcium will the plasma levels of 1,25-dihydroxyvitamin D increase to an adequate level to maintain calcium homeostasis. It is also unlikely that the parathyroid hormone-related protein in the colostrum of milk fever cows is involved in the disease. Tissue 1,25-dihydroxyvitamin D receptor concentrations decline with age, which renders older cows less able to respond to 1,25-dihydroxyvitamin D. The intestinal 1,25-(OH)_{2}D receptor numbers decline with age in the cow and thus the older cow is less able to respond to the hormone and will take longer to adapt intestinal calcium absorption mechanisms to meet lactational demands for calcium.

A perplexing situation in dairy practice is the recently calved cow with peracute coliform mastitis which may also be mildly hypocalcemic and have some of the clinical signs of milk fever. The Escherichia coli endotoxin given IV depresses serum calcium and phosphate levels so that coliform mastitis may contribute to a degree of hypocalcemia in individual cows. However, there is no evidence that cows with peracute coliform mastitis require calcium therapy similar to that used in typical milk fever.

Body condition score (BCS). A high BCS increases the risk of milk fever. The odds ratio of milk fever with a BCS >4/5 on the first milk recording day after calving was 4.3 and cows with milk fever had a postpartum pre-disease 12 kg higher body weight compared with healthy cows indicating an increased risk of milk fever due to higher body weight. Cows with subclinical hypocalcemia in the winter period had significantly higher mean body weight over the 60 days post partum than normocalcemic cows but the effect was not significant in cows calving during the summer months.

Dietary and environmental risk factors
Several dietary factors of the pregnant cow during the prepartum period (last 4 weeks) can influence the incidence of milk fever in cattle.

Dietary calcium. Feeding more than 100 g of calcium daily during the dry period is associated with an increased incidence of milk fever. A 500 kg cow requires only about 31 g of calcium to meet daily maintenance and fetal demands in late gestation. When a cow is fed a high calcium diet (>100 g Ca/d), its daily requirement for calcium can be met almost entirely by passive absorption of dietary calcium. The active transport of calcium from the diet and bone calcium resorption mechanisms are homeostatically depressed and become quiescent. As a consequence, at calving, the cow is unable to use bone calcium stores or intestinal calcium absorption mechanisms and is susceptible to severe hypocalcemia until these mechanisms can be activated, which may take several days.

Feeding prepartum diets containing a low concentration of calcium prevents milk fever by activating calcium transport mechanisms in the intestine and bone prior to parturition, thus allowing the animal to adapt more rapidly to the lactational drain of calcium. Feeding diets high in calcium just before parturition may also lower the incidence of milk fever by increasing the absorption of calcium. This will provide sufficient calcium to overcome the relative lack of calcium from bone resorption which results from a high calcium intake.

In sheep, hypocalcemia may occur in pregnant ewes fed a calcium-deficient diet over a prolonged period. A high dietary level of magnesium in late pregnancy may also predispose to hypocalcemia in pregnant ewes but this has not been documented. Ewes fed a diet with a fixed cation excess (82.3 mEq/100 g DM) had higher urine pH and lower urine calcium concentrations, lower blood ionized calcium concentrations after an overnight fast and tended to develop hypocalcemia more rapidly after an ethylendiamine tetra-acetate (NaEDTA) infusion. This suggests that a dietary fixed cation–anion balance may be a risk factor for hypocalcemia in pregnant ewes.

Dietary phosphorus. Prepartum diets high in phosphorus (>80 g P/d) also increases the incidence of milk fever and the severity of hypocalcemia. High dietary levels of phosphorus increase the serum level of phosphorus which is inhibitory to the renal enzymes that catalyze production of 1,25-(OH)_{2}D, which when decreased reduce the intestinal calcium absorption mechanisms prepartum.

Dietary cation-anion difference (DCAD). The anion–cation dietary difference exerts a strong, linear effect on the incidence of milk fever. The dietary cation–anion balance in the prepartum diet may be more important than the level of dietary calcium as a risk factor for milk fever. Prepartum diets high in cations such as sodium and potassium are associated with an increased incidence of milk fever, while diets high in anions, especially chloride and sulfur, are associated with a decrease in the incidence of the disease. Alkaline diets containing an excessive concentration of sodium and potassium can result in an increased incidence of the disease. Most forages such as legumes
and grasses are high in potassium and are alkaline. Metabolic alkalosis predisposes cows to milk fever. Under most circumstances the alkalosis is induced by the potassium in the diet. The addition of anions to the diet of dairy cows prior to parturition effectively reduced the incidence of milk fever by inducing a metabolic acidosis which facilitates bone resorption of calcium.

The quantitative relationship between feed cations and anions predict the alkalogenic or acidogenic response in the animal or the DCAD. The difference between the number of cation and anion particles absorbed from the diet determines the pH of the blood. The cation–anion difference of a diet is commonly described in milliequivalents (mEq) per kg (dry matter) DM (mEq/kg DM) feed. This value is calculated as: DCAD = (Na⁺ + K⁺) – (Cl⁻ + S⁻).[10] Calcium, magnesium and phosphorus content of feeds will also affect acid–base status but are considered to have minor importance in the calculation of the DCAD. The DCAD equation describes how the ions contained in the feeds affect the metabolic processes in the body by the absorption and further metabolism and thereby causing changes in the systemic acid–base status. Systemic acidification induced by anionic supplementation affects the function of the parathyroid (PTH) hormone. The major effect of systemic acidification is to cause an increased response to PTH which results in increased retention of calcium and enhanced mobilization of calcium from bone. A total DCAD in the range of −100 to −200 mEq/kg feed DM is effective in controlling milk fever. Most natural feedstuffs fed to dairy cows will, on a molar basis, have a surplus of sodium and potassium compared with chloride and sulfur. A composite ration, with a negative DCAD value, is difficult to achieve in commercial dairy herd conditions.

A meta-analysis of 75 feeding trials designed to study the nutritional risk factors for milk fever in dairy cattle found that the prepartum dietary concentrations of S and dietary anion–cation balance [(Na⁺ + K⁺) – (Cl⁻ + S⁻)] were the two nutritional factors most strongly correlated to the incidence of milk fever.[2] Dietary S acts as a strong anion and reduces the risk of milk fever and increasing the dietary S concentrations lowers the odds ratio of developing milk fever. Increasing dietary Na and crude protein increased the odds ratios, but to a lesser extent.

The incidence of milk fever has been decreased by the addition of chloride and sulfur in excess relative to sodium and potassium in the prepartum diet of Holstein cows. High anion diets increase the plasma levels of 1,25-(OH)₂D prior to parturition, activating intestinal calcium absorption and possibly bone calcium resorption mechanisms prior to onset of lactation.[10] Monitoring the pH of urine is a sensitive method for assessing the risk of milk fever.[12] The urine pH within 48 h prior to parturition has a significant negative correlation with serum calcium and inorganic phosphorus. The sensitivity, specificity, positive and negative predictive values of urine pH test prior to parturition, using a cut off level of above pH 8.25, were 100%, 81%, 55%, and 100%, respectively.[12]

**Effects of milk fever and subclinical hypocalcemia.** There are several consequences of milk fever and subclinical hypocalcemia including its economic importance and the disease complications which may occur.

**ECONOMIC IMPORTANCE**

Unlike many years ago, the economic losses from milk fever have decreased because calcium borogluconate is an effective treatment which many owners can administer. Significant costs are associated with veterinary intervention and losses due to complications. However, while veterinarians now treat fewer cases of uncomplicated milk fever, there may be an increase in cases which are complicated by factors other than hypocalcemia.

The literature on the effects of clinical milk fever and subclinical hypocalcemia is difficult to interpret because of the complex relationships between milk production, parity of lactation, breed of cattle, epidemiological methods used, management systems being used, and the reproducibility of the clinical observations and the accuracy of the recording systems used.[2] In general, there is insufficient information available to document the consequences of milk fever and subclinical hypocalcemia. A summary of several consequences which have been examined follows here.

**Milk fever relapses.** Milk fever cases which need repeat treatment because of relapses increase the costs.

**Downer cow complications.** The downer cow syndrome associated with milk fever cases which fail to respond within a few hours and remain recumbent for several hours or several days before subsequently standing, or die, or are euthanized represents an important cause of economic loss because of treatment costs, long-term care costs, loss of milk production and loss of the value of the animal. Acute mastitis due to environmental pathogens is a common complication of prolonged recumbency in downer cows associated with milk fever. Some studies have found downer cows had a probability of 35% of being culled in the first 150 days of lactation and a relative risk of being culled of 29.2.[2]

**Dystocia and reproductive disease.** Hypocalcemia at the time of parturition can result in uterine inertia which may cause dystocia and uterine prolapse. In general, there is an increased risk of dystocia associated with milk fever whether the farmer or the veterinarian attends to the dystocia.[2]

**Retained placenta.** Several studies have found an increased risk of retained placenta following milk fever.[2]

**Metritis.** A few studies have found an indirect relationship between milk fever and subsequent metritis.[2]

**Milk production.** There is no reliable evidence that the occurrence of milk fever or subclinical hypocalcemia in cows which recover following treatment affects milk production in the subsequent lactation. Some studies have found a limited effect, no effect or even positive effect of milk fever on milk production.

**Mastitis.** An odds ratio of 8.1 or mastitis has been estimated; for coliform mastitis an odds ratio of 9.0 and for acute clinical mastitis a relative risk of 1.5 following milk fever have been found.[2]

**Displacement of abomasum.** Odds ratios ranging from 2.3 to 3.4 for left side displacement of the abomasum occurring in dairy cows with hypocalcemia at parturition have been estimated.[2]

**Ketosis.** Studies on the occurrence of ketosis following milk fever have found relative risks or odds ratios ranging from 1.3 to 8.9 and using all the confidence intervals the relative risks/odds ratios range from 1.1 to 15.3.[3]

**Body weight.** A temporary drop in body weight occurs in cows with milk fever but there is no long-term effect. In cows with subclinical hypocalcemia in early lactation there may be some weight loss compared with cows with normal levels of calcium.[3]

**Culling.** There may be an increased probability of culling cows which have had milk fever because of the complications or direct or indirect consequences associated with the disease.[2] There is some evidence of culling cows in early lactation because of milk fever but not in late lactation.

**PATHOGENESIS**

The literature on the role of acid–base physiology on the pathogenesis of parturient hypocalcemia and the application of the DCAD in theory and practice has been reviewed.[11]

**Hypocalcemia**

Plasma calcium concentration is normally maintained between 2.1 and 2.6 mmol/L (85.2 – 10.4 mg/dL). Almost all dairy cows will experience subclinical hypocalcemia, <1.8 mmol/L (7.5 mg/dL) within 24 h after calving. In some cows, the hypocalcemia is more severe, <1.25 mmol/L (5 mg/dL).
causing neuromuscular dysfunction resulting in clinical milk fever. Without treatment, levels may continue to decline to about 0.5 mmol/L (2 mg/dL) which is usually incompatible with life.13

Hypocalcemia is the cause of the signs of typical 'milk fever'. Atony of skeletal muscle and plain muscle are well-known physiological effects of hypocalcemia. Hypophosphatemia and variations in levels of serum magnesium also occur and have secondary roles. In experimental hypocalcemia in cattle, there is:

- A marked reduction in the stroke volume and cardiac output
- A 50% reduction in arterial blood pressure
- A reduction in ruminal and abomasal tone and motility.

Total plasma calcium concentration at calving is not significantly related to fat and protein-corrected milk yield at any lactation period.14

In rare cases, pathological changes in the myocardium of hypocalcemic parturient cows have been reported. The cows were hypocalcemic, recumbent, with tachycardia, arrhythmia, and dyspnea and failed to respond to calcium therapy, however, the cause of the lesions was not determined. The plasma natriuretic peptide concentrations were elevated indicating myocardial injury.15

Experimental hypocalcemia

The literature of Na2 EDTA induced hypocalcemia has been reviewed. A standardized flow rate of 1.2 mL/kg per hour of a 5% solution of Na2 EDTA until recumbency, results in changes in plasma ionized calcium, total calcium, inorganic phosphate and magnesium comparable with spontaneous milk fever. Induced hypocalcemia in cows results in a depression of frequency and amplitude of rumen contractions as early as 1.0 mmol/L of ionized serum calcium well before any clinical signs of hypocalcemia are detectable and while feeding behavior and rumination are still normal. The induction of subclinical hypocalcemia in cows results in a linear decrease in feed intake and chewing activity as the plasma ionized calcium decreases. The reduced feed intake was observable at ionized calcium below 0.9 mmol/L before the cows had developed other signs of hypocalcemia. Feed intake approached zero when ionized calcium declined to 0.6 mmol/L. This suggests that hypocalcemia may contribute to the reduction in feed intake prepartum and depresses the rumination process ultimately leading to anorexia. Hypercalcemia induced with calcium borogluconate depresses the frequency of rumen contractions but not the amplitude.16

In experimental hypocalcemia in sheep, blood flow is reduced by about 60% to all tissues except kidney, heart, lung, and bladder in which the reduction is not as high. During periods of prolonged hypocalcemia in cows and ewes, blood flow to skeletal muscles and the alimentary tract may be reduced to 60–70% of normal for a long period and predispose to the downer cow syndrome. In both cows and sheep there is a significant increase in PO2 causing an impairment of oxygen uptake by the pulmonary blood flow and an impairment of peripheral tissue uptake of oxygen during hypocalcemia in cows and sheep. Serum calcium and serum phosphate levels are significantly lower in clinical cases than in normal, comparable cows and there is some relationship between the severity of the signs and the degree of biochemical change. The complete response to the parenteral administration of calcium salts in most cases and the occurrence of tetany coincident with hypocalcemia after the IV administration of NaEDTA is further evidence of the importance of hypocalcemia. In addition, some signs indicative of parathyroprivical tetany in other species are observed in the initial stages of milk fever:

- Early excitement
- Muscle twitching
- Tetany, particularly of the hindlimbs
- Hypersensitivity and convulsive movements of the head and limbs

The IV infusion of EDTA into cows over a period of 4-8 h results in severe hypocalcemia and paresis which is a reliable model for the reproduction of the disease. In the experimental disease, there are additional signs such as excessive salivation, excessive lip and tongue actions and tail lifting. The serum muscle enzyme levels of creatine phosphokinase (CPK) and aminotransferase (AST) increase due to muscle injury associated with prolonged recumbency. Blood glucose levels increase and serum phosphorus and potassium levels decrease. A prolongation of the ST interval of the electrocardiogram (ECG) occurs, which may be useful as a diagnostic aid if suitable mini-ECG recorders could be made available for field use.

The prolonged infusion of EDTA in sheep over 18 h at a rate to induce hypocalcemia and maintain recumbency resulted in prolonged periods of recumbency ranging from 36 to 64 h before the animals were able to stand. There are also decreases in plasma sodium, plasma potassium, and erythrocyte potassium and prolonged increases in packed cell volumes, which suggests that fluid replacement therapy may be indicated in cattle with prolonged recumbency associated with hypocalcemia. A 4-h IV infusion of EDTA in high erythrocyte potassium and low erythrocyte potassium dairy cows causes decreases in plasma inorganic phosphorus and plasma potassium which are still below normal 24 h later. The AST(SGOT), CPK and packed cell volumes (PCVs) and white blood cell (WBC) counts are also elevated 24 h later. Plasma magnesium and erythrocyte sodium and potassium were decreased but this action was delayed. The increase in PCV was most pronounced in the low erythrocyte potassium cows, which may provide some clues about the pathogenesis of the downer cow syndrome. Some cows may have a more precipitate increase in PCVs due to loss of plasma volume and an inability to mobilize calcium. A 200 mL solution of 10 g of sodium chloride and 0.5 g of potassium chloride can be given IV to sheep safely over a period of 4–8 min to study the effects of administering such hypertonic solutions in downer animals.20

Hypomagnesemia

When hypomagnesemia coexists with hypocalcemia the clinical signs continue but with normal or higher than normal levels, relaxation, muscle weakness, depression, and coma supervene. It is likely that the hypocalcemic tetany is overcome by the relative hypermagnesemia (the ratio of Ca:Mg may change from 6:1 to 2:1) approximating the ratio at which magnesium narcosis develops. There is normally a rise in serum magnesium levels at calving but in those cases of parturient paresis in which tetany is a feature serum magnesium levels are low. These low levels are in many cases expressions of a seasonal hypomagnesemia.

Hypophosphatemia

Low serum phosphorus levels occur in milk fever and contribute to the clinical signs. Some cases of milk fever may not respond to calcium injectins even though the serum calcium levels return to normal but may appear to recover when the udder is inflated and serum phosphorus levels rise. Field observations indicate sodium acid phosphate given orally or IV may result in recovery of cases not responding initially to calcium salts. However, it is difficult to reconcile the biochemical and clinical findings with low serum phosphorus levels because of the absence of recumbency in other animals with profound hypophosphatemia for long periods. A possible explanation is that the hypophosphatemia which occurs in milk fever is secondary to the hypocalcemia and recumbency rather than being a concurrent event. There is experimental evidence to support this and it also seems probable that the hypophosphatemia could prolong the duration of recumbency.
**CLINICAL FINDINGS**

### Cattle

Three stages of milk fever in cattle are commonly recognized and described.

#### Stage 1

In the first stage, the cow is still standing. This is also the brief stage of excitement and tetany with hypersensitivity and muscle tremor of the head and limbs. The animal is diseased to move and does not eat. There may be a slight shaking of the head, protrusion of the tongue, and grinding of the teeth. The rectal temperature is usually normal to slightly above normal. Stiffness of the hindlegs is apparent, the animal is ataxic and falls easily and, on going down, the hindlegs are stuck out stiffly.

Careful observations by owners and veterinarians have revealed an even earlier stage than the first one. It is characterized by anorexia, agalactia, rumen stasis, scant feces and a normal temperature, heart rate and respirations. There are no obvious signs of excitement and hypersensitivity characteristic of the first stage. Affected cows may remain in this prodromal stage for several hours; they are perplexing diagnostically and respond quickly to calcium therapy. Cows with this form of hypocalcemia may be the 'calcium cyclers' described earlier.

#### Stage 2

The second stage is prolonged sternal recumbency. Consciousness is usually depressed, the cow has a drowsy appearance in sternal recumbency, usually with a lateral kink in the neck or the head turned into the flank. When approached, some of these cows will open their mouths, extend their head and neck and protrude their tongues, which may be an expression of apprehension and fear in an animal unable to stand. The tetany of the limbs present in the first stage is not present and the cow is unable to stand. The muzzles are dry, the skin and extremities cool, and the rectal temperature subnormal (36–38°C, 97–101°F). There is a marked decrease in the absolute intensity of the heart sounds and an increase in rate (about 80 bpm). The arterial pulse is weak and the venous pressure is also low, making it difficult to raise the jugular veins. The respirations are not markedly affected, although a mild forced expiratory grunt or groan is sometimes audible.

The eyes are usually dry and staring. The pupillary light reflex is incomplete or absent and the diameter of the pupil varies from normal to maximum dilatation. A detailed examination of the pupils of cows with parturient paresis, non-pareid disorders, and non-parturient paresis found that the mean sizes of the pupils were not significantly different from one another. Rather, disparity of the size of the pupils was common. Ruminal stasis and secondary bloat are common and constipation is characteristic. There is also relaxation of the anus and loss of the anal reflex.

In cows which develop hypocalcemia a few hours before or at the time of parturition, the second stage of parturition may be delayed, which is unexpected in a mature cow. Examination of the reproductive tract usually reveals a fully dilated cervix and normal presentation of the fetus. The cow may be in any stage of milk fever and administration of calcium borogluconate IV will usually result in a rapid beneficial response and normal parturition.

Prolapse of the uterus is a common complication of milk fever and often the calcium levels are lower than in parturient cows without uterine prolapse. Thus it is standard practice to treat cases of uterine prolapse with calcium salts IV.

#### Stage 3

The third stage is lateral recumbency. The cow is almost comatose and although the limbs may be stuck out there is complete flaccidity on passive movement and the cow cannot assume sternal recumbency on its own. In general, the depression of temperature and the cardiovascular system are more marked. The heart sounds are almost inaudible and the rate increased up to 120 bpm; the pulse is almost impalpable and it may be impossible to raise the jugular veins. Bloat is usual because of lateral recumbency. Without treatment, a few animals remain unchanged for several hours but most become progressively worse during a period of several hours and die quietly from shock in a state of complete collapse.

**Concurrent hypomagnesemia.** Mild to moderate tetany and hyperesthesia persisting beyond the first stage suggests a concurrent hypomagnesemia. There is excitement and fibrillary twitching of the eyelids and tetanic convulsions are readily precipitated by sound or touch. Trismus may be present. The heart and respiratory rates are increased and the heart sounds are much louder than normal. Without treatment death occurs during a convolution.

**Concurrent hypophosphatemia.** With a concurrent hypophosphatemia, the clinical findings are typical of milk fever which responds to calcium therapy in all respects except that the cow is unable to stand after treatment.

### Sheep and Goats

The disease in pastured ewes is similar to that in cattle. The early signs include a stiffly, proppy gait and tremor of the shoulder muscles. Recumbency follows, sometimes with tetany of the limbs but the proportion of ewes with hypocalcemia which are recumbent in the early stages is much less than in cattle. A similar generalization applies to female goats. The characteristic posture is sternal recumbency, with the legs under the body or stretched out behind. The head is rested on the ground, there may be an accumulation of mucus exudate in the nostrils. The venous blood pressure is low and the pulse impalpable. Mental depression is evidenced by a drowsy appearance and depression of the corneal reflex. There is loss of anal reflex, constipation, tachycardia, hypoesthesia, ruminal stasis and tympany, salivation and tachypnea. Response to parenteral treatment with calcium salts is rapid, the ewe is normal 30 min after a SC injection. Death often occurs within 6–12 h if treatment is not administered. The syndrome is usually more severe in pregnant than in lactating ewes, possibly because of the simultaneous occurrence of pregnancy toxemia or hypomagnesemia. Fat late pregnant ewes on high grain diets indoors or in feedlots show a similar syndrome accompanied by prolapses of the vagina and intestine.

### Pigs

As in cattle, signs develop within a few hours of farrowing. There is restlessness, a normal temperature and anorexia followed by inability to rise and later lateral recumbency and coma. Milk flow is decreased.

**CLINICAL PATHOLOGY**

Total serum calcium levels are reduced to below 8 mg/dL (2.0 mmol/L), usually to below 5 mg (1.2 mmol/L) and sometimes to as low as 2 mg (0.5 mmol/L). The reduction is usually, but not always, proportional to the severity of the clinical syndrome. Average figures for total serum calcium levels in the three species are cows 5.2 ± 1.2 mg/dL (1.30 ± 0.30 mmol/L), ewes 4.6 ± 1.5 mg/dL (1.15 ± 0.37 mmol/L), goats does 3.8 ± 0.6 mg/dL (0.94 ± 0.15 mmol/L).

Total serum calcium levels are a basis for comparison between species. Blood levels of ionized calcium are a better indicator of calcium status but their estimation has been too difficult until recently. Although total serum calcium levels are used to express the animals' status with regard to calcium, it is possible that differences between the ionized and non-ionized compartments of total calcium may be more important than the total level. The development of a reliable calcium ion-selective electrode now makes it possible quickly and directly to determine the biologically active portion of calcium in plasma or serum. However, the correlation between ionized and total calcium is excellent. Equine, bovine, and ovine blood may be measured for up to 48 h without any clinically relevant alteration of blood calcium ion concentration.

Normal levels of ionized calcium (as CaF) in venous whole blood of cows are 4.3–5.1 mg/dL (1.06–1.26 mmol/L)
calving whether they have milk fever or low levels may be encountered, especially hypocalcemia in dairy cattle. There is a method of estimating serum calcium mg/dL serum, slight hypocalcemia reduced below normal in all cows at concentrations for the diagnosis of obtuse serum for use in the test kit. However, the blood sample must be centrifuged to laboratory based method. However, the test kit results and a standard between the test kit results and a standard concentration for the diagnosis of milk fever, the levels of CPK will remain elevated if muscle necrosis is progressive in animals which are not rolled from side to side every few hours to reduce the effects of compression on the large muscle groups of the pelvic limbs (see Downer cow syndrome).

**Serum magnesium** levels are usually moderately elevated to 4–5 mg/dL (1.65–2.06 mmol/L) but in some areas low levels may be encountered, especially in cows at pasture.

Serum inorganic phosphorus levels are usually depressed to 1.5–30 mg/dL (0.48–0.97 mmol/L). Blood glucose levels are usually normal, although they may be depressed if ketosis occurs concurrently. Higher than normal blood glucose levels are likely to occur in cases of long duration and are therefore an indication of a poorer than normal prognosis.

Serum muscle enzymes

Prolonged recumbency results in ischemic muscle necrosis and increases in the serum muscle enzymes creatine phosphokinase (CPK) and aspartate aminotransferase (AST) or SGOT. During prolonged recumbency following treatment for milk fever, the levels of CPK will remain elevated if muscle necrosis is progressive in animals which are not rolled from side to side every few hours to reduce the effects of compression on the large muscle groups of the pelvic limbs (see Downer cow syndrome).

**Hemogram**

Changes in the leukocyte count include an eosinopenia, a neutrophilia, and a lymphopenia suggestive of adrenal cortical hyperactivity, but similar changes occur at calving in cows which do not develop parturient paresis. High plasma cortisol levels and packed cell volumes occur in cows with milk fever and are higher still in cows that do not respond to treatment. They are expressions of stress and dehydration. Clinicopathological findings in the other species are not described in detail except with regard to depression of total serum calcium levels:

**NECROPHY FINDINGS**

There are no gross or histological changes unless concurrent disease is present.

**DIFFERENTIAL DIAGNOSIS**

A diagnosis of milk fever is based on the occurrence of paresis and depression of consciousness in animals following parturition. The diagnosis is supported by a favorable response to treatment with parenteral injections of calcium solutions and by biochemical examination of the blood. In ewes, the history usually contains some reference to recent physical stress and the disease is more common in the period preceding lambing.

In the immediate postpartum period, there are several diseases which cause recumbency in cows and their differentiation is summarized in Table 29.5.

### Table 29.5 Differential diagnosis of common causes of recumbency in parturient adult cattle

<thead>
<tr>
<th>Disease</th>
<th>Epidemiology</th>
<th>Clinical signs</th>
<th>Clinical pathology</th>
<th>Response to treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Milk fever (parturient)</td>
<td>Mature cows, within 48 h of calving, some in mid-lactation</td>
<td>Early excitement and tetany.</td>
<td>Hypocalcemia, &lt;5 mg/dL (1.25 mmol/L) calcium. High serum magnesium, &gt;3 mg/dL (1.25 mmol/L) low inorganic phosphate, &lt;3 mg/dL (0.9 mmol/L)</td>
<td>Rapid, characteristic response (muscle tremor, sweating on muzzle, defecation, urination, pulse amplitude and heart sound intensity improves first) after IV injection soluble calcium salt Variable response to calcium, phosphorus and potassium salts. Fluid therapy and provision of deep bedding and hourly rolling from side to side are necessary Rumenotomy or rumen lavage may be necessary. Alkalizing agents</td>
</tr>
<tr>
<td>parturient paresis</td>
<td></td>
<td>Then depression, coma, hypothermia, flaccidity, pupil dilation, weak heart sounds. No rumen movements. HR increases as state worsens Moderately bright, active, eating. Temp. slightly raised, HR 80–100. Unable to stand but tries – 'creepers'. When dull and depressed, are 'non-alert downers'. Long course 1–2 weeks Severe gastrointestinal atony with complete cessation of ruminal activity. Fluid splashing sounds in rumen Severe dehydration, circulatory failure. Apparent blindness, then recumbency and too weak to rise. Soft odoriferous feces</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Downer cows following milk fever</td>
<td>Most common in situation where milk fever and lactation tetany are common and intensity of treatment is lax; cows are left down too long before treatment</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Carbohydrate engorgement</td>
<td>Access to large amount readily fermentable carbohydrate when not accustomed. Enzootic in high grain rations in feedlots. Intensive IV fluid and electrolyte therapy necessary for survival</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Hypomagnesemia (lactation, grass tetany)</td>
<td>All classes of cattle, but most recently calved cows. Age no barrier and cases occur up to several months after calving. May occur in pregnant beef cattle</td>
<td>Escape, hypersensitivity, muscle tremor, tetany, Recumbent with tetanic convulsions, loud heart sounds, rapid rate. Subacute cases remain standing</td>
<td>Low serum magnesium, &lt;1.2 mg/dL (0.5 mmol/L)</td>
<td>Even after IV injection response in a severe case may take 30 min, much slower than response to calcium in milk fever</td>
</tr>
<tr>
<td>Severe toxemia (acute diffuse peritonitis, coliform mastitis)</td>
<td>Sporadic only. Mastitis most common where hygiene poor. Peritonitis due to foreign body perforation of rectum, rupture of uterus or vagina</td>
<td>Recumbency, depression to coma, sleepy, dry nose, hypothermia, gut stasis, HR over 100/min, may be grunting. Examine mammary gland. Examine abdomen for abdominal disease</td>
<td>Profound leukopenia. Serum calcium may be as low as 7–8 mg/dL (1.75–2.0 mmol/L). Examine milk (CMT)</td>
<td>Require supportive response for toxemia and shock. Response is poor and temporary. Prognosis very bad. May die if treated IV with calcium or magnesium salts.</td>
</tr>
</tbody>
</table>
Several diseases which occur at the time of parturition must be differentiated from milk fever in cattle. These are grouped here according to:

- Other metabolic diseases
- Diseases associated with toxemia and shock
- Injuries to the pelvis and pelvic limbs
- Degenerative myopathy
- Downer cow syndrome

**Metabolic diseases**

Hypomagnesemia may occur as the sole cause of recumbency or it may accompany a primary hypocalcemia so that the case presented is one of parturient paresis complicated by lactation tetany. Hyperesthesia, presented is one of parturient paresis characterized by extreme weakness or recumbency, especially after treatment for ketosis with isoflupredone. Hypokalemia is marked as ranging from 1.4 to 2.3 mEq/L. The case-fatality rate is high in spite of therapy with potassium. Hypokalemic myopathy is present at necropsy.

Ketosis may complicate milk fever, in which case the animal responds to calcium therapy by standing but continues to manifest the clinical signs of ketosis, including in some cases the nervous signs of licking, circling, and abnormal voice.

**Diseases associated with toxemia and shock**

During the immediate postparturient period, several diseases occur commonly and are characterized by toxemia.

Peracute coliform mastitis is characterized by:

- Fever initially followed by hypothermia
- Tachycardia
- Dehydration
- Weakness and recumbency
- Depression
- Ruminal stasis
- Diarrhea in some
- Enlarged mammary gland(s) with watery and serous-like secretions with small particles barely visible.

Aspiration pneumonia secondary to regurgitation and aspiration of rumen contents may occur as a complication of thirdstage milk fever. Fever, dyspnea, inspiratory grunt, severe depression and anxiety are common. Auscultation of the lungs reveals the presence of abnormal lung sounds. Aspiration pneumonia should be suspected if the animal has been lying on its side, especially if there is evidence of regurgitation of ruminal contents from the nostrils, no matter how small the amount, or if there is a history of the animal having been drenched. Abnormal auscultatory findings may not be detectable until the second day. Early diagnosis is imperative if the animal is to be saved and the mortality rate is always high.

Acute diffuse peritonitis resulting from traumatic perforation of the reticulum or uterus is characterized by:

- Severe depression
- Fever
- Weakness and recumbency
- Ruminal stasis
- Dehydration
- Grunting or groaning with each respiration
- Tachycardia
- Fluid splashing sounds on ballottement of the abdomen (paralytic ileus).

Carbohydrate engorgement results in:

- Depression
- Weakness
- Sternal recumbency
- Dehydration
- Tachycardia
- Ruminal stasis and moderate bloat
- Fluid-splashing sounds over rumen
- Low rumen juice pH
- Diarrhea
- Hypothermia
- Cool extremities
- Progressive worsening if not treated.

Many cases resemble second-stage milk fever.

Toxemic septic metritis occurs most commonly within a few days after parturition and is characterized by:

<table>
<thead>
<tr>
<th>Disease</th>
<th>Epidemiology</th>
<th>Clinical signs</th>
<th>Clinical pathology</th>
<th>Response to treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fat cow syndrome</td>
<td>Fat dairy or beef cows in late gestation or at parturition. Some predisposing cause precipitates illness in fat animals</td>
<td>Excessive body condition, anorexia, apathy, depression, recumbency and looks like milk fever, scant soft feces, ketonuria</td>
<td>Evidence of hepatic disease.</td>
<td>Will recover if begin to eat. Treat with fluids, glucose, insulin. Provide good quality palatable roughage</td>
</tr>
<tr>
<td>Physical injuries</td>
<td>Ruptured gastrocnemius, dislocation of hip, etc.</td>
<td>As for MOP with ruptured gastrocnemius, hock remains on ground when standing. Excessive lateral mobility of limb with hip dislocation</td>
<td>Increase CPK and SGOT</td>
<td>Supportive therapy, deep bedding, and frequent rolling.</td>

</tbody>
</table>
Depression
Anorexia
Fever
Tachycardia (100–120 bpm)
Ruminal stasis
Presence of foul-smelling uterine discharge found on vaginal examination.

The fetal placenta may be retained. Some affected cows are weak and prefer recumbency, which resembles milk fever. Prolapse and rupture of uterus causes varying degrees of:

- Shock with tachycardia
- Hypothermia and cool extremities
- Weakness and recumbency
- Rapid death.

A history of difficult parturition or assisted dystocia with fetotomy may be associated with rupture of the uterus. The administration of calcium salts may cause ventricular fibrillation and sudden death.

Although some elevation of the temperature may be observed in these severe toxemic states, it is more usual to find a subnormal temperature. The response to calcium therapy is usually a marked increase in heart rate and death during the injection is common. Every case of recumbency must be carefully examined as these conditions may occur either independently or as complications of parturient paresis. In our experience, about 25% of cases of postparturient recumbency in cows are due primarily to toxemia or injury rather than to hypocalcemia.

**Injuries to the pelvis and pelvic limbs**

Injuries to the pelvis and pelvic limbs are common at parturition because of the marked relaxation of the ligaments of the pelvic girdle. Seven types of leg abnormality have been described in this group at an incidence level of 8.5% in 400 consecutive cases of parturient paresis. The abnormalities included radial paralysis, dislocation of the hips and rupture of gastrocnemius muscle. In most instances the affected animals are down and unable to stand but they eat, drink, urinate and defecate normally, have a normal temperature and heart rate and make strong efforts to stand, particularly with the forelimbs.

Maternal obstetrical paralysis is the most common injury. Although this occurs most frequently in heifers after a difficult parturition, it may also occur in adult animals following an easy birth and occasionally before parturition, especially in cows in poor body condition. The mildest form is evidenced by a frequent kicking movement of the hindleg, as though something was stuck between the claws. All degrees of severity from this, through knuckling and weakness of one or both hindlegs, to complete inability to rise may occur, but sensation in the affected limb is usually normal. There is traumatic injury to the pelvic nerves during passage of the calf. There are often gross hemorrhages, both deep and superficial and histopathological degeneration of the sciatic nerves. In individual animals, injury to the obturator nerves is common and results in defective adduction of the hindlimbs. The position of the hindlimbs may be normal but in severe cases, especially those with extensive hematoma along the sciatic nerve trunk, the leg may be held extended with the toes reaching the elbow as in dislocation of the hip; however in the latter case there is exaggerated lateral mobility of the limb. Additional injuries causing recumbency near parturition include those associated with degenerative myopathy, dislocation of the hip and ventral hernia.

Dislocation of the coxofemoral joint can cause recumbency and inability to stand in some cows, while others can stand and move around. Recumbent cows are usually in sternal recumbency and the affected limb is abducted excessively. In standing cows, the affected limb is usually extended, often difficult to flex and often rotated about its long axis. The diagnostic criteria are:

- Sudden onset of lameness with the affected limb extended and possibly rotated
- Displacement of the greater trochanter of the femur from its normal position relative to the ischiatric tuber and coxal tuber of the pelvis
- Ability to abduct the limb manually beyond its normal range
- Crepitus in the hip on abduction and rotation of the limb
- Ability to palpate the femoral head per rectum or per vaginum against the cranial border of the ilium or pubis in cases of cranioventral dislocation, or in the obturator foramen in cases of caudoventral dislocation.

Manual replacement by closed reduction is successful in 80% of craniodorsal dislocation and 65% in caudodorsal dislocation. The ability to stand before reduction is the most useful prognostic aid.

**Degenerative myopathy (ischemic muscle necrosis)**

Degenerative myopathy affecting primarily the large muscles of the thighs, occurs commonly in cattle which have been recumbent for more than several hours. At necropsy, large masses of pale muscle are present surrounded by muscle of normal color. Clinically it is indistinguishable from sciatic nerve paralysis. Markedly increased serum levels of CPK occur in cows recumbent for several hours following the initial episode of milk fever due to ischemic necrosis. Persistent elevation of CPK indicates progressive ischemic muscle necrosis due to continued compression of large muscle masses of the pelvic limbs. Rupture of the gastrocnemius muscle or separation of its tendon from either the muscle or the tuber calcis may also cause myopathy.

**Downer cow syndrome**

Downer cow syndrome is a common sequel to milk fever in which the cow was in sternal recumbency for several hours before being treated with calcium. Following treatment, most of the clinical findings associated with milk fever resolved except the animal was unable to stand. Clinically, the animal may be normal except for recumbency and will commonly recover and stand normally within several hours or a few days. Most downer cows eat and drink normally, their vital signs are within the normal range and their alimentary tract function is normal. However, some are anorexic, may not drink, exhibit bizarre movements of lying in lateral recumbency, and dorsally extend their head and neck frequently, moan and groan frequently, assume a frog-legged posture with their pelvic limbs and crawl or creep around the stall and may die or are euthanized for humane reasons in a few days. The diagnostic dilemma with these cows is that they resemble milk fever and whether or not to treat them with additional amounts of calcium salts is questionable.

**Non-parturient hypocalcemia**

Paresis with mental depression and associated with low total serum calcium levels can occur in cows at times other than at parturition. The cause is largely unexplained but the syndrome occurs rarely in animals other than ruminants. Hypocalcemia may occur after gorging on grain and may be a significant factor in particular cases. Sudden rumen stasis due to traumatic reticulitis may rarely cause hypocalcemic paresis. Diarrhea, particularly when cattle or sheep are placed on new lush pasture, may also precipitate an attack. Access to plants rich in oxalates may have a similar effect, particularly if the animals are unaccustomed to the plants. Affected animals respond well to calcium therapy but relapse is likely unless the primary cause is corrected. The differential diagnosis of diseases of non-parturient cows manifested principally by recumbency is also summarized in Table 29.5.
Hypocalcemic paresis in sheep and goats

Hypocalcemia in sheep must be differentiated from pregnancy toxemia in which the course is much longer, the signs indicate cerebral involvement and the disease is restricted to pregnant ewes. There is no response to calcium therapy and a positive test for ketonuria is almost diagnostic of the disease. At parturition, goats are susceptible to enterotoxemia and hypoglycemia (rarely), both of which present clinical signs similar to parturient paresis.

Hypocalcemia in sows

Hypocalcemia is rare in sows. The disease must be differentiated from the mastitis, metritis and agalactia complex, which is characterized by:

- Fever
- Agalactia
- Anorexia
- Toxemia
- Enlarged mammary glands.

Treatment

Every effort should be made to treat affected cows as soon as possible after clinical signs are obvious. Treatment during the first stage of the disease, before the cow is recumbent, is the ideal situation. The longer the interval between the time the cow first becomes recumbent and treatment, the greater the incidence of the downer cow syndrome due to ischemic muscle necrosis from prolonged recumbency. Complications of milk fever occur when cows have been in sternal recumbency for more than 4 h. Farmers must be educated to appreciate the importance of early treatment. Cows found in lateral recumbency (third stage) should be placed in sternal recumbency until treatment is available. This will reduce the chances of aspiration if the cow regurgitates. Cows that have difficulty finding solid, non-slip footing beneath them, for example, a slippery barn floor or slippery mud, will often not try to stand and may develop ischemic myonecrosis. Avoidance of this complication necessitates the placement of rubber or other mats under the cow or transportation of the cow to a piece of pasture with a dense sward on it. A temperature of greater than 39°C (102°F) is an indication of a higher than average mortality rate due to pre-existing complications.

Standard treatment

Calcium borogluconate at 10–200 g is the treatment of choice. The solutions available vary from 18 to 40% calcium borogluconate. Most cows with milk fever can be treated successfully with 8–10 g of calcium (calcium borogluconate is 8.3% calcium). For cattle, 400–800 mL of a 25% solution is the usual dose. The dose rate of calcium is frequently under discussion. There is a general tendency for veterinarians to underdose with calcium salts, largely because of toxic effects which tend to occur when all of the calcium is given IV. As an initial dose a large cow (540–590 kg) requires 800–1000 mL of a 25% solution and a small cow (320–360 kg) 400–500 mL. Underdosing increases the chances of incomplete response, with inability of the cow to rise, or of relapse. In general, 12 g of calcium is superior to 8 g, which in turn is superior to 6 g.

The standard rate of administration is a rapid intravenous administration of the calculated dose of calcium borogluconate (often supplemented with phosphorus, magnesium, and glucose) over a period of 15 min. Hypercalcemia (up to 22 mg/dL) occurs following IV administration of calcium borogluconate over a period of 12–15 min. The plasma calcium concentration will gradually decline over a period of several hours by which time calcium homeostasis should begin to occur and levels return to normal by 12–24 h following treatment. However, in some cows calcium homeostasis is ineffective and subclinical or clinical hypocalcemia may recur.

Because up to 50% of cows may not respond to the initial rapid administration, it has been postulated that the increases in electrolytes are only transient and that slower IV infusion would be more effective.25 The slow infusion of a calcium solution via an IV indwelling catheter over 6 h was compared with the conventional single IV administration of 600 mL of a 40% calcium borogluconate solution containing 18.78 g calcium gluconate and borogluconate with 6% magnesium hypophosphite (11.82 g magnesium hypophosphite) over 15 min in cows recumbent with milk fever.25 Cows receiving the rapid infusion responded more quickly and stood sooner and their demeanor returned to normal more quickly.

Toxemic cows are very susceptible to the administration of calcium. The intravenous (IV) route is preferred because the response is rapid and obvious. The heart should be auscultated throughout the intravenous administration for evidence of gross arrhythmia, bradycardia, and tachycardia. If any of these occurs, the intravenous administration should be interrupted and continued only after the heart sounds return to normal. If the cardiac irregularity continues, the remainder of the solution can be given subcutaneously. The best recommendation is to give as much of the solution as possible intravenously and the remainder subcutaneously. The common practice of giving half the dose intravenously and half subcutaneously is a reasonable compromise because with this method there are fewer relapses. If a cow has been previously treated subcutaneously by the farmer, additional calcium given intravenously may cause toxicity if the improved circulation enhances the absorption of the subcutaneous calcium.

SC route

The subcutaneous (SC) route is commonly used by farmers who treat affected cows at the first sign of hypocalcemia, preferably during the first stage when the cow is still standing or as prophylaxis to all high-risk cows immediately after calving. The SC route has also been used by veterinarians when the effects of IV administration of calcium are uncertain or if an unusual response occurs during IV administration. There are limitations to the effectiveness of SC calcium solutions given to cows with milk fever.27 Cows given 300 mL of 33.3% or 40% calcium borogluconate SC had serum calcium levels of 1.4 mmol/L; those receiving 600 mL had serum calcium levels of 2.1 mmol/L, at mean intervals of 4.8 and 12.0 h between treatments by the herdsmen and veterinary attention.27 At the time of sampling, 48% of cows receiving 600 mL of calcium borogluconate had a serum calcium level below 2.0 mmol/L. If the veterinarian is unable to treat the cow within 1 h, a dose of 600 mL of 40% calcium borogluconate should be given SC in two sites and massaged well to promote absorption. Waiting for more than 1 h to assess the effect of one treatment SC is regarded as conducive to development of the downer cow syndrome. The cow should then be placed in a dry area with her limbs positioned to minimize ischemic necrosis covered with straw and tarpaulins until the veterinarian arrives.

Toxemic cows are very susceptible to the IV administration of calcium borogluconate and death may occur. In such cases the heart rate increases markedly (up to 160 bpm), there is respiratory distress,
trembling and collapse and the cow dies within a few minutes. SC or IP administra­tion is preferred in cows with severe toxemia due to aspiration pneumonia, metritis, and mastitis.

**Oral route**
A further aid to parenteral therapy with solutions of calcium salts, especially for the purpose of increasing recovery rates and preventing relapses, is the oral administration of gels containing calcium chloride, which are described under prevention.

**Typical response to calcium borogluconate**
Cows with milk fever exhibit a typical pattern of response to calcium borogluconate IV if the response is favorable, including:
- Belching
- Muscle tremor, particularly of the flanks and often extending to the whole body
- Slowing and improvement in the amplitude and pressures of the pulse
- Increase in the intensity of the heart sounds
- Sweating of the muzzle
- Defecation.

The feaces are in the form of a firm fecal ball with a firm crust and covered with mucus, occasionally with a few flecks of blood. Urination usually does not follow until the cow stands. A slight transitory tetany of the limbs may also be observed. Many cows will eat and drink within minutes following successful treatment if offered feed and water.

The rate of response to treatment is affected by many factors as set out below and it is unwise to quote what might be expected as an acceptable rate of recovery after treatment. This is particularly true if cows are treated by the farmer and only difficult cases are presented to the veterinarian. In general, if all cases are considered and there are no exceptional circumstances, recovery can be expected immediately after treatment in about 60% of cases and in a further 15% after 2 h; 10% have recoveries complicated by one of the diseases discussed earlier and 15% can be expected either to die or to require disposal. Of those which recover after one treatment, 25–30% can be expected to relapse and require further treatment.

**Unfavorable response to calcium borogluconate**
An unfavorable response is characterized by a marked increase in heart rate in cows affected with toxemia and acute heart block in apparently normal animals, especially with overdosage, with too rapid injection and in cases in which treatment has been unduly prolonged. In the latter, the maximum tolerated dose of calcium borogluconate by IV administration is about 250 mL of a 25% solution. Overdosage may occur when farmers treat cases unsuccessfully by multiple SC injections and these are followed by IV dosage. When the peripheral circulation is poor, it is probable that the calcium administered SC is not absorbed until the circulation improves following the IV injection and the large doses of calcium then absorbed cause acute toxicity. In all cases of IV injection, the circulation must be monitored closely. Some degree of arrhythmia occurs in most cases but if there is gross arrhythmia or a sudden increase in heart rate, the injection should be stopped temporarily or continued with great caution. In normal circumstances at least 10 min should be taken to administer the standard dose. The acute toxic effect of calcium salts seems to be exerted specifically on heart muscle with a great variety of defects occurring in cardiac action; the defect type depends on the specific calcium salt used and the speed of injection. ECG changes after induced hypercalcemia show increased ventricular activity and reduced atrial activity. Atropine is capable of abolishing the resulting arrhythmia.

Sudden death may also occur after calcium injections if the cow is excited or frightened, which may be due to an increased sensitivity to epinephrine. When affected cows are exposed to the sun or a hot, humid atmosphere, heatstroke may be a complicating factor. In such cases an attempt should be made to reduce the temperature to below 39.5°C (103°F) before the calcium is administered. The incidence of cardiac arrhythmia and other abnormalities as detected by ECG during treatment with calcium salts IV is so high that there are doubts expressed about the suitability of this form of treatment.

Chronic toxicity may also occur. In laboratory animals, severe uremia due to extensive calcium deposits in the kidney occur after the SC injection of calcium chloride and borogluconate and similar deposits are often seen at necropsy in cows dying after multiple injections of calcium salts administered at short intervals.

**Failure to respond to treatment**
A failure to respond favorably to treatment may be due to an incorrect or incomplete diagnosis, or inadequate treatment. A poor response to treatment includes: (1) no observable changes in the clinical findings immediately following the calcium administration or (2) the animal may respond to the calcium in all respects with the exception of being unable to stand for varying periods of time following treatment. An inadequate response also includes relapses after successful recovery, which usually occur within 48 h of the previous treatment. Relapses are more common in certain individual cows such as mature Jersey cows, which may experience as many as five or six episodes around one calving. Also, the incidence of relapse is much higher in cases which occur just before calving than in those which occur afterwards. The needs of individual animals for calcium replacement vary widely, depending on their body weight and the degree of hypocalcemia. Incomplete responses may be more common in older cows and may be associated with diminished skeletal reserves of calcium and inability of the normal mechanisms to maintain serum calcium levels during the period of excessive demands of lactation. The duration of the illness and the posture of the cow also affect the response. In an extensive field study, there were no downer cows or deaths in cows still standing when first treated, 13% of downers and 2% of deaths occurred in cows in sternal recumbency and 37% of downers and 12% of deaths occurred in cows in lateral recumbency when first treated. Therefore, in general, the longer the period from onset of milk fever to treatment, the longer the period of post-treatment recumbency and the higher the case-fatality rate. In another study, 67% of cows recovered after a single treatment, 90% after two treatments, and 92–99% after three treatments. After routine treatment, 37% of cases rose unassisted within 10 min, 23% required some assistance, 26% recovered after longer periods of recumbency, and 14% died or were destroyed or sold for slaughter. The best procedure to follow if response does not occur is to revisit the animal at 12-hourly intervals and check the diagnosis. If no other cause of the recumbency can be determined, the initial treatment can be repeated on a maximum of three occasions. Beyond this point, further calcium therapy is seldom effective. A low body temperature, due probably to exposure to low environmental temperature and increased wind velocities, is positively correlated with a high proportion of deaths and poor responses.

At the second visit, solutions containing either phosphorus, magnesium, or dextrose may be administered, depending upon the clinical signs presented and the results of available biochemical tests. Glucose is usually administered as 500 mL of a 40% solution, sodium acid phosphate as 200 mL of a 15% solution, and magnesium sulfate as 200–400 mL of a 15% solution. Composite solutions containing calcium, magnesium, phosphorus and glucose are also in common use as initial treatments. There is controversy about these so-
called ‘polypharmacy’ preparations. They have no advantage, but are likely to remain popular when milk fever cases are complicated by metabolic disorders other than hypocalcemia. They have no effect on the relapse rate when compared with calcium salts alone.

Udder insufflation
Insufflation of the udder with air was an alternative treatment for cows which continued to relapse following repeated calcium injections. With the availability and effectiveness of orally administered calcium gels, udder insufflation cannot be recommended.

GENERAL MANAGEMENT AND CLINICAL CARE PROCEDURES
The care of the cow and the calf following milk fever is important. The calf should be removed from the cow and for the first 48 h only sufficient milk should be drawn for the calf’s maintenance. A gradual return to full milking can then be permitted. If the cow is recumbent for any length of time, she must be kept propped up in sternal recumbency and not left in lateral recumbency, which may result in regurgitation and aspiration pneumonia. The cow should be rolled from side to side every few hours and provided with adequate bedding or moved to a suitable non-slip ground surface. In extreme climatic conditions, erection of a shelter over the cow is advisable if she cannot be moved to permanent shelter. If a cow is recumbent for more than 48 h, assisted lifting using appropriate cow lifters several times daily should be considered. However, heroic measures to get cows to stand should be avoided. Gentle nudging in the ribs or the use of an electric prod are the maximum stimulants advised. The best assistance that can be given to a cow attempting to stand is a good heave at the base of the tail when she is halfway up.

CONTROL
Various methods for the control of milk fever in ruminants, especially dairy cows, are available. They include dietary management during the transition period before and after calving, administration of calcium gels orally at the time of parturition and administration of vitamin D and its metabolites and analogs immediately before parturition to enhance the mobilization of calcium. When the incidence of milk fever increases to above 10% of high-risk cows (third or later lactations), a specific control program is necessary. When the incidence is low, a specific control program may not be economical and the alternative is to monitor cows carefully at the time of parturition and for 48 h after parturition and treat affected animals during the first stage of the disease if possible.

Various aspects of the literature on the principles of control of milk fever in cattle, under different circumstances have been reviewed.29-31 The different strategies for the control of milk fever in dairy cows has been examined by expert opinions.32 The two control strategies predicted to be most relevant were calcium gel orally peripartum used alone and in combination with a low-calcium diet. Several control strategies for milk fever in dairy herds have been evaluated by stochastic simulation in order to analyze the technical and economic effects at the herd level and to assess frameworks for decision support system development.33 The simulated technical and economic effects indicated a complex interaction between herd and control strategy. In general, the most comprehensive control strategies were economically inferior to similar but less comprehensive control strategies.

Dietary management during prepartum period
For purposes of optimal nutritional management of dairy cows which are fed prepared feeds (not pasture-based), the dry period is divided into at least two distinct categories – cows in the early and middle portion of the dry period (far-off or regular dry cow group) and cows in the final 3 weeks prior to their calving date (pre-fresh, transition, close-up, near, lead feeding, or steam-up group).31 Large herds may have additional subgroups of dry cows depending on management circumstances and facilities available. Special attention must be given to the mineral nutrition of the close-up group. Minerals should be provided to close-up cows in known quantities, either as part of a grain mixture or total mixed ration (TMR).

Calcium and phosphorus nutrition
Level of calcium in diet
Diets high in calcium during the prepartum period can result in a high incidence of milk fever and diets low in calcium will reduce the incidence of milk fever in dairy cows. Feeding more than 100 g of calcium daily during the dry period is associated with an increased incidence of milk fever. A cow weighing 500 kg requires only about 33 g/daily of calcium to meet maintenance and fetal calcium demands in the last 2 months of late gestation.30 Low calcium diets (20 g Ca/d) fed during the last 2 weeks before parturition are highly reliable and effective. The low levels of dietary calcium activate the calcium homeostatic mechanisms before calving and the cow is more able to absorb calcium from the digestive tract and to mobilize calcium from bone reserves. At least 14 days of a low calcium diet are required to be effective in minimizing the incidence of milk fever. Feeding dry cows rations low in calcium results in activation of the calcium homeostatic mechanisms before calving making the cow able to mobilize the large quantities of calcium for the final stages of prenatal growth and colostrum production. When dietary calcium availability is decreased below calcium requirements, the cow is brought into negative calcium balance. This leads to a secretion of parathyroid (PTH) which increases renal reabsorption of calcium within minutes, stimulates calcium resorption from bone within hours to days, and stimulates renal vitamin D metabolism to towards production of 1,25-dihydroxyvitamin D (1,25-(OH)2D) within hours or days. The (1,25-(OH)2D) stimulates the active transport of calcium across the intestinal epithelial cells. During bone resorption, urinary excretion of pyridinoline and deoxypyridinoline, derived from collagen breakdown, is increased.

Practicality of feeding diets low in calcium
There are practical problems with the implementation of the recommendation to feed diets low in calcium. It is difficult to reduce the amounts of calcium and phosphorus fed to cows for several reasons:

- Inability to grow sufficient quantities of feeds, such as corn silage, for the entire herd
- Suitability of land for legume crops which are high in calcium
- Inability to add sufficient phosphorus to lower the ratio of calcium to phosphorus to palatability when quantities of phosphorus are added to the ration.

Most farms utilizing home-grown forages, especially alfalfa, find it difficult to obtain forages which are low in calcium. A low calcium diet can be achieved by replacing some or all alfalfa hay in the dry cow diet with grass hay and using additional corn silage and concentrates. While feeding diets low in calcium during the prepartum period is very effective, the very low calcium intake required necessitates that the cow be in negative calcium balance and in a state of withdrawal of calcium from bone.

Binding dietary calcium
It is possible to prevent milk fever and subclinical hypocalcemia by adding a substance to the feed capable of binding dietary calcium and making it unavailable for absorption. The oral administration of sodium aluminum silicate or zinc oxide to cows in late lactation results in a decrease in total serum calcium.34 Supplementing the dry cow ration with sodium aluminum silicate (zeolite A) at the rate of 1.4 kg of
zeolite pellets per day (0.7 kg of pure zeolite) for the last 2 weeks of pregnancy results in an increase in plasma calcium around calving. Plasma magnesium and inorganic phosphate levels were decreased and serum 1,25-(OH)₂D₃ was significantly increased. Feed intake was decreased among zeolite-treated cows during the last 2 weeks of pregnancy but there was no effect on milk yield, milk fat, and milk protein in the subsequent lactation. The addition of zeolite to the daily ration during the last month of pregnancy prevented parturient paresis and subclinical hypocalcemia in Jersey cows. Feeding a vegetable oil supplement (soya bean oil) to pregnant pastured dairy cattle during the last 2–3 weeks of pregnancy is effective in preventing milk fever and increases milk solids production in early lactation. The same supplement has been used to stimulate calcium absorption and reduction in susceptibility to fasting-induced hypocalcemia in pregnant ewes. Following supplementation, the ewes are fasted overnight to challenge calcium homeostasis. Following fasting, there is a greatly increased capacity to absorb calcium.

**Level of phosphorus in diet**

Increased levels of dietary phosphorus, >80 g/head per day, can also increase the incidence of milk fever. The increased intake increases the serum level of phosphorus which has an inhibitory effect on renal enzymes. These enzymes catalyze the production of 1,25-(OH)₂D₃, which when lowered will reduce intestinal calcium absorption. If the reduction of calcium is impractical, the lowering of phosphorus intake may be beneficial.

**Calcium and phosphorus ratio in diet**

If the ration is low in calcium, the resulting negative balance of calcium can be expected to stimulate activity of the parathyroid gland. Early researchers made use of this physiological mechanism by feeding a high phosphorus/low calcium ration to cows during the last month of pregnancy. With a Ca:P ratio of 6:1, 30% of cows developed parturient paresis; at a Ca:P ratio of 1:1, 15% developed the disease; and at a ratio of 1:3.3, no cases occurred. Although there is no apparent effect on the subsequent lactation there is the possibility, if the negative balance of calcium is prolonged or repeated frequently, that such a ration may contribute to the development of osteoporosis. Dietary phosphorus concentrations can have an influence on calcium homeostasis.

**Acidiﬁying rations in the prepartum diet:**

Cation–anion difference (DCAD)

A more reliable method of controlling milk fever in dairy cows when the calcium intake exceeds NRC requirements is to manipulate the dietary cation–anion difference (DCAD) during the prepartum period. Diets high in cations, especially sodium and potassium, tend to induce milk fever compared with those high in anions, primarily chloride and sulfur, which can reduce the incidence. Because most legumes and grasses are high in potassium, many of the commonly used prepartum diets are alkaline resulting in metabolic alkalosis. The feeding of diets which are high in ratio of calcium to phosphorus and containing an excess of anions relative to cations will result in mild metabolic acidosis completely compensated by nonrespiratory mechanisms (decreased blood bicarbonate and base excess: PCO₂ and pH are unaffected). There is increased concentration of serum calcium due to an increase in the intestinal absorption of calcium. Two parathyroid hormone (PTH) dependent functions; bone resorption, and renal production of 1,25-dihydroxyvitamin D₃, are enhanced in cows fed diets with added anions which increase their calcium to milk fever and hypocalcemia.

The DCAD is calculated from the equation DCAD in mEq/kg DM = [(Na + K) – (Cl + S)]. The equation does not include other dietary cations and anions such as Ca²⁺, Mg²⁺, and PO₄³⁻ which have a minor role. Most studies indicate that a DCAD of −50 to 100 mEq/kg DM is optimal for the prevention of milk fever. Supplementation of diets in the last 3 weeks prepartum with anionic salts at a rate sufficient to decrease DCAD to −15 mEq/100 g of dietary DM and urine pH to 6.0 prevented most cases of parturient hypocalcemia. Except for cows pregnant with twins, that rate of supplementation did not affect DM intake and energy balance. A moderate rate of supplementation to reduce the DCAD to 0 mEq/100 g dietary DM and urine pH to 7.3 also did not decrease feed intake or energy status but was less effective in preventing parturient hypocalcemia. Monitoring urine pH can be a useful aid to find the effective intermediate inclusion rate and it is suggested that a urine pH of about 6.5 is ideal.

Commercial anionic products fed to non-lactating dairy cows in a total mixed ration, after 4 days reduced urine pH below the desired threshold of 6.5.

The equation assigns the same acidifying potency to each mEq of Cl and SO₄, but Cl is absorbed to a greater extent than SO₄. Equation of the DCAD of a diet requires use of the equivalent weights of the electrolytes. The equivalent weight is equal to the molecular weight divided by the valence. A milliequivalent (mEq) is used to express equivalent weights: 1 mEq equals 1/1000 of an equivalent. Table 29.6 provides reference values for calculating equivalent weights of important electrolytes and converting from percent diet dry matter (DM) to mEq/kg. Once mEq are calculated, the DCAD can then be determined by subtracting the anions from the cations.

The DCAD is calculated from the percent element in the diet dry matter. The equation is as follows: mEq/100 g DM = [(% Na + 0.023) + (% K + 0.039)] – [(% Cl + 0.0355) + (% S + 0.016)]. Based on current evidence, the range which achieves the lowest incidence of milk fever is a DCAD of −10 to −15 mEq/100 g DM or −100 to 150 mEq/kg DM.

Most typical diets fed to dry cows have DCADs of about 100–250 mEq/kg DM. Addition of a cationic salt such as sodium bicarbonate to the dry cow diets increases the DCAD and increases the incidence rate of milk fever. Adding an anion source or a mixture of anionic salts containing Cl and S relative to Na and K to the diet lowers the DCAD and reduces the incidence of milk fever. Commonly used sources of anion salts include the Cl and SO₄ salts of calcium, ammonium and magnesium. The phosphate salts have not been used because they are only weakly acidifying.

The addition of anions to the diet to reduce dietary DCAD is limited because of problems with palatability of the anionic salt sources commonly used. If the diet DCAD is >250 mEq/kg, it is difficult to add enough anionic salts to...
lower the DCAD to the recommended \(-100\) mEq/kg of the diet without affecting palatability.

In one study, the incidence of milk fever was 47% when prepartum cows were fed a ration with a DCAD of \(+330\) mEq/kg dietary DM and 0% when the prepartum ration had a balance of \(-128.5\) mEq/kg dietary DM. \(^4^0\) The incidence of milk fever was reduced by the addition of chloride and sulfur in excess relative to sodium and potassium in the diet. \(^4^0\) Because anions are considered acidogenic and cations alkalogenic, an excess of acid-forming elements in periods of calcium stress will increase the concentration of calcium in the blood, either by intestinal absorption or bone mobilization. \(^3^1\) Cows fed prepartum diets containing alfalfa haylage with added chlorides of magnesium, ammonia, and calcium tended to have higher plasma calcium concentrations than those receiving the prepartum diet. \(^3^1\) The reductions in dry matter intake when more than 300 mEq of anionic salts/kg diet DM are supplemented in the diet. \(^3^3, ^3^4\) The reductions in dry matter intake are commonly ascribed to decreased palatability but may represent a response to the metabolic acidosis induced by the salts. \(^4^1\) The duration of feeding anion salts ranges from 21 to 45 days before expected parturition. At least 5 days of consumption are necessary for maximal benefit.

Ammonium chloride. Ammonium chloride is more effective than most other salts as an acidifier. The addition of ammonium chloride salts to prepartum diets offers considerable promise as a practical and reliable method of control of milk fever. Experimentally, the addition of ammonium chloride and ammonium sulfate, each at 100 g/head per day, to the prepartum diets 21 days prior to parturition, decreased the incidence of milk fever from 17% to 4% in the unsupplemented group to 4% in the supplemented group. The advantages of ammonium salts are that they:

- Do not require the use of diets low in calcium
- Are relatively inexpensive
- Are convenient to use
- Are safe to feed.

Strategies for supplementing anion sources

A systematic protocol for the addition of anions to a prepartum diet and monitoring its effects is as follows:

1. 1.5-1.8% DM or provide daily intake of about 150 g/head per day. Negative DCAD diets increase urinary calcium excretion and thus more dietary calcium is necessary to meet requirements.
2. Elevate the dietary calcium to 1.5-1.8% DM or provide daily intake of about 150 g/head per day. Negative DCAD diets increase urinary calcium excretion and thus more dietary calcium is necessary to meet requirements.
3. Monitor dry matter intake of the prepartum cow group. Consider more palatable anion sources or a reduced dose of anion sources if dry matter intake is depressed. Low dry matter intakes in prepartum cows increases the risk for fatty liver and ketosis after calving.
4. After 1 week of feeding anionic salts, monitor the pH of close-up dry cows. Urinary pH is an accurate indication of optimal dietary acidification. Collect urine from at least six cows at one time and average the urinary results. Adjust the dose of supplemental anions to achieve an average urinary pH of between 6.0 and 7.0.

DCAD and acid-base balance of dairy cows on pasture-based diets

The literature on the nutritional strategies for the prevention of hypocalcemia for dairy cows in pasture-based systems has been reviewed. \(^6\) The dairy industries of southern Australia and New Zealand are based largely on fresh pasture and pasture silage and grazed pasture is the key determinant of the DCAD. The concentration of potassium is often in excess of 4% and the DCAD >500 mEq/kg DM, in pasture-based diets yet the incidence risk of milk fever is not higher than those in other countries where dietary potassium is much lower. For a considerable part of spring and early summer, the DCAD of pasture in those countries may be in excess of +500–700 mEq/kg DM. \(^2^9, ^3^9\) The variation in the DCAD of pasture and the difficulty in accurately assessing dry matter intake makes an accurate reduction in DCAD difficult to achieve practically. \(^5^4\) Pasture
cation–anion difference in those conditions is not greatly influenced by stocking rate or associated management practices. The urine pH of grazing dairy cows in southeastern Australia remains relatively constant throughout the year despite changes in stage of lactation, management practices, season, weather, and large changes in DCAD. It appears that a very low DCAD (<150 mEq/kg DM) is required to alter systemic pH substantially. The DCAD of pasture throughout the year was negative, the urinary output of -12 to +69 mEq/100 g. With decreasing DCAD, the pH of the blood and urine pH and to decrease the incidence of hypocalcemia.5,9

The dietary cation–anion difference and the health and production of pasture-fed dairy cows in early lactation in southeastern Australia has been examined in an indoor feeding experiment.56 The dairy industry there is largely perennial ryegrass-based and supplemented with cereal grains, pasture hay, and pasture slage. The DCAD can range from 0 to +76 mEq/100 g. Blood pH and urine pH are reduced when a low DCAD ration is fed, but there is a threshold level, between +52 and +102 mEq/100 g, above which little change in systemic pH occurs.56 As DCAD increased from +21 to +127 mEq/100 g, DMI intake and milk yield decreased in nonlactating periparturient cows fed freshly cut pasture supplemented with varying levels of salts to alter the DCAD which ranged from -12 to +69 mEq/100 g.57 With decreasing DCAD, the pH of the blood and urine decreased resulting in a nonrespiratory systemic acidosis. When the DCAD was negative, the urinary output of calcium increased. No differences in milk production due to alteration of the DCAD. Due to the high DCAD in the base diet offered to pasture-fed dairy cows and the requirement for a negative DCAD to increase calcium absorption, it is unlikely that the DCAD concept is a practical means of preventing milk fever in pasture-fed cows.

In these pasture-based systems, sulfur (S) is considered a more important dietary constituent in determining the risk of hypocalcemia than either chloride or potassium.55 The absorption efficiency of S is less than either Cl or K and would not be expected to incur the same change in systemic pH. Thus its importance in hypocalcemia prevention, does not fit with the current understanding of how manipulation of DCAD influences calcium homeostasis. Studies indicate that pre-calving dietary S is more important in the control of hypocalcemia than either K or Cl concentration. Although the effects of a systemic acidosis on Ca absorption is accepted, the effect of S on periparturient Ca homeostasis when absorption of S is low in comparison to Cl, Na, or K suggest that there are mechanisms involved that are not related to acid–base balance. Dietary S concentration was more important in the control of hypocalcemia than either dietary K or Cl concentration.

An increased incidence of milk fever may occur in pastured-based dairy when the diet is supplemented with Cl and S, even though calcium absorption, as indicated by urine calcium concentration increases. The increased incidence may be due to a greater demand for dietary calcium after calving following a reduction in the pH of body fluids pre-calving and the fact that pasture-based diets, as opposed to total mixed rations, are generally low in calcium. Supplementation of cows with calcium after calving increased plasma calcium concentration on the day of calving and during the subsequent 14 days.48 Milk production was not affected by pre- or post-calving treatments.

Experimentally, the application of potassium fertilizer on pasture resulted in a DCAD ranging from 350 to 550 mEq/kg DM but calcium homeostasis in pasture-based dairy cows was not changed.49 Plasma concentrations were increased and the risk of clinical periparturient hypocalcemia was reduced by MgCl2 and MgSO4 delivered by 150 g MgCl2, 200 g MgSO4 and 35 g MgO/head daily for 21 days prepartum.49 After calving cows were supplemented with 150 g CaCO3/head per day for 4 days. Improvements in calcium homeostasis were not due to an altered systemic pH.

The optimum DCAD for lactating cows grazing fresh pasture and the effect of deviating from the optimum on milk production has been examined under experimental manipulating the dietary DCAD using a drench in early-lactation dairy cows in New Zealand.49 Dietary cation–anion differences ranged from +23 to +88 mEq/100 g of DM. As DCAD increased, there was a linear increase in blood pH and HCO3 concentration and blood base excess. Plasma concentrations of Mg, K, Cl declined as DCAD increased and Na increased. Urinary excretion of Ca decreased as DCAD increased. Increasing DCAD did not significantly affect milk yield or milk protein but the concentration and yield of milk fat increased linearly. Milk production results suggest that DCAD for optimal production on pasture diets may be higher than the +20 mEq/100 g DM previously identified for total mixed rations.

Summary of macromineral nutritional strategies for the prevention of hypocalcemia in the soon-to-calf, or transition dairy cow in pasture-based systems. (Transition period is defined as 3–4 weeks prepartum and 3–4 weeks postpartum)

Circumstances and principles:

- When dairy cows are dried off, they are commonly moved onto nonirrigated pastures until calving. In the summer, dry cows would be put onto actively growing tropical pasture, whereas in autumn, winter and spring, the pasture is most likely to be tropical pasture carried over from the previous summer. This carryover pasture is likely to be supplemented with medium quality hay, silage and grain or molasses 2–3 weeks before calving. Anionic salts have been added to these diets.
- The DCAD on a yearly basis ranges from 0 to 80 mEq/100 g DM.
- The incidence of milk fever in Australia ranges from 1.6 to 5.4% but in some years, the incidence in individual herds may reach 20%. The incidence of subclinical hypocalcemia can range widely, up to 40% of apparently normal cows had subclinical hypocalcemia (total plasma calcium <1.9 mmol/L during the first 12 days of lactation).
- The concentration of ionized calcium in blood plasma is under elaborate homeostatic control. This provides for the maintenance of a pool of readily available calcium which can be drawn on for the deposition of maternal and fetal bone and for colosrum and milk.
- The traditional method of preventing hypocalcemia has been to restrict dietary calcium intake during the dry period which stimulates renal synthesis of 1,25-dihydroxyvitamin D3 prior to calving. The cow must be in negative calcium balance.
- In temperate climates, reducing dietary calcium to recommended low levels can be difficult to achieve but in tropical pastures the levels are already low.
- Excessive levels of potassium may be the most important dietary risk factor for milk fever in Australian feeding systems. Potassium contents of pastures may be as high as 4–5% of DM. The use of potassium fertilizers exacerbates the problem. Potassium and dietary DCAD peak in winter and are lowest in autumn. The majority of cows in Victoria, Australia, calve in winter to early spring when the potassium levels are high. Excess potassium results in alkalosis which reduces the sensitivity of bone and renal tissue to PTH.
Hypomagnesemia influences calcium homeostasis and diets high in potassium reduce the concentration of plasma magnesium. Magnesium supplementation of the transition diet should be done to ensure that magnesium requirements are met (0.2–0.4% of DM).

Excessive dietary phosphorus increases the concentration of phosphorus in plasma which can induce hypocalcemia and increase the incidence of milk fever at calving. Supplements likely to increase the dietary intake of phosphorus above 35 g/day should not be fed to cows in the weeks prior to calving.

Excessive intakes of sodium can contribute to the development of metabolic alkalosis and should be avoided.

Options for reducing the risk of hypocalcemia in pasture-fed dairy cows:

**Low calcium intake prepartum.** A low calcium diet in the prepartum period will activate calcium homeostasis at calving. An alternative is to feed calcium binding agents for 1–3 weeks prepartum.

**Magnesium supplementation.** Hypomagnesemia influences calcium homeostasis, potentially predisposing the cow to milk fever at calving. Diets high in potassium can reduce the concentration of plasma magnesium and may be a mechanism linking high dietary potassium to hypocalcemia. Recommended concentrations for dietary magnesium levels are within the range of 0.2–0.4% of total DM intake. Plasma levels are readily elevated when magnesium is added to the diet.

**Calcium supplementation.** Oral administration of gels of calcium chloride or calcium propionate immediately after calving is effective in preventing milk fever. Feeding cows an excess of calcium in the form of calcium carbonate during the first few weeks of lactation is beneficial. Increasing dietary concentration of calcium from 0.68% to 1.02% DM within 8 h of calving has an immediate effect on plasma calcium.6

**Manipulating dietary DCAD with anion feeds.**

The concept of manipulating the DCAD to reduce hypocalcemia under North American and European circumstances is well documented.6 Addition of anionic salts to the diet of transition dry cows to achieve a metabolic acidosis improves the ability of the cow to mobilize calcium at parturition. The pH of both blood and urine consistently fall in response to an appropriate decline in dietary cation excess. For the transition dry cow, the DCAD must fall to between −10 and −15 mEq/100 g DM to prevent milk fever.

In pasture-fed systems, such as in Australia and New Zealand, the pasture diets are high in DCAD (+50 mEq/100 g DM). The more positive the pasture DCAD, the more difficult it is to balance it with anionic salts. Because anionic preparations are relatively unpalatable, cows will not eat enough for total DCAD to fall below 0 mEq/100 g DM.

An alternative to anionic salts is to select feedstuffs with low to moderate DCAD. Lower quality hays and straws have a lower DCAD than high quality forages. However, the feedstuffs must be analyzed before making such a recommendation. Lower quality roughages are also low in calcium. Concentrates with high negative DCAD include molasses and breeder’s grain. Molasses is high in potassium but also high in sulfur.

Measurement of urine pH as a method of monitoring the efficacy of DCAD manipulations and its on-farm use should be encouraged. Urine pH is unlikely to fall to any degree until DCAD of the diet drops below approximately 10–20 mEq/100 g DM. For protection against milk fever, the urine pH needs to be maintained between 5.5 and 6.2 in the last weeks before calving. This could be reduced to a cut-off in the range of pH 6.5–7.0.3,5,7 Calcium gel dosing

The oral administration of easily absorbed calcium salts such as calcium chloride providing 40–50 g calcium per dose as a bolus, a gel, a paste or a liquid, given in 3–4 doses beginning 12–24 h before calving, to 24 h after calving will prevent a significant proportion of milk fever cases.38 The oral administration of one or two doses as a supplement to intravenous calcium borogluconate is also effective in reducing the incidence of relapses. Calcium chloride is caustic and can cause oral lesions. The use of calcium formate (350 mL of 48.6% aqueous suspension), four times at approximately 12 h intervals, had no adverse effects on cows and is considered a safe form of calcium supplementation on adult dairy cows.39 Oropharyngeal abscesses secondary to trauma and laceration caused by the administration of the boluses may occur.

Vitamin D and its metabolites or analogs Vitamin D3 (cholecalciferol) administered parenterally was historically a popular prophylactic against milk fever. However, because of the potential for toxicity of vitamin D injections and expense of its analogs, these are no longer used. The literature on the role of vitamin D in calcium homeostasis and its use in the prevention of periparturient paresis in cattle has been reviewed.4 Their uses are summarized here and advantages and disadvantages outlined.

In an attempt to reverse the negative calcium balance of susceptible cows the administration of vitamin D and its analogs have been used to increase intestinal absorption of calcium. Vitamin D3 is hydroxylated in the liver and the resulting metabolite is 25-hydroxycholecalciferol. This is metabolized in the kidney to 1,25-dihydroxycholecalciferol, which has an active hypercalcemic effect but is difficult to synthesize. One of its analogs, 1α-hydroxycholecalciferol is as active, is easy to prepare, and is used pharmacologically.

Oral dosing with vitamin D3 and the parenteral administration of vitamin D3 and dihydrotachysterol all have their proponents. Oral dosing with 20 million IU of vitamin D3/d for 5 days to cows immediately prior to calving can markedly reduce the expected incidence of milk fever. The exact date of calving is often difficult to determine and if the administration is discontinued for up to 4 days before calving, an unusually high incidence of the disease may follow, probably because of the depression of parathyroid activity which follows the administration. The danger of causing metastatic calcification also exists as this has been produced with smaller doses (10–20 million IU/daily for 10 days). Pregnant cows are more susceptible to calcification than non-pregnant animals. Treatment with larger doses or for longer periods than those recommended earlier should be avoided because of the danger of toxic effects. Smaller doses reduce the risk of calcification but also reduce the degree of calcium retention.

A single dose of 10 million IU of vitamin D3 IM given 2–8 days before parturition has been considered as optimal. A dose of 1 million units per 45 kg BW has given consistently better results. This may explain the variable results and why results have been more favorable in Jersey cattle. If the cow fails to calve after the 8th day, another 10 million units may be administered and repeated every 8 days until the cow calves. Subclinical calcification may occur in vessel walls but this is unlikely if dietary calcium and phosphorus intake is adequate. Single doses of 40 million units of vitamin D can be lethal. One of the disadvantages of this method is the likelihood that cows which do not calve at the anticipated time can be more seriously affected than if they receive no treatment. The hypercalcemic effect of cholecalciferol by injection is very much longer when it is administered by IM injection (up to 25 days) than by IV injection (up to 3 days) for this reason and because occasional cases of shock occur after the IV administration, especially if more than one injection is given, the IM route is preferred. The injection of vitamin D is preferred to feeding it and...
a protection rate of up to 80% can be anticipated. It is estimated that 95% of Jersey cattle are protected.

Other compounds with vitamin D activity but which avoid the possibility of causing hypervitaminosis D and are therefore useful in the prevention of milk fever are:

- **25-Hydroxycholecalciferol** injected IM at 8 mg 3-10 days before calving and repeated at weekly intervals. Single doses of 4 mg are not effective in reducing the occurrence of parturient hypocalcemia or milk fever. When 1,25-(OH)_2D is given IM between 1 and 4 days of calving, it is effective in preventing milk fever. When administered less than 24 h or more than 4 days before calving, parturient paresis is not effectively prevented. Repeated injections at 4-7 day intervals until calving can be used, but toxicity can be a problem. A third problem with this metabolite is that the IM injection can result in milk fever 1-2 weeks after parturition because the exogenous metabolite may inhibit the endogenous production in some cows and when the exogenous product is cleared from the body, the cow is unable to produce sufficient 1,25-(OH)_2D to maintain enhanced intestinal absorption of calcium.

- **24-F, 1,25-dihydroxyvitamin D_3** given at 100-150 μg 5 days before the expected date of parturition was effective.23 Cows which did not calve within 7 days were given a second dose. The incidence of milk fever in untreated controls, those receiving 100 and 150 mg, was 85%, 43%, and 29%, respectively. The use of SC-released product implanted 7 days before parturition and repeated at 7 day intervals until calving resulted in milk fever in 80% of controls and 9% in treated cows. The SC pellet maintained levels of the vitamin D metabolite for about 10 days, compared with the IM injection, which results in very high concentrations in the plasma in the first 48 h after injection.

- **1α-hydroxyvitamin D_3** at 350 μg IM is effective as a preventive to milk fever if given 72 and 24 h before parturition. If calving has not occurred naturally within 72 h, a second injection is given. Parturition is induced if calving has not occurred 2 days after the second injection. The preferred site of injection is the serratus muscle of the neck, which results in a more effective response. To avoid the problems created by cows not calving at the predicted time, a combined regimen including induction of parturition by the administration of corticosteroid with the injection of 1α-hydroxycholecalciferol is reported to be successful. Injection of cows with the same vitamin D analog plus a prostaglandin (cloprostrenol) was unsuccessful in preventing milk fever. A dose of 700 μg given 6-8 days before calving is also recommended. Another recommendation suggests 500 μg at 2-5 days prior to parturition. An evaluation of routine use of 1α-hydroxyvitamin D_3 indicated that cows which developed retained placenta and metritis may be at greater risk of not conceiving within 150 days from calving. There is some transfer of the metabolite from the maternal to fetal plasma. Injection within 24 h of the onset of milk fever is ineffective, but if it is given more than 24 h and less than 1 week before the onset of the disease, the protection is excellent.

**General management practices**

The following management practices are suggested:

- Avoid overfattening by either reducing exercise and allowing the animals to eat to satiety, thus keeping cows on feed
- Avoid stresses at the time of parturition
- Provide a clean well-bedded box stall with conditions conducive to cow comfort and allow the animal to exercise
- Make frequent observations of cows prone to milk fever from 48 h before to 48 h after parturition for evidence of milk fever and immediate treatment will reduce the incidence of the downer cow syndrome associated with milk fever
- At calving the cow should receive an oral dose of a calcium salt in a gel, as set out later, followed by a diet with a high calcium content (over 1% of dry matter). The critical day is the day of calving and a sharp increase in calcium intake on this day can significantly reduce the occurrence of milk fever
- If hypomagnesemia is a likely concomitant, the diet should be supplemented with 60 g magnesium oxide daily.

**REVIEW LITERATURE**

DOWNER COW SYNDROME (NON-AMBULATORY COWS WITH NON-PROGRESSIVE NEUROLOGICAL FINDINGS)

ETIOLOGY

Most commonly, the downer cow is a complication of milk fever. Ischemic necrosis of the large muscles of the pelvic limbs and injuries to the tissues around the hip joint and of the obturator muscles are common in cows which do not fully recover and stand but remain recumbent following treatment for milk fever. Injuries to the musculoskeletal system are also common as a result of cows 'spread-eagling' their hindlimbs if they are unsteady during parturition or forced to stand or walk on a slippery floor immediately before or following parturition. Dystocia due to an oversized calf may result in extensive edema of the pelvic tissues and vulva, and failure of the cow to stand following parturition. If these cows develop milk fever, it is unlikely they will be able stand following treatment with calcium.

EPIDEMIOLOGY

Occurrence

The disease occurs most commonly within the first 2 or 3 days after calving in high-producing dairy cows immediately following milk fever. Cattle may also become persistently recumbent for many reasons other than complications of milk fever such as peracute coliform mastitis and carbohydrate engorgement. Downer cows can be divided generally into non-ambulatory cows with non-progressive neurological findings and non-ambulatory with progressive neurological findings indicative of the presence of lesions in the nervous system as the cause of the recumbency.2 A survey of bovine veterinarians in the USA in 1998 collected data on non-ambulatory dairy and beef cows with non-progressive neurological findings, 85% of cases fit into three categories: injury/trauma, septicemia/toxemia, or non-responsive milk fevers. Of the total, 3.3% remain undiagnosed. In non-ambulatory beef cows with non-progressive neurological findings, trauma/injury, septicemia, and other neurological cases accounted for 78% of cases. Of the population studied, 0.12% of cows developed non-ambulatory non-progressive neurological findings syndrome for a case rate of 2476/10² cows. Of the total, 73% failed to recover. Of the beef cows, 0.0053% remain undiagnosed, which implies that 4.3% of all beef cows with non-ambulatory non-progressive CNS findings were unknown and undiagnosed and 96% were diagnosed.

Of the total number of non-ambulatory progressive CNS cases reported for dairy cattle, the percentage was 0.027% for a case rate of 554/10⁶. Of these, 17.7% were unknown or undiagnosed indicating that 82% of progressive CNS dairy cattle cases were diagnosed. The progressive CNS cases of unknown cause represented 0.0047% of the study's cattle population, or a rate of 94 cases/10⁶ dairy cows. Seventy-one of the cases failed to recover for a mortality of 375 cases per million dairy cows in the study.

The profile of a progressive CNS dairy cow case found that other known CNS diseases, septicemia/toxemia, unknown CNS diseases, and non-responsive milk fever to be the most frequently reported cases.

Of the total number of non-ambulatory progressive CNS cases reported in beef cattle, the percentage was 0.018%. Of these, 9.0% were of unknown etiology indicating that 91% of progressive CNS beef cow cases were diagnosed by veterinarians. The unknown progressive CNS case rate was 32 cases/10⁶ beef cattle. The total deaths in progressive CNS cases accounted for a mortality rate of 282/10⁶.

The profile of progressive CNS beef cow cases found that four categories accounted for 83.4% of the total cases: injury/trauma, known infectious agent, septicemia, toxemia, and known CNS disease.

Incidence

The incidence as a complication of milk fever is high because many affected animals are high producers and of high economic value. Accurate data on the incidence are not available because of variations in the nomenclature used and the accuracy of diagnoses. For example, some observations report that all cases are caused by nerve injury.2 Cases included in this classification are classified by others as maternal obstetric paralysis, obturator paralysis, or hypophosphatemia. Because it is a
syndrome lacking in clinical definition and 'includes all those other cases' which cannot be otherwise classified, the incidence varies depending on the clinical acuity of the individual veterinarian, and on various environmental factors in different areas. However, the incidence seems to be increasing, particularly in intensive dairy farming areas, although this impression could arise from the increased necessity to effect a cure in valuable animals.

A mail survey of 723 dairy herds in Minnesota found a downer cow incidence of 21.4/1000 cow years at risk.³ The overall outcome was that 33% recovered, 23% were slaughtered and 44% died. The owners perceived that downer cows were high producers (48%) or average producers (46%), with only 6% being low producers. Approximately 58% occurred within 1 day of parturition and 37% occurred during the first 100 days of lactation. The incidence was highest (39%) during the three coldest months: December, January, and February. In New Zealand, the prevalence ranges from 3 to 5% of all dairy cows at calving time.⁴

In a clinical and laboratory survey of 433 periparturient recumbent cows in New Zealand, 39% recovered, 30% died, and 32% were destroyed.⁴ The case-fatality rate was 11% higher in pre-calving recumbent cows than post-calving cows.

An audit of 21 slaughter plants in the USA in 1993 found 1.1% of arriving dairy cows were non-ambulatory, and in 1999, 1.5%.⁵ In 1993, 1.0% of beef cows arriving at slaughter plants were non-ambulatory and in 1999, 0.7%.⁶

Risk factors
Animal risk factors

Complication of milk fever. Prolonged recumbency after a long delay in the treatment of milk fever is a major risk factor. Prolonged recumbency before treatment for milk fever (more than 4-6 h) results in ischemic necrosis due to obstruction of the blood supply, especially in a heavy cow if she lies on one leg for a long period.⁶ Cows which develop milk fever while in a standing tie-stall may slide backwards into the gutter behind the stall, resulting in extreme pressure to their pelvic limbs and leading to ischemic necrosis.

A case-control study to identify risk factors for the development of downer cow syndrome within 30 days post partum in 12 dairy herds over 2705 lactations found that clinical hypocalcemia and stillbirth increased the risk of the disease five-fold.⁷ Cows with retained placenta and dystocia were also more likely to develop downer cow syndrome than cows without either problem.

A marked increase in the CPK levels in cows with milk fever and failure to stand after repeated treatments is supporting evidence for ischemic necrosis associated with prolonged recumbency as a major cause of downer cow syndrome.¹ The CPK levels increase markedly between the first and second treatments, which indicates that muscle damage has occurred and the levels are highest in cows which do not recover.

Experimentally, enforced recumbency of cattle for 6, 9, or 12 h with one hindlimb positioned under the body results in downer cow syndrome. Affected cows are unable to stand and the affected limb is swollen and held rigid similar to the injured limbs of human patients with compartmental/crush syndrome.

Surveys have shown that downer dairy cattle have 3.3-fold-higher prevalence of E. coli 0157:H7 than healthy cattle within a certain time frame and geographic area.⁸ Culled dairy cows account for approximately 17% of the ground beef produced in the US and thus downer cattle harboring E. coli 0157:H7 may be an important source of contamination of ground beef which is commonly processed from downer cattle.

Traumatic injuries to pelvis and pelvic limbs. Traumatic injuries to the nerves of the pelvis and hindlimbs are present in 25% or more of downer cows.¹ The sciatic and obturator nerves are vulnerable to injury by pressure from the calf moving through the pelvic canal during parturition. Pressure injuries on the superficial nerves (radial and peroneal) of the extremities also occur in recumbent cows.

Serum electrolyte imbalances. Serum electrolyte imbalances or deficits may be associated with prolonged recumbency following treatment for parturient paresis.

Hypocalcemia. A persistent hypocalcemia following treatment for milk fever may exist in a downer cow but is unlikely to be the principal cause because treatment with calcium salts does not resolve the signs, even temporarily. However, the use of an insufficient amount of calcium for the initial treatment of milk fever in large, heavy cows may result in an incomplete response and failure of the cow to stand. If these cows are not retreated soon enough with an adequate amount of calcium, ischemic necrosis of the limb muscles occurs and leads to prolonged recumbency. In many cases, even after the cow is given a sufficient amount of calcium, prolonged recumbency occurs due to the ischemic necrosis.

Hypophosphatemia. The serum levels of inorganic phosphorus decline to below normal along with a hypocalcemia in cases of milk fever. Following treatment of milk fever with calcium borogluconate, the levels of serum calcium and phosphorus return to normal if the animal responds favorably and stands normally. Following treatment for milk fever, some cows do not or are unable to stand and their serum phosphorous levels are subnormal. This persistent hypophosphatemia has been regarded as a cause of downer cow syndrome associated with milk fever. Many veterinarians claim that these cows respond to treatment with phosphorus. However, persistent recumbency is associated with subnormal levels of serum phosphorus which increase to normal if the cow stands regardless of treatment with or without phosphorus. Mature dairy cows may become recumbent in early lactation and subnormal levels of serum phosphorus may be present.⁹ Other cows in the herd may be lame due to demineralization of bones associated with a dietary deficiency of phosphorus.

Hypomagnesemia. A low serum level of hypomagnesemia has been associated with the downer cow, especially when it accompanies hypocalcemia. But it is usually manifested by a tetanic hyperesthetic state which is not part of downer cow syndrome. Hypokalemia is, with hypophosphatemia, the most commonly quote cause, especially in the so-called 'creeper' cows, which are bright and alert and crawl about, but are unable to rise.¹⁰

Hypokalemia. Ischemia due to prolonged recumbency associated with milk fever, may increase the cell membrane permeability of muscle fibers and allow ion loss of potassium from the cell; this in turn causes the myotonia, which appears to be the basis of downer cow syndrome. This view is supported by the low serum and muscle potassium levels in downer cows. Claims are made that potassium salts are successful in treatment but these have been difficult to evaluate.¹¹

Hypokalemia occurs in dairy cows which have been treated with isoflupredone acetate for ketosis.¹² Affected animals are weak, recumbent and severely hypokalemic with serum potassium levels ranging from 1.4 to 2.3 mEq/L.

Environmental and management risk factors

A slippery ground surface is a major risk factor. Cattle which must walk across slippery floors, especially at the time of calving, may slip and fall and injure the large muscles of the pelvic limbs, resulting in an inability to stand. Prolonged recumbency results in ischemic necrosis and downer cow syndrome.

Summary

Dowmer cow syndrome is a complication of the recumbency associated with milk fever. A delay of 4 h or more in that treatment of cows with milk fever may result in ischemic necrosis of the muscles of the pelvic limbs. Traumatic injury to leg muscles at the time of parturition or when the
cow is unsteady and falls during the first stage of milk fever will also result in the inability of the cow to stand following treatment of milk fever.

PATHOGENESIS
Several different primary factors or diseases can result in recumbency.

Prolonged recumbency before treatment
A long delay in the treatment of milk fever can result in pressure damage and the subsequent inability to stand after treatment for the primary disease. Prolonged recumbency results in pressure damage, which occurs secondarily and is a factor common to all cases.3

Regardless of the cause, the prolonged recumbency results in varying degrees of ischemic necrosis of major muscles of the hindlimbs, particularly the semitendinous muscle and muscles caudal to the stifle. Prolonged compression of the muscle leads to tissue anoxia, cell damage and inflammation which causes swelling; the swelling causes a further increase in pressure which limits tissue perfusion and leads to a detrimental cascade of events. The thick fascial boundaries of the semitendinous muscle prevent expansion which results in pressure-induced compartmental syndrome. Sciatric nerve damage due to pressure also occurs and may contribute to downer cow syndrome. Experimental external compression of the pelvic limb of the goat, to simulate limb compression in recumbent cows, resulted in a marked reduction in nerve condition velocity of the peroneal nerve which was associated with clinically evident limb dysfunction. Damage to the peroneal nerve will result in hyperflexion of the fetlock if and when the cow is able to stand.

Traumatic injury to limb muscles and nerves immediately prior to parturition or at the time of parturition can also result in prolonged recumbency and subsequent pressure damage.3

Experimental sternal recumbency
Experimentally induced sternal recumbency with one hindlimb positioned under the body to simulate prolonged recumbency will result in a swollen rigid limb within 6–9 h.12 Following injury to the muscle cells, the serum levels of CPK are markedly elevated at about 12 h after the onset of recumbency. Proteinuria and in some severe cases myoglobinuria occur between 12 and 36 h after the onset of prolonged recumbency, due to the release of myoglobin from damaged muscles. In cows which make efforts to stand but cannot do so, continued struggling results in rupture of muscle fibers and hemorrhage which increases the severity.

Acute focal myocarditis may occur in about 10% of cases resulting in tachycardia, arrhythmia, and the unfavorable response to IV calcium salts observed in some cases. The cause of the myocardial lesion is unknown but repeated administration of calcium salts has been suggested.1 Downer cows with a poor prognosis also have greatly enhanced adrenocortical function.10

The prolonged recumbency can result in additional complications such as acute mastitis, decubitus ulcers, and traumatic injuries of the limbs.

The pathogenesis of the non-alert downer cow is not understood.13 Most have had an initial episode of milk fever but do not respond satisfactorily. Within 1 or 2 days, affected cows have a preference for lateral recumbency and exhibit expiratory moaning and groaning. They represent about 2% of all cases of milk fever.

Experimental prolonged hypocalcemia
Experimental prolonged hypocalcemia may provide some clues about the pathogenesis of downer cow syndrome as a complication of milk fever. The prolonged infusion of ethylenediamine tetra-acetic acid (EDTA) in sheep over 18 h at a rate to induce hypocalcemia and maintain recumbency results in prolonged periods of recumbency, ranging from 36 to 64 h before the animals are able to stand.14 There are also decreases in plasma sodium, plasma potassium, and erythrocyte potassium and prolonged increases in packed cell volumes, which suggests that fluid replacement therapy may be indicated in cattle with prolonged recumbency associated with hypocalcemia.15 A 4-h IV infusion of EDTA in high erythrocyte potassium and low erythrocyte potassium dairy cows causes decreases in plasma inorganic phosphorus and plasma potassium which are still below normal 24 h later.16 The AST, CPK, and PCVs and WBC counts are also elevated 24 h later. Plasma magnesium and erythrocyte sodium and potassium were decreased but this was delayed. The increase in PCV was most pronounced in the low erythrocyte potassium cows, which may provide some clues about the pathogenesis of downer cow syndrome. Some cows may have a more precipitate increase in PCVs due to loss of plasma volume and an inability to mobilize calcium. As a basis for studying the effects of hypertonic solutions to correct these abnormalities in downer animals, a 200 mL solution of 10 g of sodium chloride and 0.5 g of potassium chloride can be given IV to sheep safely over a period of 4–8 min.17

CLINICAL FINDINGS
The downer cow syndrome may occur independently, or follow apparent recovery after treatment for milk fever, except for the prolonged recumbency. In the typical case, affected cows either make no effort or are unable to stand following treatment for parturient paresis. About 30% of cows treated for milk fever will not stand for up to 24 h following treatment. Those which are unable to stand after 24 h and after two treatments are classified as downers. They are usually bright and alert and, although the appetite is reduced, the cow eats and drinks moderately well. The temperature is normal and the heart rate may be normal or elevated to 80–100 bpm. Tachycardia and arrhythmia occur in some cows, especially immediately following the administration of calcium IV and sudden death has occurred. Respirations are usually unaffected. Defecation and urination are normal but proteinuria is common and if marked may indicate extensive muscle damage.

Some affected cows may make no effort to stand. Others will make frequent attempts to stand but are unable to fully extend their pelvic limbs and lift their hindquarters more than 20–30 cm from the ground. These frequent attempts to stand result in 'crawling' or 'creeping' along the ground with both hindlegs in a partially flexed position and displaced posteriorly—the frogleg attitude. On a non-slippery surface (bare ground, sand pack, or deep bedding) some cows are able to stand with some assistance by lifting on the tail head or with the use of lap slings. Those cows which do not make an effort to stand usually cannot stand even with assistance and if supported with hip slings will usually make no effort to bear weight with either the hindlimbs or the forelimbs. Their limbs appear stiff, painful, or numb and they are unable or reluctant to bear weight. Damage to the peroneal nerve is usually present when there is hyperflexion of the fetlock joints, which is evident if and when the cow is able to stand and bear weight on the hindlimbs.

In some cases, the hindlimbs are extended on each side of the cow and reach up to the elbows on each side. In this position, the cow is bearing considerable weight on the medial thigh musculature and causing ischemic necrosis. This abnormal position of the legs may also be due to dislocation of one or both hip joints or associated with traumatic injuries surrounding the hip joints with or without rupture of the ligamentum teres. Regardless of the cause, the cow prefers this leg position and invariably will shift the legs back to the normal position if they are placed in their normal position.

In some cows, the signs may be more marked and bizarre, including a tendency to lie in lateral recumbency with the head drawn back. When placed and propped up in sternal recumbency, these cows appear
almost normal but, when they are left alone, within a short period of time they revert to the position of lateral recumbency. Still more severe cases are hyperesthetic and the limbs may be slightly stiff but only when the cow is lying in lateral recumbency. These severe cases do not usually eat or drink, have been described as ‘non-alert downers’, and are thought to have brain damage which has not been documented.\textsuperscript{13}

Complications in the downer cow syndrome are common and often result in death or the need for euthanasia. Coliform mastitis, decubitus ulceration, especially over the prominences of the hock and elbow joint, and traumatic injuries around the tuber coxae caused by the hip slings are common. When these complications occur in the early stages of the disease, they commonly interfere with any progress being made and become the focus of clinical attention.

The course of the disease is variable and dependent on the nature and extent of the lesions and the quality of the care and comfort which is provided for the cow during the first few days. About 50% of downer cows will stand within 4 days or less if cared for properly. The prognosis is poor for those which are still recumbent after 7 days, although some affected cows have been down for 10–14 days and subsequently stood up and recovered. Death may occur in 48–72 h following the onset and is usually associated with myocarditis.

\textbf{Clinical examination of the downer cow}

Clinical examination of the downer cow can be very difficult and challenging depending on the environmental circumstances and the physical size of the animal. Many different metabolic, nutritional, musculoskeletal, toxic, neurological, neoplastic, inflammatory, and infectious diseases can cause recumbency in cattle.\textsuperscript{18-20} It is very important to obtain an adequate history of the case on the first visit to the animal. Key aspects of the history include age of the animal, duration of recumbency, any previous clinical abnormalities before the recumbent stage such neurological in the case of bovine spongiform encephalopathy, or spinal cord lymphomatosis, any previous treatments with particular attention to mineralocorticoids which may cause hypokalemia, the anatomical location of any parenteral injections, time since recent parturition, diet and accidental access to new feeds, sudden unaccustomed exercise, and an assessment of the management provided.

The environment and the ground surface surrounding the recumbent animal may provide clues about the possibility that the animal slipped, fell, and was injured.

A systematic physical examination of all accessible body systems is necessary. The animal should be examined visually from a distance for evidence of abnormalities of the carriage of the head and neck, the position of the limbs, observe any attempts of the animal to stand or creep along the ground surface.

The details of the clinical examination are presented in Chapter 1. The standard close clinical examination is necessary to determine body temperature, heart rate and pulse, respiratory rate, and the state of the major body systems such as the respiratory tract, cardiovascular system, central nervous system for mental state, and gastrointestinal tract, mammary gland, reproductive tract, any of which may indicate the presence of abnormalities associated with shock which results in recumbency.

In the recently calved cow, particular emphasis must be given to adequate examination of the udder for mastitis, the uterus for metritis, and the gastrointestinal tract for diseases associated with toxemia and dehydration and shock (acute diffuse peritonitis, carbohydrate engorgement), which results in recumbency. A urine sample must always be obtained and tested for ketones, and the presence of myoglobinuria. A vaginal examination of the uterus should always be done along with a rectal examination.

Careful systematic examination of the musculoskeletal system includes palpating the muscles, bones, joints, and feet of each limb, including passive flexion and extension of each limb is necessary. The coxofemoral joints are examined for evidence of dislocation. The vertebral column is examined for evidence of painful sites or displacement of vertebrae. It is important to examine both sides of the animal which means rolling the cow over from side to side; often the animal may have to be rolled over more than once to repeat a particular examination.

A neurological examination includes examination of the withdrawal reflexes and sensation of all four limbs, reflex arcs of the spinal cord, careful examination of lumbar and sacral areas including sensation and tone in the tail, and examination of the cranial nerves.

The examination can be extended by lifting the downer cow with appropriate lifters and observing if the animal extends its limbs and attempts to bear weight. While the animal is being assisted to stand, additional examinations of other parts of the body can be made.

\textbf{CLINICAL PATHOLOGY}

The calcium, phosphorus, magnesium and glucose levels of the blood are within the normal range and the results of hematological examinations are usually consistent with those found in normal cows which have recently calved. The CPK and AST levels are usually markedly elevated by 18–24 h after the onset of recumbency and continue to elevate within the next few days. Continued elevation of CPK levels indicates continued muscle damage. In experimentally induced recumbency in cows, the CPK levels remained within normal limits for the first 6 h. However, by 12 h there was a marked increase to mean values of 12 000 U/L rising to 40 000 U/L by 24 h. There may be moderate ketonuria. A marked proteinuria is usually evident by 18–24 h after the onset of recumbency. The proteinuria may persist for several days or be absent within a few days. In severe cases, the urine may be brown and turbid because of severe myoglobinuria. Low arterial blood pressures and abnormal electrocardiograms (ECGS) have been observed in some animals.

Elevations of serum urea, muscle enzymes, and laboratory evidence of inflammation are considered the best prognostic indicators of an unfavorable recovery.\textsuperscript{4} The recovery rate was lower in cows with a total protein:fibrinogen ratio less than 10:1, and evidence of neutropenia and/or left shift.\textsuperscript{6} Cows with a serum urea level above 25 mmol/L and serum creatinine levels above 130 mmol/L had a poor prognosis.

The CPK levels need to be interpreted in relation to the days of recumbency when the sample was taken. Critical levels may be highest initially (up to 50 times the upper normal reference range) and reduce to 10 times normal range at 7 days of recumbency.

In a series of 262 recumbent dairy cows serum samples were analyzed for creatine phosphokinase (CPK), lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) to evaluate the value of serum enzyme activities for predicting a failure to recover.\textsuperscript{21} The most common diagnosis was milk fever 61.1%, dystocia 11.1%, mastitis 8.4%, and trauma 6.9%. The prior probability of the cow not recovering was 0.24, 0.69, and 0.81 on days 1, 2, 3, and 4 of recumbency. The optimal cut-off points maximizing the sensitivity and specificity of the tests were 2330, 2225, and 171 U/L for CPK, LDH, and AST, respectively. The predictive value of AST was significantly better with optimal cut-off points of 128 and 189 U/L, respectively. AST provided the best predictive indicator of whether a recumbent cow would not recover, the best results being obtained with serum samples taken on the first day of recumbency.
NECROPSY FINDINGS

Hemorrhages and edema of the skin of traumatic origin are common. The major pathological changes consist of hemorrhages and degeneration of the medial thigh muscles. Hemorrhages around the hip joint with or without rupture of the ligamentum teres are also common. Local areas of ischemic necrosis of the musculature (gracilis, pectineus, and adductor muscles) occur at the anterior edge of the pelvis symphysis. Eosinophilic infiltration of ruptured necrotic thigh muscles of downer cows has been described. Hemorrhages and edema of the nerves of the limbs (obturator, ischiatic, peroneal, radial) are also common and usually associated with severe muscle damage. The heart is dilated and flabby and histologically, there is focal myocarditis. There is fatty degeneration of the liver and the adrenal glands are enlarged. Histologically, there are also degenerative changes in the glomerular and tubular epithelium of the kidneys.

DIFFERENTIAL DIAGNOSIS

The diagnosis of downer cow syndrome is made after all other known causes of recumbency have been eliminated in a cow which had milk fever and failed to stand within 24 h following two successive courses of treatment. The other common causes of prolonged recumbency are described under the differential diagnosis of milk fever (Table 29.5). It is difficult and time consuming to examine a downer cow thoroughly to eliminate all other causes of recumbency. Only by repeated careful clinical examination will the clinician avoid the embarrassment of failing to detect the presence of coliform mastitis, a fractured leg or a dislocated hip.

TREATMENT

The prognosis of a downer cow depends on the cause of the recumbency and whether or not treatment is indicated or if euthanasia should be recommended because of the presence of abnormalities which are unlikely to respond favorably to treatment and also be economical. If the prognosis is poor, euthanasia on the farm should be recommended. If the prognosis is favorable, the clinician should inform the owner about the nature of the treatment which will be necessary and its duration which may be several days of supportive care and therapy, and should outline the costs which will be incurred.

Fluid and electrolyte therapy

Many treatments including the injections of magnesium salts, phosphates, corticosteroids, stimulant tonics, and vitamin E and selenium have been used without consistent success. The use of parenteral solutions containing potassium, calcium, magnesium, and phosphorus has been recommended but there is no scientific evidence that these electrolytes, in addition to what was probably given to the cow already, are indicated or are of any beneficial value. Large quantities of fluid and multiple electrolyte therapy by the oral or parenteral route is indicated for cows which may not be drinking normal quantities of water. Multiple electrolytes can be added to the drinking water if the cow is drinking normally.

Bedding and clinical care

The most important aspect of treatment is to provide the most comfortable bedding possible and to roll the cow from side to side several times daily to minimize the extent of ischemic necrosis and para-analgesia which results from prolonged recumbency. With conscientious care and the provision of good bedding, palatable feed and liberal quantities of water, most cows will attempt to stand with some difficulty and assistance within 24 h, and will stand unassisted and normally 1 or 2 days later. A sand or dirt pack is the ideal ground surface which facilitates standing when downer cows attempt to stand. If affected cows are left on a slippery ground surface, they will not make an effort to stand and will become progressively worse. Cows should be milked normally and the udder kept clean by washing with germicide soap before milking, and post-milking teat dips applied.

Assisted lifting to aid standing

The clinician and farmer are commonly faced with the questions of whether or not to lift a recumbent cow which has not attempted to stand within a few hours after treatment for milk fever. The guiding principle should be the behavior of the cow. If the cow makes an effort to stand on her own or by some coaxing such as a gentle nudge in the ribs, she should be assisted to stand by insuring a good non-slip ground surface, deep bedding, and lifting up on the tailhead when she attempts to stand. The cow should be rolled from side to side every few hours and encouraged to stand a few times daily. With good clinical care, most cows with the uncomplicated form of downer cow syndrome secondary to milk fever will stand in 12-24 h.

Lifting devices

Several different kinds of cow-lifting devices have been used to assist downer cows to stand. Hip lifters, which fit and tighten over the tuber coxae, and body slings like harnesses are designed to fit around the abdomen and thorax of the animal. These devices can assist a downer cow to stand if she makes some effort on her own and it appears that ‘if she were given some help she could stand’. For those cows which make some effort to stand, the hip lifters or slings can be applied and the animal lifted to the standing position. If the animal bears weight on all four legs, she should be allowed to stand with the aid of the devices for 20-30 min and then lowered down. This procedure should be repeated several times daily. In most cases, such downer cows will stand on their own within a few days. While the cow is in the standing position, she can be milked and other clinical examinations can be carried out.

The hip lifters can result in traumatic injuries to the tissues surrounding the tuber coxae if not used judiciously. Animals which make no effort to stand and bear weight on their own must not be left suspended in the lifter for more than a few minutes but lowered immediately. If the hip lifters are not applied carefully, the animal may slip out of the device while she is being lifted, which commonly results in tissue injury around the tuber coxae; fractures of the coxae have even occurred. These injuries are often unnoticed clinically, contribute to persistent recumbency and the true extent of the lesions are evident at necropsy. Lifting devices must be used carefully by experienced personnel.

Body slings which fit around the abdomen and thorax of the animal appear to be the ideal ‘animal lifter’ because they distribute the weight over several sites in contrast to the hip lifters, which concentrate the weight over the tuber coxae. However, the body slings are cumbersome to apply to a recumbent animal, and require more time and experienced personnel to insure proper application. When the slings are applied properly, they do appear to allow the lifted animal to stand comfortably for 30 min or more and promote recovery.

Lifting cows which make no effort to stand on their own is usually unsuccessful. When lifted, they usually do not bear any significant weight.

A water flotation tank has been designed for the management of downer cows. A prototype consists of a metal tub with inside dimensions of 92 in long, 43 in wide, and 51 in deep. The system is affordable, portable, durable, effective, and simple to use. The downer cow is pulled into the tub on a mat and the ends of the tub closed to make a water-tight container with an open top like a bath tub. With the cow’s head held up by a halter, the tub is filled with water at 100–102°F as quickly as possible. Cows in lateral recumbency will roll into sternal recumbency when 12–24 in of water are in the container and will usually attempt to stand when the
tub is one-half to two-thirds full. Cows are allowed to stand in the water for 6–8 h. If the water temperature falls below 95°F, more hot water is added. When the decision is made to remove the cow, the water is drained and the end of the tub opened, which allows the cow to walk out preferably onto a ground or grass surface. A success rate of 46% has been reported. However, the success rate could be higher if the selection of cases for flotation are more rigorous. Cows with ruptured tendons, fractures, luxated coxofemoral joints, septic polyarthritis, and other physical injuries of the musculoskeletal system are not good candidates for flotation. The most suitable case for flotation would appear to be the downer cow as a sequel to milk fever.

**Handling, transportation, and disposition of non-ambulatory cattle**

There has been considerable controversy and disparity among veterinarians and livestock producers about the handling, transportation, and disposition of non-ambulatory cattle. Economics has a major influence on decision making in these cases. There has been no common understanding of whether or not they are fit for transportation and which ones are fit for slaughter for salvage. When the owner and veterinarian are faced with a downer cow which is valuable, and the cause of the recumbency is uncertain, the tendency is to either attempt to provide treatment for several days and assess the progress, or consider slaughter for salvage. In the case of valuable breeding animals which are recumbent as a complication of milk fever, or a disease such as acute carbohydrate engorgement, peracute mastitis, supportive, and specific therapy are commonly selected. In the case of downer cattle of commercial value, slaughter for salvage has been a common option. Cattle producers would like to obtain as much financial return as possible by slaughter for salvage. Cattle affected with complications of milk fever (ischemic necrosis of the pelvic limbs), traumatic injuries of the musculoskeletal system and other diseases not associated with toxemia or sepsis were commonly submitted to slaughter for salvage. Transportation of these compromised animals has always been an animal welfare issue because of the difficulty of loading them humanely because of their size. The mere act of lifting, pulling, dragging, and by other means of forcefully loading an animal weighing 500–800 kg onto a truck cannot be done without considerable pain and discomfort to the animal. However, beginning in the 1990s worldwide, concern emerged from the public about the handling and disposition of non-ambulatory animals particularly downer cows regardless of the cause of their recumbency. Government animal health regulatory agencies, livestock associations, and veterinary associations began drafting regulations on the care and handling of non-ambulatory recumbent animals like the downer cow.

The downer cow syndrome is an animal welfare issue and the veterinarian should be proactive about the problem. Society is concerned about how downer animals are cared for and handled and the methods used for their disposition. If recovery does not occur within a few days the prognosis is uncertain and the owner and veterinarian must decide whether to continue providing clinical care to the downer cow or if the animal should be euthanized. In the USA in 1990–1992, 117 301 recumbent cattle were slaughtered at federally inspected abattoirs. Many consumers believe that meat derived from any non-ambulatory animal is unwholesome.

Disposition of downer cows in the USA

In December 2003, the US Department of Agriculture issued a ban on the slaughter and sale of non-ambulatory cattle for food. The ban applies to all states and at all federally-inspected slaughter plants.

Disposition of downer cows in Canada

In Canada, the Health of Animals Regulations states ‘no person shall load or cause to be loaded on any railway car, motor vehicle, aircraft, or vessel and no one shall transport or cause to be transported an animal (a) that by reason of infirmity, illness, injury, fatigue or any other cause cannot be transported without undue suffering during the expected journey’. The Canadian Veterinary Medical Association’s position statement regarding non-ambulatory livestock states: ‘if the animal is to be moved to a suitable processing facility, a veterinary inspection of the non-ambulatory animal must be performed on the premises of origin. The animal must be accompanied by an antemortem veterinary certificate declaring whether the animal can or cannot be humanely loaded, that the animal is fit for slaughter and that the owner has observed all applicable withdrawal times for drugs used. The loading and transportation of non-ambulatory animals must be performed in a manner to avoid pain, suffering and distress to the animal and upon arrival at the processing facility, the animal must be humanely stunned or euthanized on the vehicle prior to unloading. Equipment currently being used includes slide boards and mats, forklifts, front-end loaders, hand carts, slings, ‘cow caddys’ and stone boats or sleds. In those situations where the non-ambulatory animal is passed for slaughter, but where the veterinarian deems loading and transportation inhumane, the Canadian Veterinary Medical Association recommends on-farm slaughter. Non-ambulatory animals deemed unfit for slaughter should be humanely euthanized on-farm and the carcass disposed of in accordance with local regulations’. In order to quantify the frequency of non-ambulatory cattle being transported to federally inspected slaughter plants and auction markets, the Canadian Food Inspection Agency conducted a national, non-statistical survey, focusing on inspection sites at 19 slaughter facilities and 3 auction markets across Canada. These represent only a portion of all such federally inspected facilities. During the year 2001, 7382 non-ambulatory cattle were observed to arrive at these sites. Of this total, 89.8% were classified as dairy carcasses, while 10.2% were beef carcasses. The data strongly suggested that the vast majority of non-ambulatory animals originate on-farm, with less than 1% becoming non-ambulatory in transit or accidentally. Inspection led to carcass condemnation in 37% of non-ambulatory dairy animals. In 2003, the Canadian Food Inspection Agency (CFIA) conducted stakeholder consultations on the evaluation of non-ambulatory livestock for fitness for transport. Stakeholder comments indicated that the small potential salvage value does not justify the animal suffering, human health hazards, reduced meat quality and negative impact on the image of the Canadian livestock industry that are associated with the loading of non-ambulatory livestock.

Most often, producers ship non-ambulatory livestock because they see no alternative – be it due to provincial restrictions, lack of inspectors, or missing infrastructure. Veterinarians have a professional responsibility to educate producers in the prevention, proper care, handling, and humane disposition of the non-ambulatory animal.

On 18 December, 2004 a proposal to amend the Health of Animals Regulations was published in Canada Gazette I. The proposed amendment would define a non-ambulatory animal as ‘an animal of the bovine, caprine, cervid, cameld, equine, porcine, or rattle species that is unable to stand without assistance or to move without being dragged or carried’. It would also clarify that:

* no person shall load or cause to be loaded on a conveyance or unload or cause to be unloaded a non-ambulatory animal for any purpose other than for transport for veterinary treatment or diagnosis on the advice of a veterinarian, and that
non-ambulatory animal may be loaded on a conveyance or unloaded for purposes other than for veterinary treatment or diagnosis if the animal has first been rendered unconscious.

The Canadian Food Inspection Agency declared its Compromised Animals Policy, which is accessible at http://www.inspection.gc.ca/english/animal/hasan/transport/policies.html

Definitions used

Compromised animal. An animal with reduced capacity to withstand the stress of transportation, due to injury, fatigue, infirmity, poor health, distress, very young or old age, impending birth, or any other cause. Some animals can be transported under certain conditions without being exposed to additional suffering. Others, such as non-ambulatory animals, animals with a body condition score indicating emaciation or weakness, or animals with severe lameness, would endure additional suffering during the transportation process and must not be transported except for veterinary treatment or diagnosis. This is true of any condition associated with pain that will be aggravated by transport.

Non-ambulatory animal. 'Non-ambulatory animal' means livestock or an animal that is unable to stand without assistance or to move without being dragged or carried, regardless of size or age. Non-ambulatory animals are also called 'downers'.

Disposition of downer cows in Europe

A proposed Council Regulation on the protection of animals during transport and related operations would define fitness of transport and ban the transport of animals deemed unfit. Animals that are injured or that present physiological weaknesses or pathological processes shall not be considered fit for transport. This includes animals that are unable to move independently without pain or to walk unassisted, and animals with severe open wounds. All member states of the EU would have to comply with the New Council Regulation. Access at: www.europa.eu.int/eur-lex/en/com/pdf/2003/com2003_0425en03.pdf

CONTROL

The early detection and treatment of milk fever will reduce the incidence and severity of downer cow syndrome. Under ideal conditions, cows should be treated during the first stage of milk fever before they become recumbent. Once recumbent, cows should be treated as soon as possible and not delayed for more than 1 h. Cows with milk fever should be well-bedded with liberal quantities of straw, or moved to a soft-ground surface. Recumbent cows should be coaxed and assisted to stand if possible after treatment for milk fever. If they are unable to stand, they should be rolled from one side to the other every few hours if possible. It is usually difficult to get owners to comply with this recommendation but frequent rolling from side to side is necessary to minimize the ischemic necrosis. Dairy cows should be placed in a comfortable well-bedded box stall prior to calving and should be left in that box stall until at least 48 h after parturition in the event that milk fever develops.

ACUTE HYPOKALEMIA IN CATTLE

Hypokalemia in cattle may occur secondary to:

- Anorexia
- Diarrhea
- Upper gastrointestinal obstruction
- Right-sided displacement and torsion of the abomasum
- Impaction of the abomasum

In most cases, the hypokalemia is not severe enough to cause weakness and recumbency.

Hypokalemia resulting in severe weakness and recumbency has occurred in dairy cattle treated with isoflupredone acetate for ketosis. Serum potassium levels were below 2.3 mM. Cows ranged in age from 2 to 7 years, all had a history of moderate to severe ketosis and had calved within the previous 30 days. Most had been also treated with insulin, IV glucose, and oral propylene glycol for the ketosis. However, not all cases have been treated with corticosteroids. The disease has occurred in cattle of all age groups and a common history was the occurrence of a fever or a infectious disease. Potential contributory factors to the development of significant hypokalemia in the chronically ketotic cow include reduced potassium intake subsequent to metabolic alkalosis and hyperglycemia, kaluresis resulting from hyperglycemic osmotic diuresis, and increased potassium loss from the mineralocorticoid effects of exogenously administered corticosteroids. Excessive use of corticosteroids with mineralocorticoid activity in cows with mastitis may also lead to hypokalemia.

Affected cows are recumbent, profoundly weak, appeared flaccid and lay in sternal or lateral recumbency. They are unable to support the weight of their heads off the ground and commonly hold them in their flanks. Profound weakness of the lateral cervical muscles may occur. Anorexia is common. Cardiac arrhythmias are detectable on auscultation and atrial fibrillation is present on electrocardiography.

Treatment includes IV and oral administration of potassium chloride and fluid therapy but the response is commonly ineffective. Addition of potassium chloride to a 0.9% saline solution given as a continuous IV infusion at rates of up to 300 mmol of potassium per hour (approximately 0.4 mmol/kg per h) has been used in a 3-year-old cow. Oral supplementation with potassium chloride salt at 230 g two to three times daily for 3 days was associated with recovery. Palatable hay and propylene glycol orally are recommended. In a series of 14 cases, treatment consisted of potassium chloride given IV and orally at an average total daily dose of 42 g/100 kg BW (26 g orally and 16 g IV) for an average of 5 days, resulting in recovery in 11 cases after an average of 3 days. During recumbency,
affected cattle require special attention to minimize ischemic necrosis of muscles of the pelvic limbs.

At necropsy, muscle necrosis is present in the pelvic limbs and histological examination of non-weight bearing muscle reveal multifocal myonecrosis with microphage infiltration and myofiber vacuolation, which is characteristic of hypokalemic myopathy in man and dogs. It is important to note that myopathy is also present in muscles not subject to ischemia of recumbency.

Potassium excretion by the kidneys is via secretion by the distal tubular cells. Aldosterone or other steroids with mineralocorticoid activity enhance distal tubular secretion of potassium by increasing permeability of the tubular luminal membranes to potassium and increasing losses of potassium in the urine.

Glucocorticoids are often used to treat ketosis and the most commonly used are dexamethasone and isoflupredone acetate. Dexamethasone has little mineralocorticoid activity compared with prednisone and prednisolone, which are related chemically to isoflupredone. Dexamethasone is recommended for the treatment of ketosis in dairy cattle at a single dose of 10-20 mg IM, and repeated if necessary, 12-24 h later. Field observations indicate that repeated doses of isoflupredone acetate decrease plasma concentrations of potassium by 70-80%, which suggests a strong mineralocorticoid activity. It is recommended that isoflupredone be used judiciously and animals be monitored for plasma potassium and any evidence of weakness and recumbency. Treatment with oral potassium chloride may be required but treatment may be ineffective.

**TRANSIT RECUMBENCY OF RUMINANTS**

Transit recumbency (tetany) occurs after prolonged transport, usually in cows and ewes in late pregnancy. It is also recorded in lambs transported to feedlots, and in cows, sheep and goats to abattoirs. It is characterized by recumbency, alimentary tract stasis, and coma, and is highly fatal. It occurs in most countries. Large losses are encountered when cows and ewes in late pregnancy are moved long distances by rail, truck, or on foot.

Although cows of any age in late pregnancy are most commonly affected, the disease has also been recorded in cows recently calved, bullocks, steers, dry cows, and lambs. Risk factors include:

- Heavy feeding before shipment
- Deprivation of feed and water for more than 24 h during transit
- Unrestricted access to water
- Exercise immediately after unloading

There is an increased incidence of the disease during hot weather. The cause is unknown, although physical stress is an obvious factor. In lambs there is:

- Restlessness
- Staggering
- Partial paralysis of hindlegs
- Early assumption of lateral recumbency.

Death may occur quickly, or after 2-3 days of recumbency. There is a mild hypocalcemia (7-7.5 mg/dL; 1.75-1.87 mmol/L). The recovery rate even with treatment is only fair.

Clinical signs may occur while the cattle are still on the transportation vehicle or up to 48 h after unloading. In the early stages, animals may exhibit excitement and restlessness, trismus, and grinding of the teeth. A staggering gait with paddling of the hindlegs and recumbency occur, and are accompanied by stasis of the alimentary tract and complete anorexia. Animals that do not recover gradually become comatose and die in 3-4 days. There may be a moderate hypocalcemia and hypophosphatemia in cattle. In sheep of various ages, some are hypocalcemic and hypomagnesemic and some are hypoglycemic but some have no detectable biochemical abnormality. There are no lesions at necropsy other than those related to prolonged recumbency. Ischemic muscle necrosis is the most obvious of these lesions. The relationship of the disease to transport or forced exercise is diagnostic.

Some cases respond to treatment with combined calcium, magnesium, and glucose injections. Repeated parenteral injections of large volumes of electrolyte solutions are recommended. In lambs, the SC injection of a solution of calcium and magnesium salts is recommended but the response is usually only 50%, due probably to an intercurrent myonecrosis.

If prolonged transport of cows or ewes in advanced pregnancy is unavoidable, they should be fed on a moderately restricted diet for several days beforehand and provided with adequate food, water, and rest periods during the trip. The administration of an ataractic before loading is highly recommended, especially for nervous animals. On unloading, they should be allowed only limited access to water for 24 h and should be allowed a minimum of exercise for 2-3 days.

**LACTATION TETANY OF MARES (ECLAMPSIA, TRANSIT TETANY)**

Lactation tetany of mares is caused by hypocalcemia and is characterized by abnormal behavior progressing to incoordination and tetany. The precise cause of the hypocalcemia has not been determined, but the cause of the clinical signs is a marked reduction in serum concentration of ionized calcium. The effect of feeding diets high in calcium, such as alfalfa hay, during late pregnancy, and of abrupt changes in diet after parturition, have not been investigated in horses as they have in cattle (see Milk fever).

The disease was most common when draft horse breeding was widely practiced but is uncommon now. The mortality rate is high in untreated animals. Most cases occur in lactating mares, either at about the 10th day after foaling or 1-2 days after weaning. High-producing mares grazing on lush pasture are most susceptible and in many instances are engaged in hard physical work. The housing of wild ponies, or prolonged transport may precipitate an episode. The latter has been a particularly important factor in the etiology of the disease in Britain and has been credited with precipitating it even in stallions and dry mares. Occasional cases occur without there being any apparent cause.

The disease has occurred in a 20-year-old gelding pony. Hypocalcemia with clinical signs also occurs in horses used for prolonged exercise, such as endurance racing or 3 day eventing.

Many mild cases which recover spontaneously occur after transport but the mortality rate in some shipments may be greater than 60%. Mares that develop the disease at the foal heat or at weaning are usually more seriously affected and the mortality rate is high if mares are not treated in a timely fashion.

Severely affected animals sweat profusely and have difficulty in moving because of tetany of the limbs and incoordination. The gait is stiff and the tail is slightly raised. Rapid, labored respirations and wide dilatation of the nostrils are often accompanied by synchronous diaphragmatic flutter ('thumps') evident as a distinct thumping sound from the thorax. Muscular fibrillation, particularly of the masseter and shoulder region, and trismus are evident but there is no prolapse of the membrana nictitans. Affected animals are not hypersensitive to sound but handling may precipitate increased tetany. The temperature is normal or slightly elevated, and although...
the pulse is normal in the early stages, it later becomes rapid and irregular. The mare may make many attempts to eat and drink but appears to be unable to swallow and passage of a stomach tube can be difficult. Urination and defecation are in abeyance, and peristalsis is reduced.

Within about 24 h the untreated mare becomes recumbent, tetanic convulsions develop and become more or less continuous; the mare dies about 48 h after the onset of illness. The tetany and excitement in the early stages may suggest tetanus but there is no prolapse of the third eyelid and there is the usual relationship to recent foaling or weaning and physical exertion. The anxiety and muscle tremor of laminitis may also be confused with those of lactation tetany, especially as it may occur in mares which have foaled and retained the placenta. Pain in the feet is the diagnostic feature of this latter disease.

Hypocalcemia occurs with serum levels in the range of 4–6 mg/dL (1–1.5 mmol/L) and the degree of hypocalcemia has been related to the clinical signs.5 When serum calcium levels are higher than 8 mg/dL (2 mmol/L) the only sign is increased excitability. At levels of 5–8 mg/dL (1.25–2 mmol/L) there are tetanic spasms and slight incoordination. At levels of less than 5 mg/dL (1.25 mmol/L), there is recumbency and stupor. It is the concentration of ionized calcium that is important and some animals, such as horses used for 3 day eventing, can have normal total calcium concentrations but abnormally low ionized calcium concentrations as a result of changes in acid-base status. If possible, serum concentrations of ionized calcium should be measured in horses with clinical signs suggestive of hypocalcemia. Hypomagnesemia with serum magnesium levels of 0.9 mg/dL (0.37 mmol/L) has been observed in some cases but only in association with recent transport. Hypermagnesemia has been reported in other cases.

Treatment by IV administration of calcium borogluconate as recommended in the treatment of parturient paresis in cattle results in rapid, complete recovery. The dose for a 500 kg mare is 300–500 mL of a 25% solution of calcium borogluconate or gluconate administered slowly (over 15–30 min) intravenously. One of the earliest signs of recovery is the voiding of a large volume of urine. Occasional cases which persist for some days are recorded.

REFERENCES
are available to the young calf but mobilization decreases with age and in the adult ruminant there is little mobilization in response to short-term deficits of magnesium. In ruminants, this control mechanism for magnesium can maintain adequate concentrations of magnesium in bodily fluids in most production circumstances but it can fail where there is a high requirement for magnesium coupled with a decreased intake. This combination leads to hypomagnesemia and hypomagnesemic tetany as a possible outcome.

Lactation
Increased requirement for magnesium is almost always associated with the loss of magnesium in the milk during lactation. Whereas the amount of magnesium in milk is not high (12 mg/kg) the loss of magnesium to milk represents a significant proportion of the dietary intake of magnesium. As a consequence of this drain, most instances of hypomagnesemia occur in lactating animals around the period of peak milk production, although in some circumstances the demands of late pregnancy are the cause of the increased requirement. The decreased intake of magnesium can result from an absolute deficiency of magnesium in the diet or because the availability or absorption of magnesium from the diet is impaired. These factors determine the circumstances of occurrence of the disease and are the factors that can be manipulated for control.

Factors influencing absorption of magnesium
In the adult ruminant, magnesium absorption occurs in the forestomach with little absorption in the abomasum and small intestine. Some absorption occurs in the large intestine, particularly in sheep, however it cannot compensate for malabsorption in the forestomach.

Na:K ratio in rumen
Magnesium is transported across the epithelium of the forestomachs by an active sodium-linked ATPase-dependent transport system. Absorption, and the serum magnesium concentration, is influenced by the Na:K ratio in the rumen, which is determined by the dietary and salivary concentrations of sodium and potassium. Absorption of magnesium increases with an increasing Na:K ratio to plateau at a ratio of 5:1. Absorption is significantly impaired if the Na:K ratio is less than 3:1.

Young rapidly growing grass is low in sodium and high in potassium, can result in sodium deficiency in ruminants that graze it, and can significantly depress the Na:K ratio in the rumen fluid, causing impairment of magnesium absorption. Depression is observed at dietary potassium concentrations of greater than 22 g/kg dry matter.

Saliva normally has a high Na:K ratio but where there is a deficit of sodium in the diet, a proportion of sodium in saliva may be replaced with potassium under the influence of aldosterone, which further negatively influences the uptake of magnesium.

Approximately 40% of the total magnesium available in extracellular fluid is secreted daily in saliva and 20% of this is reabsorbed in the forestomach. When animals are on tetany-prone grass, this absorption is impaired, which accounts for the susceptibility of ruminants to hypomagnesemia compared with monogastric animals.

Other factors influencing absorption
Young grass fertilized with nitrogenous fertilizers has an increased crude protein which is readily fermentable and leads to increased ammonia concentrations. A sudden rise in ruminal concentrations of ammonia impairs magnesium absorption in the rumen. The uptake of magnesium is also influenced by the carbohydrate content of the diet, magnesium absorption is improved with increasing amounts of readily degradable carbohydrates. The mechanism of this action is not known but low concentrations of readily degradable carbohydrate in tetany-prone pastures in combination with high concentrations of protein may be important to the occurrence of the syndrome. Volatile fatty acids provide the energy for the active transport of magnesium across the rumen wall and increase magnesium absorption.

Other dietary substances have been proposed to influence the absorption of magnesium including calcium and phosphorus, organic acids such as citric acid and transaconitate, fatty acids, and aluminum, but the significance of their role is controversial.

Magnesium in pastures and tetany hazard
The dietary intake of magnesium in grazing animals is directly related to the magnesium concentration in pastures but other elements in pastures also influence magnesium absorption by the ruminant as detailed earlier.

Required magnesium concentrations
Hypomagnesemia can result from the ingestion of pastures that have insufficient magnesium to meet dietary requirements. The estimated magnesium concentration in pasture required to meet the dietary requirement for pregnant or lactating cattle varies from 1.0 to 1.3 g/kg dry matter (DM) for pregnant cattle, depending upon the stage of pregnancy, and 1.8–2.2 g/kg DM for lactating cattle with both estimates assuming minimal interference of absorption by other elements in the pasture.

The recommended minimal ‘safe’ concentration of magnesium in pastures is 2 g/kg DM for lactating and pregnant cattle with a preference for a concentration of 2.5 g/kg DM.

Magnesium availability in pastures and hazard
Hypomagnesemia can also occur in animals grazing pastures with adequate concentrations of magnesium but that contain high concentrations of potassium and nitrogen, which as detailed earlier, impair absorption of magnesium in the rumen. Pastures with concentrations of potassium of greater than 30 g K/kg DM and nitrogen greater than 40 g N/kg dry matter are considered hazardous.

An alternate method for estimating the potential hazard of a pasture is to calculate the K/(Ca + Mg) ratio using milliequivalent (mEq) values for this estimate. Pastures with ratios above 2.2 are considered a risk.

Winter hypomagnesemia
The occurrence of hypomagnesemia is not restricted to cattle grazing lush pastures and it also occurs in the winter periods. In housed lactating dairy cattle being fed conserved feeds, hypomagnesemia probably has the same genesis as that in grazing cattle being associated with a high lactational drain of magnesium in combination with the feeding of conserved feeds prepared from pastures with marginal magnesium concentrations. It also occurs in cattle outwintered on poor quality feed.

Hypomagnesemia and hypocalcemia
In some outbreaks of hypomagnesemic tetany, there is also hypocalcemia and, although it is of less severe degree than in parturient paresis, there is increasing evidence that the actual onset of clinical tetany may be associated with a rapid fall in serum calcium levels superimposed on a pre-existing hypomagnesemia. This is particularly true for wheat pasture poisoning but can also apply to outbreaks with different predisposing factors.

Chronic hypomagnesemia can have a profound effect on calcium homeostasis. Hypomagnesemia reduces the production and secretion of parathyroid hormone, reduces hydroxylation of vitamin D in the liver, and also causes target organ insensitivity to the physiological effects of parathyroid hormone and 1,25-dihydroxyvitamin D. Chronic subclinical hypomagnesemia can increase susceptibility to milk fever and can predispose to episodes of milk fever and...
In summary, it appears that a number of factors are capable of causing hypomagnesemia in ruminants and that under particular circumstances one or other of them may be of major importance.

In lactation tetany of cows and ewes, the ingestion of abnormally large amounts of potassium and low levels of calcium in the diet leads to hypomagnesemia and also hypocalcemia.

Hypomagnesemic tetany in cattle wintered at pasture and exposed to inclement weather is associated with low magnesium intake and inadequate caloric intake, and possibly to the resultant hyperactivity of the thyroid gland.

Although the above suggestions as to the most important etiological factors in each set of circumstances in which lactation tetany occurs may be valid, undoubtedly combinations of these and other factors have etiological significance in individual outbreaks of the disease. The worst combination of causative factors, and the most common circumstances in which the disease occurs, is inadequate energy intake with a low dietary content of magnesium (grass pasture) in recently calved cows during a spell of cold, wet, and windy weather.

One other important factor is the variation between individual animals in susceptibility to hypomagnesemia and to the clinical disease. These variations are quite marked in cattle and in intensively managed, high-producing herds it is probably worthwhile to identify susceptible animals and give them special treatment.

high ratio of potassium to calcium and magnesium (e.g. Dactyliis glomerata, Lolium perenne, Phalaris arundinacea) are more likely to cause grass tetany than those with low ratios (e.g. Bromus inermis, Poa pratensis, Agrostis spp.). On soil types where the disease is common, cool-season grass pastures top-dressed with nitrogenous fertilizers are dangerous and their toxicity may be increased by the application of potash. Warm-season grasses do not have the same risk and grass tetany is not a problem in cattle grazing tropical grasses.

Cereal pastures
The greater tendency of cereal grazing to cause hypomagnesemia, is related to a high content of potassium as well as a low content of magnesium. Tetany hazard, in order of decreasing hazard, is wheat, oats, barley, rye.14

Season
High concentrations of potassium and nitrogen and low concentrations of sodium and soluble carbohydrates occur in pastures during the early growing season and during rapid growth following cold, wet periods. Pasture magnesium concentrations may not be depressed but the K/(Ca + Mg) ratio is increased.18

Fertilization
Application of potash and nitrogenous fertilizers to pastures will decrease the concentration of calcium and magnesium in plants and will also increase the concentration of potassium and nitrogen. There is some evidence that nitrate sources of nitrogen depress magnesium less than ammonium sources of nitrogen.

Soil type
The availability of magnesium to the plant is influenced by soil type and some deficiencies in plant magnesium can be corrected by soil fertilization with magnesium.19 There is no strong association with any one soil type but high potassium concentrations are consistently associated with increased risk for tetany.

Highly leached, acid, sandy soils are particularly magnesium deficient and the most likely to respond to liming and magnesium fertilization. In very acidic soils, high aluminum concentrations may depress magnesium uptake by plants.

A local knowledge of soil type and its influence on magnesium, potassium, calcium, and nitrogen uptake by pastures can allow the judicious selection or avoidance of the use of pastures for at-risk groups during periods of risk for hypomagnesemia.12

Animal and management risk factors
Dry matter intake
The dry matter and energy intake of ruminants can influence susceptibility to hypomagnesemia.20 A reduction in dry matter intake must reduce the magnesium intake and, in situations where hypomagnesemia is already present, a further depression of serum magnesium levels can be anticipated when complete or partial starvation occurs. An insufficient intake of fiber in the winter months can precipitate hypomagnesemia in pastured cows and ewes and lipolysis is accompanied by a fall in serum magnesium.

Period of food deprivation
Many outbreaks of hypomagnesemia are preceded by an episode of stress or temporary starvation. Whether chronic hypomagnesemia pre-exists or not, a period of starvation in lactating cows and ewes is sufficient to produce a marked hypomagnesemia and the fall may be sufficiently great to cause clinical tetany.

A period of bad weather, yarding, transport, or movement to new pastures or the introduction to unpalatable pastures may provide such a period of partial starvation.

Alimentary sojourn
Diarrhea is commonly associated with lactation tetany on spring pasture and by decreasing the alimentary sojourn may also reduce magnesium absorption.

Climate
A close association between climatic conditions and serum magnesium levels has also been observed. Reduced levels occur in adult cattle and sheep exposed to cold, wet, windy weather with little sunshine and no access to shelter or supplementary feed. Supplementary feeding appears to reduce the effect of inclement weather on serum magnesium levels and it is possible that failure to eat, or depression of appetite, and a negative energy balance during bad weather may be a basic contributing cause to hypomagnesemia in these circumstances.

Animal movement
Epinephrine release will result in a precipitous fall in serum magnesium and this may explain the common observation that clinical cases are often precipitated by excitement or movement of the herd.

Intensive dairies
Intensive dairies that apply effluent on a daily basis can allow the judicious selection or avoidance of the use of pastures for at-risk groups during periods of risk for hypomagnesemia.

Hypomagnesemia in sheep
Hypomagnesemia occurs in sheep, particularly in Australia and the United Kingdom. The disease is not common but appears to be increasingly associated with pasture improvement practices, and can cause heavy losses in individual flocks. It is more common in ewes bred for milk and lamb production. In outbreaks, ewes with twins are more likely to develop clinical disease than those with singles and the main occurrence is in ewes 1-4 weeks after lambing with cases up to 8 weeks after lambing.

Disease is often precipitated by a management procedure involving movement and temporary food deprivation and cases will occur within the first 24 h following this and for a few days afterwards. As in cattle, disease occurs when ewes are placed on lush grass pastures but it is especially common where ewes in early lactation are placed on young cereal pastures. Losses usually cease when the flock is moved onto rough, unimproved pasture.

Cases also occur in sheep which are exposed to inclement weather when on low nutritive intake. Simultaneous hypomagnesemia and ketosis can occur in ewes after lambing if they are exposed to low feed availability. These cases do not respond well to treatment. Hypomagnesemia in ewes is predisposed by prior pregnancy toxemia in the flock.

PATHOGENESIS
Most evidence points to hypomagnesemia as the cause of the tetanic signs observed but the concurrent hypocalemia may have a contributory effect and in many instances may even be the dominant factor. Most clinical cases of the disease have serum magnesium levels below 1 mg/dL (0.41 mmol/L) compared with the normal levels in cattle of 1.7-3 mg/dL (0.70-123 mmol/L) and there is a striking relationship between the incidence of the clinical disease and the occurrence of a seasonal hypomagnesemia.

The reduction in serum levels of magnesium is concurrent with a marked fall in the excretion of magnesium in the urine. In affected herds and flocks, many clinically normal cows and sheep have low serum magnesium levels. In some of these circumstances a concurrent hypocalemia may be the precipitating cause.

Magnesium has many influences on impulse transmission at the neuromuscular system, including effects on the release of acetylcholine, on the sensitivity of the motor end plate, on the threshold of the muscle membrane and on activation of the cholinesterase system. These offer an attractive hypothesis for the muscular irritability seen with the disease. However, it has also been established that magnesium concentrations in the cerebrospinal fluid are more predictive of clinical disease than those in serum, which would indicate that alterations in CNS function are more important than alterations in peripheral nerve function. It is also evident that CSF levels of magnesium in hypomagnesemic
animals rise significantly after treatment with a magnesium salt. The need for this to happen would explain the delay of about 30 min after an IV injection before recovery occurs.

**CLINICAL FINDINGS**
For convenience, lactation tetany is described in acute, subacute and chronic forms.

**Acute lactation tetany**
The animal may be grazing at the time and suddenly cease to graze, adopt a posture of unusual alertness and appear uncomfortable; twitching of the muscles and ears is also evident. There is severe hyperesthesia and slight disturbances precipitate attacks of continuous bellowing, and occasionally aggression. The gait becomes staggering and the animal falls with obvious tetany of the limbs, which is rapidly followed by clonic convulsions lasting for about a minute. During the convulsive episodes there is:
- Opisthotonos
- Nystagmus
- Champing of the jaws
- Frothing at the mouth
- Pricking of the ears
- Retraction of the eyelids.

Between episodes, the animal lies quietly but a sudden noise or touch may precipitate another attack. The temperature rises to 40-40.5°C (104-105°F) after severe muscle exertion; the pulse and respiratory rates are also high. The absolute intensity of the heart sounds is increased so that they can be heard some distance away from the cow. Death usually occurs within 5-1 h and the mortality rate is high because many die before treatment can be provided. The response to treatment is generally good if the animal is treated early.

**Subacute lactation tetany**
In this form of the disease, the onset is more gradual. Over a period of 3-4 days, there is slight inappetence, wildness of the facial expression and exaggerated limb movements. The cow often resists being driven and throws her head about as though expecting a blow. Spasmodic urination and frequent defecation are characteristic. The appetite and milk yield are diminished and ruminal movements decrease. Muscle tremor and mild tetany of the hindlegs and tail with an unsteady, straddling gait may be accompanied by retraction of the head and trismus. Sudden movement, noise, the application of restraint or insertion of a needle may precipitate a violent convulsion.

Animals with this form of the disease may recover spontaneously within a few days or progress to a stage of recumbency with a similar but rather milder syndrome than in the acute form. Treatment is usually effective but there is a marked tendency to relapse.

**Chronic hypomagnesemia**
Many animals in affected herds have low serum magnesium levels but do not show clinical signs. There may be sudden death. A few animals do evidence a rather vague syndrome including dullness, unthriftiness and indifferent appetite and may subsequently develop one of the more obvious syndromes. In lactating cows, this may be the development of paresis and a milk fever-like syndrome that is poorly responsive to calcium treatment. Depressed milk production has also been attributed to chronic hypomagnesemia in dairy herds in New Zealand. The chronic type may also occur in animals which recover from the subacute form of the disease.

**Parturient paresis with hypomagnesemia**
This syndrome is described under parturient paresis and consists of paresis and circulatory collapse in an adult cow which has calved within the preceding 48 h but in which dullness and flaccidity are replaced by hyperesthesia and tetany.

**CLINICAL PATHOLOGY**
Serum or urinary magnesium concentrations can be used for clinical cases. Where an animal is dead and hypomagnesemia is suspect, a presumptive diagnosis can be made from samples taken from other at-risk animals in the group, or from the vitreous humor of the dead animal. An acute phase inflammatory response with leukocytosis and increased numbers of neutrophils and monocytes has been recorded in ruminants and laboratory animals fed magnesium deficient diets.

**Serum magnesium concentrations**
Normal serum magnesium concentrations are 1.7-3 mg/dL (0.70-1.23 mmol/L). These levels in cattle are often reduced in seasonal subclinical hypomagnesemia to between 1 and 2 mg/dL (0.41 and 0.82 mmol/L) but risk for tetany is not present until the level falls to below 1.2 mg/dL (0.49 mmol/L).

The average level at which signs occur is about 0.5 mg/dL (0.21 mmol/L) and in sheep it is suggested that clinical tetany does not occur until the serum magnesium level is below 0.5 mg/dL (0.21 mmol/L).

Serum magnesium in some animals may fall to as low as 0.4 mg/dL (0.16 mmol/L) without clinical illness. This may be due to individual animal variation in the degree of ionization of the serum magnesium and in the difference between serum and CSF concentrations. It is also possible that a transitory elevation of serum concentrations occurs after violent muscular exercise.

Total serum calcium levels are often reduced to 5-8 mg/dL (1.25-2.00 mmol/L) and this may have an important bearing on the development of clinical signs. Serum inorganic phosphate levels may or may not be low.

In what pasture poisoning of cattle there is hypocalcemia, hypomagnesemia, and hyperkalemia. In acute tetany, serum potassium levels are usually dangerously high and may contribute to the high death rate.

**CSF magnesium concentrations**
Magnet concentrations in CSF can be used as a diagnostic procedure but CSF is not easily or safely collected in tetany cases. Fluid collected up to 12 h after death can be used diagnostically. Levels in CSF of 1.25 mg/dL (0.51 mmol/L) were found in tetanic cows with hypomagnesemia (serum magnesium levels of 0.54 ± 0.41 mg/dL; 0.22 ± 0.17 mmol/L). In clinically normal cows with hypomagnesemia comparable levels in CSF were 1.84 mg/dL (0.74 mmol/L) and in serum 0.4 mg/dL (0.16 mmol/L). In normal animals CSF levels are the same as in plasma, i.e. 2.0 mg/dL (0.82 mmol/L) and up. The magnesium content of ventricular CSF may be quite different to that of lumbar CSF. It is also more responsive to changes in magnesium levels of the blood and is preferred for diagnosis at necropsy.

**Urine magnesium concentrations**
The occurrence of low urine magnesium levels is good presumptive evidence of hypomagnesemia.

**Herid diagnosis**
The kidney is the major organ of homeostasis and it has been argued that analysis of urine magnesium status is a more accurate method of assessing herd magnesium status than serum magnesium concentrations. The magnesium status of a herd, and the need to supplement the diet to prevent lactation tetany, can be established from:
- serum magnesium levels
- urinary magnesium fractional clearance ratios
- creatinine-corrected urinary magnesium concentrations
- urine magnesium concentrations.

Laboratory charges for urine magnesium fractional clearance ratios are expensive. The determination of the creatinine-corrected urinary magnesium concentration from 10 cows in a herd has been found to be a more sensitive indicator of magnesium status of the herd than estimates from serum, and a better predictor...
of response to supplementation. Values of less than 1.0 mmol/L indicate that a positive response to supplementation is likely.\textsuperscript{27} Urine magnesium concentrations below 1.0 mg/dL (0.4 mmol/L) indicate a danger for tetany.

**NECROPSY FINDINGS**

There are no specific findings. Extravasations of blood may be observed in SC tissues and under the pericardium, endocardium, pleura, peritoneum, and intestinal mucosa. Agonal emphysema may also be present.

The magnesium content of the bovine vitreous humor is considered to be an accurate estimate of magnesium status for 72 h after death, provided the environmental temperature does not exceed 23°C (73°F) and there is not growth of bacterial contamination after sampling which can result in a false low magnesium concentration.\textsuperscript{25,28} The addition of a small amount of 4% formaldehyde (3% of the vitreous humor volume) will allow accurate analysis for periods up to 72 h after sampling.\textsuperscript{28}

Concentrations in the aqueous humor are not stable after death.\textsuperscript{27}

**DIFFERENTIAL DIAGNOSIS**

**Cattle**
- Acute lead poisoning
- Rabies
- Nervous ketosis
- Bovine spongiform encephalopathy

**Sheep**
- Hypocalcemia
- Phalaries poisoning
- 'Stagger' syndromes

**TREATMENT**

IV administration of preparations containing magnesium or calcium and magnesium is used. The efficiency of the various treatments appears to vary from area to area, and even within areas under different conditions of management and climate. Response rates and recovery rates are much higher in cases treated early in the clinical course. IV chloral hydrate may be administered to reduce the severity of convulsions during treatment with magnesium. Case fatality, even with therapy, can be high, especially in advanced cases.

Combined calcium/magnesium therapy

The safest general recommendation is to use a combined calcium-magnesium preparation (e.g. 500 mL of a solution containing 25% calcium borogluconate and 5% magnesium hypophosphite for cattle, 50 mL for sheep) IV followed by a SC injection of a concentrated solution of a magnesium salt. The details and risks of administration of the type of solution is given in the section on parturient paresis. A combination of 12% magnesium adipate and 5% calcium gluconate at a dose rate of 500 mL is also used.

**MAGNESIUM THERAPY**

When magnesium solutions are used 200–300 mL of a 20% solution of magnesium sulfate may be injected IV; this is followed by a rapid rise in serum magnesium concentration which returns to preinjection levels within 3–6 h. A much slower rise and fall occurs after SC injection and for optimum results the SC injection of 200 mL of a 50% solution of magnesium sulfate has been recommended. A rise in serum magnesium of 0.5 mg/dL (0.21 mmol/L) occurs within a few minutes and subsequent levels do not go above 5 mg/dL (2.06 mmol/L). In cases where serum magnesium levels are low because of a seasonal hypomagnesemia, the injection of magnesium salts is followed by a rise and then a return to the subnormal preinjection levels.

The IV injection of magnesium salts is not without danger. It may induce cardiac dysrhythmia, or medullary depression may be severe enough to cause respiratory failure. If signs of respiratory distress or excessive slowing or increase in heart rate are noticed, the injection should be stopped immediately and, if necessary, a calcium solution injected.

The substitution of magnesium lactate for magnesium sulfate has been recommended to provide a more prolonged elevation of serum magnesium levels. A dilute solution (3.3%) causes minimal tissue injury and can be administered IV or SC. Magnesium gluconate has also been used as a 15% solution at dose rates of 200–400 mL. High serum magnesium levels are obtained more slowly and are maintained longer than with magnesium sulfate.

The feeding of magnesium-rich supplements, as described under control later, is recommended after parenteral treatment.

**PROVISION FOR FURTHER CASES**

The predisposing factors that lead to a case of hypomagnesemia apply to the herd as a whole and it is probable that further clinical cases will occur before the effects of corrective strategies are in effect. In extensive range situations, it is advisable to instruct the owner on how to treat cases as a delay in treatment can markedly increase the rate of treatment failures. SC treatment is within the realm of most, but successful therapy is also recorded by the rectal infusion of 30 g of magnesium chloride in a 100 mL solution; serum concentrations of magnesium return to normal levels within 10 min of administration.\textsuperscript{29}

**CONTROL**

Where possible, animals at high risk should be moved to low-risk pastures during the grass tetany season. High-risk pastures can be grazed by low-risk animals, steers or yearling heifers for example, during this period.

The occurrence of hypomagnesemia can be corrected by the provision of adequate or increased amounts of magnesium in the diet. A requirement as high as 3.0 g/kg DM diet may be required for lactating cows on spring pasture. The problem is in determining an adequate delivery system and this will vary according to the management system. Thus blocked minerals containing magnesium or foliar dressing of magnesium may be adequate delivery systems where there is a high stocking density of cattle, but they are totally inadequate or economically unfeasible on range with one cow per 20 acres.

Magnesium oxide is commonly used for supplementation but other magnesium salts can be used and they have an approximate equivalent availability.\textsuperscript{30} The biological availability of magnesium from magnesium carbonate, magnesium oxide, and magnesium sulfate for sheep is influenced by particle size but has been determined as 43.8%, 50.9%, and 57.6%, respectively.

**FEEDING OF MAGNESIUM SUPPLEMENTS**

The preventive measure which is now universally adopted is the feeding of magnesium supplements to cows during the danger period. The feeding of magnesite (containing not less than 87% magnesium oxide), or other sources of magnesium oxide, prevents the seasonal fall in serum magnesium levels. Daily administration by drenching, or in the feed, of at least 60 g of magnesium oxide per day is recommended to prevent the disease. This is not always completely effective and in some circumstances large doses may be necessary. Daily feeding of 120 g is safe and effective but 180 g daily may cause diarrhea. The dose for sheep is 7 g daily or 14 g every second day. Magnesium phosphate (53 g/d) is also a safe and effective way of insuring a good intake of magnesium. The protection afforded develops within several days of commencing administration and terminates abruptly after administration ceases.

**PROBLEMS WITH PALATABILITY**

The problem with magnesium supplements is with getting the stock to eat the required amount as they are unpalatable. This can be partially countered by mixing the supplement with molasses in equal parts and allowing free access to the mixture, or feeding it in ball feeders, but uniform intake by all animals does not
occur and at-risk animals may still develop hypomagnesemic tetany. Similarly, magnesium blocks may have limited efficacy in preventing hypomagnesemia. Salt blocks can help repair the sodium deficiency associated with young spring grasses and improve the Na:K ratio in the rumen. If they also contain Mg they can be an aid in prevention but usually, by themselves, do not guarantee freedom from risk for tetany.

Spraying on hay
One method of attempting to insure an adequate intake of magnesium is to spray it on hay and to feed this hay as a supplement during periods of grass tetany risk. The common practice is to:

1. Mix magnesite with molasses
2. Dilute mixture with water
3. Spray mixture onto hay in the windows when it is being made
4. Inject mixture into the bales before feeding or spray onto the hay at feeding
5. Determine the level of application by the amount of hay intended to be fed.

Depending upon local circumstances, this method may or may not be effective, as cattle and sheep will frequently not eat hay when on spring pasture unless they are confined for that purpose.

Pellets
Magnesium-rich pellets suggest themselves as a means of supplementation when the additional cost can be borne. Palatability is again a problem and care needs to be taken to include palatable material in the pellets; alternatively they may be mixed with other grain or molasses for feeding. Calves should be restricted from access as magnesium oxide at high levels of intake (2% and 4% of the ration) is toxic to calves and causes diarrhea with much mucus in the feces.

In some high-risk situations it may be advisable to provide magnesium in several forms to insure adequate intake.

Routine daily drenching
A once-daily oral administration of magnesium oxide or magnesium chloride to lactating dairy cows (to provide 10 g magnesium per cow), administered with a drenching gun just before the cows leave the milking parlor, is used in New Zealand to insure adequate supplemental magnesium during periods of high risk. The cows become used to the procedure (and the farmers adept at carrying it out) and it causes minimal disruption of management.

Heavy magnesium 'bullets'
The use of heavy 'bullets' of magnesium to prevent hypomagnesemia has been effective in laboratory trials and they are available commercially in some countries. The objective is to place a heavy 'bullet' of magnesium in the rumen from which it constantly liberates small amounts of magnesium—about 1 g/d. This objective is achieved and the occurrence of the clinical disease is usually greatly reduced but not eliminated. In dangerous situations, it is customary to administer up to four bullets at a time. As with all bullets, there is a proportion lost by regurgitation and by passage through the gut. A special sheep-sized 'bullet' is used in ewes with similar results.

Top dressing of pasture
This, together with magnesium-rich fertilizers, raises the level of magnesium in the pasture and decreases the susceptibility of cattle to hypomagnesemia. For top dressing, calcined magnesite (1125 kg/ha) or magnesium oxide (5600 kg/ha) are satisfactory, the former resulting in a greater increase in pasture magnesium.

Other magnesium-containing fertilizers can be used depending on cost. The duration of the improved magnesium status varies with the type of soil: greatest on light sandy loams on which a dressing of 560 kg/ha of calcined magnesium can provide protection for 3 years. On heavy soils protection for only 1 year is to be expected. To avoid unnecessary expense, it may be possible to top dress one field with the magnesium fertilizer and keep this field in reserve for spring grazing. Fertilization with magnesium is expensive and the response of pastures varies markedly with the soil type. It is advisable to seek agronomic advice.

Foliar dusting and spraying
The magnesium content of pastures can be raised much more quickly by spraying with a 2% solution of magnesium sulfate at fortnightly intervals or by application of very finely ground magnesium oxide to the pasture (30 kg/ha) before grazing commences. The technique is referred to as 'foliar dusting or spraying' and has the advantage over feed supplementation that the intake is standard. It is very effective in cattle in maintaining serum magnesium levels and preventing the occurrence of the clinical disease.

Dusting is with 20–50 kg MgO/ha can provide protection for up to 3 weeks but the duration is adversely influenced by wind and rain. A MgO-bentonite-water slurry sprayed onto pastures (26 kg MgO and 2.6 kg bentonite/ha) is effective in providing protection in high rainfall periods.

Provision of drinking water
The problem with water medication may provide a delivery system for magnesium on management systems such as extensive range pastures where other methods may have limited success. Water sources other than the medicated supply need to be fenced off or otherwise restricted. The addition of magnesium sulfate (500 g/100 L) or magnesium chloride hexahydrate (420 g/100 L) to the water supply during the risk period for hypomagnesemia has proved effective.

Management of pasture fields
The economics of daily farming make it necessary to produce maximum pasture growth, and the development of tetany-prone pastures is unavoidable in many circumstances. In some areas it may be possible to reduce the danger of such pastures by encouraging the development of legumes. In other areas the period of legume growth does not coincide with the period of maximum risk for grass tetany.

Restricting the amount of potash added to pastures, especially in the period immediately preceding the risk period for tetany, or using potash fertilizers in the autumn or late spring after the period of risk, can reduce risk of the disease. The grazing of low-risk animals on high-risk pastures is another strategy. Insuring that ample salt is available during the danger period to counteract the high intake of potassium can also reduce risk of the disease.

Plant geneticists are developing cultivars of cool-season grasses with high magnesium content that could be used for grazing during the tetany season. Lactating sheep grazing a high magnesium cultivar of perennial ryegrass (Lolium perenne cv Radmore) in the spring have shown higher blood magnesium concentrations than sheep grazing control cultivars and cultivars of tall fescue (Festuca arundinacea) with high Mg and Ca concentrations and low tetany potential are also available.

Provision of shelter
In areas where winter pasturing is practiced, the observation that serum magnesium levels fall during the winter and in association with inclement weather suggests that cattle and sheep should be provided with shelter at such times. If complete housing is impractical, it may be advisable to erect open access shelters in those fields that have no tree cover or protection from prevailing winds. Fields in which lactating cows are kept should receive special attention in this regard. Unfortunately, the disease is most common on highly improved farms, where most natural shelter has been removed and it is desired to keep the cows on the highly improved pasture to maintain milk production or fatten calves rapidly.
Time of calving
In areas where the incidence of the disease is high, it may be advisable to avoid having the cows calve during the cold winter months when seasonal hypomagnesemia is most likely to develop. Unfortunately it is often important to have cows calve in late winter to take advantage of the flush of spring growth when the cows are at the peak of their lactation.

Feeding on hay and unimproved pasture
Because of the probable importance of lush, improved, grass pasture in producing the disease, the provision of some grain, hay or rough grazing may reduce its incidence. It is most important that the periods of fasting, such as occur when cattle or sheep are yarded or moved or during bad weather, should be avoided, especially in lactating animals and when seasonal hypomagnesemia is likely to be present.

REVIEW LITERATURE

Hypomagnesemic tetany of calves

ETIOLOGY
The disease results when the dietary intake of magnesium is inadequate for the requirements of the calf. Affected animals may have concurrent hypocalcemia.

Magnesium homeostasis in the calf
Milk has low concentrations of magnesium. A milk diet provides adequate magnesium for the requirements of a growing calf up to a body weight of approximately 50 kg, but if milk is the sole diet, the intake of magnesium will be inadequate for requirements once his body weight is reached. The deficit will be perpetuated if the other feeds that are eaten are also low in magnesium.

In the young calf, magnesium is absorbed in the intestine; however, the efficiency of magnesium absorption decreases markedly up to about 3 months of age, when maximum susceptibility to the disease occurs. The efficiency of absorption is decreased by a reduction in transit time in the intestine caused by diarrhea.

In contrast to adult cattle, young cattle can mobilize body stores of magnesium, which are principally located in the skeleton. Approximately 40% of the magnesium stored in the skeleton can be mobilized, which will protect against a short-term deficit.

Hypomagnesemic tetany in calves is often complicated in field cases by the coexistence of other diseases, especially enzootic muscular dystrophy.

EPIDEMIOLOGY
Occurrence
The disease is not common. Cases may occur sporadically or a number of deaths may occur on the one farm within a short period of time.

Risk factors
The disease can occur under a number of different circumstances.

Most commonly, hypomagnesemic tetany occurs in calves 2–4 months of age or older which are fed solely on a diet of whole milk, and calves receiving the greatest quantity of milk and growing most rapidly are more likely to be affected because of their greater need for magnesium for incorporation into developing soft tissues. It is most likely to occur in calves being fattened for veal. Those cases which occur on milk replacer appear to be related to chronic scouring and low magnesium content of the replacer. This problem is less common than it once was because most modern commercial milk replacers have added adequate magnesium.

A significant loss of magnesium in the feces also occurs in calves allowed to chew fibrous material such as bedding; the chewing stimulates profuse salivation and creates greater loss of endogenous magnesium. Peat and wood shavings are bedding materials known to have this effect.

Cases have also been reported in calves fed milk-replacer diets or milk, concentrates, and hay, and in calves running at pasture with their dams. Deaths due to hypomagnesemic tetany have also occurred in 3–4-month-old calves whose hay and silage rations were low in magnesium content.

Hypomagnesemia also occurs in young cattle, about 6 months of age, which are being fattened intensively indoors for the baby beef market. The phosphorus content of their diet is high and a lack of vitamin D is probable. The situation is exacerbated by a shortage of roughage. The hypomagnesemia is accompanied by a hypocalcemia.
Experimental reproduction
A condition closely resembling the field syndrome has been produced experimentally by feeding an artificial diet with a very low content of magnesium; a high calcium content and biochemical hypomagnesemia is readily produced in calves with a diet based on skim milk and barley straw. Hypomagnesemia has also been produced experimentally in very young foals by feeding a diet with a very low magnesium content. The clinical signs are similar to those in calves, and the calcification found in the walls of vessels of calves also occurs in foals.

PATHOGENESIS
On affected farms, calves are born with normal serum magnesium levels of 2–2.5 mg/dL (0.82–1.03 mmol/L) but the levels fall gradually in the succeeding 2–3 months, often to below 0.8 mg/dL (0.33 mmol/L). Tetany does not occur until the serum magnesium falls below this concentration and is most severe at concentrations below 0.6 mg/dL (0.25 mmol/L), although some calves in a group may have concentrations even lower than this and show few clinical signs.

Magnesium deficiency inhibits the release and action of parathyroid hormone and this is believed to be the genesis of the concurrent hypocalcemia. It is probable that depression of the serum calcium level precipitates tetany in animals rendered tetany prone by low serum magnesium levels. Tetanic convulsions can occur in hypocalcemic calves in the absence of hypomagnesemia.

Hypomagnesemic tetany is not related in any way to enzootic muscular dystrophy, although the diseases may occur concurrently.

CLINICAL FINDINGS
The first sign in the experimental disease is constant movement of the ears. The temperature is normal and the pulse rate accelerated. Hyperesthesia to touch, and grossly exaggerated tendon reflexes with clonus, are present. Shaking of the head, opisthotonos, ataxia without circling and a droopy, backward carriage of the ears are constant. There is difficulty in drinking due to the animal’s inability to get to the bucket. Initially, the calves are apprehensive, show agitation and retraction of the eyelids when approached, and are hypersensitive to all external stimuli but show no tetany. Later, fine muscle tremors appear, followed by kicking at the belly, frothing at the mouth and spasticity of the limbs. Convulsions follow, beginning with stamping of the feet, head retraction, champing of the jaws and falling.

During the convulsions the following signs are present:
- Jaws are clenched
- Respiratory movements cease
- There are tonic and clonic movements of the limbs
- There is involuntary passage of urine and feces
- There are cycles of protrusion and retraction of the eyeballs.

The pulse rate rises to 200–250/min and the convulsions disappear terminally. The pulse becomes impalpable and cyanosis appears before death.

In field cases the signs are almost identical but are rarely observed until the terminal tetanic stage. Older calves usually die within 20–30 min of the onset of convulsions but young calves may recover temporarily only to succumb to subsequent attacks. Cases which occur in young calves with scours, usually at about 2–4 weeks of age, show ataxia, hyperesthesia, opisthotonos and convulsions as the presenting signs. The convolution is usually continuous and the calves die within 1 h.

CLINICAL PATHOLOGY
Serum magnesium levels below 0.8 mg/dL (0.33 mmol/L) indicate severe hypomagnesemia and clinical signs occur with levels of 0.3–0.7 mg/dL (0.12–0.29 mmol/L). Normal values are 2.2–2.7 mg/dL (0.9–1.11 mmol/L). Erythrocyte magnesium concentrations are also low, indicating a chronic deficiency. Serum calcium levels tend to fall when serum magnesium levels become very low and are below normal in most clinical cases.

The estimation of the magnesium in bone (particularly ribs and vertebrae) is a reliable confirmatory test at necropsy. Values below a ratio of 70:1 for calcium:magnesium may be regarded as normal and above 90:1 are indicative of severe magnesium depletion. In the normal calf the ratio is about 55:1. Absolute bone calcium values are not decreased and are often slightly elevated. An acidental increase is the marked increase in serum creatinine phosphokinase levels observed in calves after an acute attack of hypomagnesemic tetany.

NECROPSY FINDINGS
There is a marked difference between the necropsy lesions of some natural cases and those in the experimental disease. In field cases, there is often calcification of the spleen and diaphragm, and calcified plaques are present in the aorta and endocardium, together with hyaline degeneration and muscle atrophy. In other cases necropsy lesions similar to those in enzootic muscular dystrophy occur.

In experimentally produced cases these lesions are not evident but there is extensive congestion in all organs, and hemorrhages in unsupported organs, including:
- Gallbladder
- Ventricular epicardium
- Pericardial fat
- Aorta
- Mesentery wall
- Intestinal wall.

The lesions are obviously terminal and are associated with a terminal venous necrosis. Some field cases present a picture identical to this.

DIFFERENTIAL DIAGNOSIS
- Acute lead poisoning
- Enterotoxemia caused by Clostridium perfringens Type D
- Polioencephalomalacia
- Tetanus
- Vitamin A deficiency
- Meningitis

TREATMENT
Response to magnesium injections (100 mL of a 10% solution of magnesium sulfate) is only transitory because of the severe depletion of bone reserves of magnesium. This dose provides only a single day’s requirements. Follow-up supplementation of the diet with magnesium oxide or carbonate as described later is advisable. Chloral narcosis or tranquilization with an ataractic drug may be essential to avoid death due to respiratory paralysis during convulsions.

CONTROL
The provision of a hay that is high in magnesium, such as alfalfa, helps to prevent the disease as will well-formulated concentrates.

Supplementary feeding of magnesium
If begun during the first 10 days of life, supplementary magnesium feeding will prevent excessive falls of serum magnesium, but if begun after the calf is 7 weeks old, may not prevent further depression of the levels. Supplementation should continue until at least 10 weeks of age. Daily feeding of the magnesium compound and fairly accurate dosing are necessary to avoid scurvy or inefficient protection. For calves of average growth rate appropriate dose rates are 1 g/d for calves to 5 weeks of age, 2 g/d for calves 5–10 weeks of age and 3 g/d for calves 10–15 weeks of age of magnesium oxide or twice this dose of carbonate. Supplementation of the diet with magnesium restores serum calcium levels to normal as well as correcting the hypomagnesemia.

Magnesium alloy bullets
Two bullets of the sheep size (together releasing approximately 1 g/d of mag-
nesium) per calf, have shown high efficiency in preventing the clinical disease and also the hypomagnesemia which precedes it. Calves kept indoors and fed largely on milk should get adequate mineral supplement and vitamin D (70,000 IU vitamin D₃/d). Magnesium utilization will not be affected but calcium absorption, which is often sufficiently reduced to cause a concurrent hypocalcemia, will be improved.

REFERENCES

KETOSIS, SUBCLINICAL KETOSIS, ACETONEMIA

Synopsis
Etiology A multifactorial disorder of energy metabolism. Negative energy results in hypoglycemia and ketonemia (the accumulation in blood of acetocetate, β-hydroxybutyrate and their decarboxylation products acetone and isopropanol).

Epidemiology Primary ketosis and subclinical ketosis occur predominantly in well-conditioned cows with high lactation potential, principally in the first month of lactation with a higher prevalence in cows with a higher lactation number. Loss of body condition in the dry period and immediately post partum. Secondary ketosis occurs when other disease reduces feed intake.

Clinical findings Cattle show wasting with decrease in appetite, fall in body condition and milk production. Some have short periods of bizarre neurological and behavioral abnormality. Response to treatment is good. Subclinical ketosis is detected by tests for ketones, usually in milk or urine.

Clinical pathology Hypoglycemia, ketonemia, ketonuria, or elevated ketones in milk.

Necropsy findings None specific.

Diagnostic confirmation Ketonemia, ketonuria or elevated ketones in milk.

Treatment In cattle, parenteral glucose with corticosteroid and oral glucose precursors such as propylene glycol, occasionally insulin. In cattle, the disease responds readily to treatment and is self-limiting.

Control Correction of energy imbalance. Herd biochemical monitoring coupled with condition scoring.

ETIOLOGY
Glucose metabolism in ruminants

The maintenance of adequate concentrations of glucose in the blood is critical to the regulation of energy metabolism. The ruminant absorbs very little dietary carbohydrate as hexose sugar because dietary carbohydrates are fermented in the rumen to short chain fatty acids, principally acetate (70%), propionate (20%) and butyrate (10%). Consequently, glucose needs in ruminants must largely be met by gluconeogenesis. Propionate and amino acids are the major precursors for gluconeogenesis with glycerol and lactate of lesser importance.

Propionate is produced in the rumen from starch, fiber, and proteins. It enters the portal circulation and is efficiently removed by the liver, which is the primary glucose-producing organ. Propionate is the most important glucose precursor; an increased availability can spare the hepatic utilization of other glucose precursors, and production of propionate is favored by a high grain inclusion in the diet.

Amino acids. The majority of amino acids are gluconeogenic and are also important precursors for gluconeogenesis. Dietary protein is the most important quantitative source but the labile pool of body protein is also an important source; together they contribute to energy synthesis and milk lactose synthesis as well as milk protein synthesis.

Dietary acetate is transported to peripheral tissues and to the mammary gland and metabolized to long chain fatty acids for storage as lipids or secretion as milk fat.

Energy balance In high-producing dairy cows there is often a negative energy balance in the first few weeks of lactation. The highest dry matter intake does not occur until 8–10 weeks after calving but peak milk production is at 4–6 weeks and energy intake may not keep up with demand. In response to a negative energy balance and low serum concentrations of glucose and insulin, cows will mobilize adipose tissue with consequent increases in serum concentrations of non-esterified fatty acids (NEFA) and subsequently BHBA. The hepatic mitochondrial metabolism of fatty acids promotes both gluconeogenesis and ketogenesis. Cows partition nutrients during pregnancy and lactation and are in a lipolytic stage in early lactation and at risk for ketosis during this period.

Hepatic insufficiency in ketosis

Hepatic insufficiency has been shown to occur in bovine ketosis but it does not occur in all cases. It has been suggested that ketosis can be divided into two types. In type I, or spontaneous ketosis, it is proposed that the gluconeogenic pathways are maximally stimulated and ketosis occurs when the demand for glucose outstrips the capacity of the liver for gluconeogenesis because of an insufficient supply of glucose precursors. Rapid entry of non-esterified fatty acids (NEFA) into hepatic mitochondria occurs and results in high rates of ketogenesis and high blood ketones. There is little conversion of NEFA to triglycerides resulting in little fat accumulation in the liver. In type II ketosis, manifest with fatty liver, gluconeogenic pathways are not maximally stimulated and consequently mitochondrial uptake of NEFA is not as active and NEFA become esterified in the cytosol, forming triglyceride. The capacity of cattle to transport triglyceride from the liver is low, resulting in accumulation and fatty liver. The occurrence of a fatty liver can further suppress hepatic gluconeogenic capacity. Hepatic insufficiency may occur more commonly in those cows predisposed to ketosis by overfeeding in the dry period.

Ketone formation

Ketones arise from two major sources: butyrate in the rumen and mobilization of fat. A large proportion of butyrate produced by rumen fermentation of the diet is converted to β-hydroxybutyrate (BHBA) in the rumen epithelium and is absorbed as such. Free fatty acids produced from the mobilization of fat are transported to the liver and oxidized to produce acetyl-CoA and NADH.

Acetyl-CoA may be oxidized via the TCA cycle or metabolized to acetocetyl-CoA. Its oxidation via the TCA cycle depends upon adequate supply of oxaloacetate from the precursor propionate. If propionate, and consequently oxaloacetate, is deficient, oxidation of acetocetyl-CoA via the TCA cycle is limited and it is metabolized to acetoacetyl-CoA and subsequently to acetacetate and BHBA.

The ketones BHBA and acetacetate can be utilized as an energy source. They are normally present in blood and their concentration is a result of the balance between production in the liver and utilization by the peripheral tissues.

Role of insulin and glucagon

The regulation of energy metabolism in ruminants is primarily governed by insulin and glucagon. Insulin acts as a glucoregulatory hormone stimulating glucose use by tissues and decreasing hepatic gluconeogenesis. Blood insulin concentrations decrease with decreasing insulin: glucagon ratios. Insulin also acts as a liporegulatory hormone stimulating lipogenesis and inhibiting lipolysis. Glucagon is the primary counter-regulatory hormone to insulin. Their counteracting effects play a central role in the homeostatic control of glucose. A low insulin: glucagon ratio stimulates lipolysis in adipose tissue and ketogenesis in the liver. Cows in early lactation have low insulin: glucagon ratios because of low blood insulin and are in a catabolic state. Elevated ketones may...
stimulate insulin production and may act as a negative feedback. Regulation is also indirectly governed by somatotropin, which is the most important determinant of milk yield in cattle and is also lipolytic. Factors that decrease the energy supply to ruminants, that increase the demand for glucose, or that increase the utilization of body fat as an energy source are likely to increase ketone production and ketonemia. There is, however, considerable cow-to-cow variation in risk for clinical ketosis.

**ETIOLOGY OF BOVINE KETOSIS**

It is not unreasonable to view clinical ketosis as the top end of a spectrum of a metabolic state that is common in heavily producing cows in the post-calving period. This is because high-yielding cows in early lactation are in negative energy balance and are subclinically ketotic as a result. This can be predisposed by nutritional inadequacies during the dry period. Ruminants are particularly vulnerable to ketosis because, although very little carbohydrate is absorbed as such, a direct supply of glucose is essential for tissue metabolism, particularly the formation of lactose. The utilization of volatile fatty acids for energy purposes is also dependent upon a supply of available glucose. This vulnerability is further exacerbated, particularly in the cow, by the tremendous rate of turnover of glucose. In the period between calving and peak lactation, the demand for glucose is increased and cannot be completely restrained. Cows will reduce milk production in response to a reduction of energy intake, but this does not follow automatically nor proportionately in early lactation because hormonal stimuli for milk production overcome the effects of reduced food intake. Under these circumstances, lowered blood glucose levels result in lowered blood insulin. Long chain fatty acids are released from fat stores under the influence of both a low blood insulin:glucagon ratio and the influence of high somatotropin concentration, and this leads to increased ketogenesis.

**Individual cow variation**

The rate of occurrence of negative energy status, and therefore the frequency of clinical cases, has undoubtedly increased sharply in the recent past because of the steep increase in the lactation potential of the modern dairy cow. Because of the mammary gland's metabolic precedence in the partitioning of nutrients, especially glucose, milk production continues at a high rate, causing an energy drain. In many individual cows, the need for energy is beyond their capacity for dry matter intake but there is between-cow variation in risk under similar nutritional stress. Clinical ketosis has been produced in recently calved dairy cows by reducing the daily feed intake by 15–20% ad libitum and supplementing it with 1,3-butanediol, a ketogenic substrate. The biochemical characteristics of ketosis including depletion of hepatic glycogen and major increases in hepatic stores of triglycerides and ketone bodies were produced but ketosis was only produced in those cows that had a predisposition to the disease.

**Types of bovine ketosis**

There are many theories on the cause, biochemical and hormonal pathogenesis of ketosis, and the importance of predisposing factors. Reviews of these studies are cited at the end of this disease section. In general, it can be stated that clinical ketosis occurs in ruminants when they are subjected to demands on their resources of glucose and glycogen that cannot be met by their digestive and metabolic activity. Lean has presented a classification of the disease based on its natural presentation in intensively and extensively managed dairy herds, and one that accounts for the early lactational demand for glucose, a limited supply of propionate precursors and preformed ketones or mobilized lipids in the pathogenesis. Such a classification includes the following geneses of ketosis, which will be discussed in turn:

- **Primary ketosis (production ketosis)**
- **Secondary ketosis**
- **Alimentary ketosis**
- **Starvation ketosis**
- **Ketosis due to specific nutritional deficiency**

**Primary ketosis (production ketosis)**

This is the ketosis of most herds, the so-called estate acetonemia. It occurs in cows in good to excessive body condition that have high lactation potential and are being fed good-quality rations but that are in a negative energy balance. There is a tendency for the disease to recur in individual animals, which is probably a reflection of variation between cows in digestive capacity or metabolic efficiency. A proportion of cases appear as clinical ketosis but a much greater proportion occur as cases of subclinical ketosis in which there are increased levels of circulating ketone bodies but no overt clinical signs.

**Secondary ketosis**

This occurs where other disease results in a decreased food intake. The cause of the reduction in food intake is commonly the result of abomasal displacement, traumatic reticulitis, metritis, mastitis, or other diseases common to the postparturient period. A high incidence of ketosis has also been observed in herds affected with fluorosis. An unusual occurrence reported was an outbreak of acetonemia in a dairy herd fed on a ration contaminated by a low level (9.5 ppm) of lincomycin, which caused ruminal microbial dysfunction. The proportion of cases of acetonemia which are secondary, and their diagnosis as such, are both matters of great interest as a significant proportion of cases of ketosis are secondary to other disease.

**Alimentary ketosis**

This form is due to excessive amounts of butyrate in silage and possibly also due to decreased food intake resulting from poor palatability of high butyrate silage. Silage made from succulent material may be more highly ketogenic than other types of ensilage because of its higher content of preformed butyric acid. Spoiled silage is also a cause and toxic biogenic amines in silage, such as putrescine, may also contribute. This type of ketosis is commonly subclinical but it may predispose to the development of production or primary ketosis.

**Starvation ketosis**

This occurs in cattle that are in poor body condition and that are fed poor-quality feedstuffs. There is a deficiency of propionate and protein from the diet and a limited capacity of gluconeogenesis from body reserves. Affected cattle recover with correct feeding.

**Ketosis due to specific nutritional deficiency**

Specific dietary deficiencies of cobalt and possibly phosphorus may also lead to a high incidence of ketosis. This may be due in part to a reduction in the intake of total digestible nutrients (TDN), but in cobalt deficiency, the essential defect is a failure to metabolize propionic acid into the tricarboxylic acid (TCA) cycle. The problem is restricted to the cobalt deficient areas of the world, although the occurrence of cobalt deficiency in high-producing dairy cows in non-deficient areas has been described.

There is a marked nadir in food intake around calving, followed by a gradual increase. This increase is quite variable between cows, but in the great majority of cases does not keep pace with milk yield. The net result is that high-yielding dairy cows are almost certain to be in negative energy balance for the first 2 months of lactation.

**EPIDEMIOLOGY**

**Occurrence**

Ketosis is a disease of dairy cattle and is prevalent in most countries where intensive farming is practiced. It occurs mainly...
in animals housed during the winter and spring months and is rare in cows that calve on pasture. In housed or free-stalled cattle it occurs year around. The occurrence of the disease is very much dependent upon management and nutrition and varies between herds. As might be expected, lactational incidence rates vary between herds and a recent review of eleven epidemiological studies showed a lactation incidence rate for ketosis that varied from 0.2-10.0%.14

Rates of subclinical ketosis are influenced by the cut-point of plasma BHBA used for definition but are much higher, especially in undernourished herds, and can approach 40%.2,15-19

Animal and management risk factors
There are conflicting reports on the significance of risk factors for ketosis and subclinical ketosis which probably reflect that the disease can be a cause or effect of interacting factors. The disease occurs in the immediate postpartum period with 90% of cases occurring in the first 60 days of lactation.16-20 Regardless of specific etiology, it occurs most commonly during the first month of lactation, less commonly in the second month, and only occasionally in late pregnancy. In different studies, the median time to onset following calving has varied from 10 to 28 days,20,21 with some recent studies showing a peak prevalence of subclinical ketosis in the first 2 weeks post-calving.2,15 A prolonged previous inter-calving interval increases risk.2

Age. Cows of any age may be affected but the disease increases from a low prevalence at the first calving to a peak at the fourth. Lactational incidence rates of clinical ketosis of 1.5% and 9%, respectively were found in a study of 2415 primiparous and 4360 multiparous cows.22 Clinical ketosis can also recur in the same lactation.

Herd differences in prevalence are very evident in clinical practice, and in the literature, with some herds having negligible occurrence. Although apparent differences in breed incidence are reported, evidence for an heritable predisposition within breeds is minimal.2,20,23 Feeding frequency has an effect with the prevalence much lower in herds that feed TMR ad libitum compared with herds that fed roughage and concentrate separately of that feed twice a day.

Body condition score (BCS). There are conflicting reports on the relation between BCS at calving and ketosis but it is suggested that studies that have found no relationship have not had many fat cows in the herds examined.24,25 Fat body condition post partum was observed to be associated with a higher first test day milk yield, milk fat to protein ratio of >1.5, increased body condition loss and a higher risk for ketosis.25 In another study, cows with a BCS ≥3.25 at parturition and that lost 0.75 BCS in the first 2 months of lactation developed subclinical ketosis.26 Body condition loss during the dry period also increases risk for ketosis in the following lactation.2,27,28

Season. There is no clear association with season. In some but not all summer grazing areas, a higher risk is generally observed in cattle during the winter housing period.2,29 Higher prevalence has been observed in the late summer and early winter in Scandinavian countries.30

Other interactions. There is a greater risk for the development of ketosis in cows that have an extended long dry period, that develop milk fever, retained placenta, lameness or hypomagnesemia.2,25,28,31-35 Cows with twins are also at risk for ketosis in the terminal stages of pregnancy.36,37

There is a bidirectional relation between risk for displaced abomasum and risk for ketosis, but in a field study of 1000 cows in 25 herds, cows that had a serum BHBA greater than 1400 μmol/L in the first 2 weeks of lactation had odds of 4:1 that displaced abomasums would be diagnosed 1-3 weeks later.38 In another study of 1010 cows a serum concentration of 1500 μmol/L or greater in the first 2 weeks of lactation was found to be associated with a threefold increase in ketosis or displaced abomasums.2

Economic significance
Clinical and subclinical ketosis are major causes of loss to the dairy farmer.2,19,39 In rare instances the disease is irreversible and the affected animal dies but the main economic loss is due to the loss of production while the disease is present, the possible failure to return to full production after recovery and the increased occurrence of periparturient disease.1,2 Both clinical and subclinical ketosis are accompanied by decreased milk yields and lower milk protein and milk lactose2,16,35,40 and increased risk for delayed estrus and lower first service conception rates, increased inter-calving intervals40,41 and increased risk of cystic ovarian disease, metritis and mastitis and increased involuntary culling.1,35,42 A year 2001 report has estimated the loss from a single case of subclinical ketosis at US$145.19

PATHOGENESIS
Bovine ketosis
The principal metabolic disturbances observed, hypoglycemia and ketonemia, may both exert an effect on the clinical syndrome. However, in the experimental disease in cattle, it is not always clear what determines the development of the clinical signs in cases that convert from subclinical to clinical ketosis.43 In many cases, the severity of the clinical syndrome is proportional to the degree of hypoglycemia and this, together with the rapid response to parenterally administered glucose in cattle, suggests hypoglycemia as the predominant factor. This hypothesis is supported by the development of prolonged hypoglycemia and a similar clinical syndrome to that of ketosis, after the experimental, IV or SC injection of insulin (2 units/kg BW).

However, in most field cases the severity of the clinical syndrome is also roughly proportional to the degree of ketonemia. This is an understandable relationship as ketone bodies are produced in larger quantities as the deficiency of glucose increases. However, the ketone bodies may exert an additional influence on the signs observed. Acetoacetic acid is known to be toxic and probably contributes to the terminal coma in diabetes mellitus in man.

The nervous signs which occur in some cases of bovine ketosis are thought to be caused by the production of isopropyl alcohol, a breakdown product of acetoacetic acid in the rumen, although the requirement of nervous tissue for glucose to maintain normal function may also be a factor in these cases.

Spontaneous ketosis in cattle is usually readily reversible by treatment; incomplete or temporary response is usually due to the existence of a primary disease with ketosis present only as a secondary development, although fatty degeneration of the liver in protracted cases may prolong the recovery period. Changes in ruminal flora after a long period of anorexia may also cause continued impairment of digestion.

Immunosuppression has been demonstrated with energy deficiency and ketosis.44,45 The higher susceptibility of ketotic postpartum cows to local and systemic infections may be related to impairment of the respiratory burst of neutrophils which occurs with elevated levels of BHBA.46

CLINICAL FINDINGS
Two major clinical forms of bovine ketosis are described – wasting and nervous – but these are the two extremes of a range of syndromes in which wasting and nervous signs are present in varying degrees of prominence.

The wasting form is the most common of the two and is manifest with a gradual but moderate decrease in appetite and milk yield over 2-4 days. In herds that feed components separately, the pattern of appetite loss is often unusual in that the cow first refuses to eat grain, then ensilage but may continue to eat hay. The appetite may also be decreased.

Production diseases
Body weight is lost rapidly, usually at a greater rate than one would expect from the decrease in appetite. Farmers usually describe affected cows as having a ‘woody’ appearance due to the apparent wasting and loss of cutaneous elasticity due presumably to disappearance of subcutaneous fat. The feaces are firm and dry but serious constipation does not occur. The cow is moderately depressed and the hangdog appearance and disinclination to move and to eat may suggest the presence of mild abdominal pain.

The temperature and the pulse and respiratory rates are normal and although the ruminal movements may be decreased in amplitude and number, they are within the normal range unless the course is of long duration when they may virtually disappear. A characteristic odor of ketones is detectable on the breath and often in the milk.

Very few affected animals die, but without treatment the milk yield falls and although spontaneous recovery usually occurs over about a month, as equilibrium between the drain of lactation and food intake is established, the milk yield is never fully regained. The fall in milk yield in the wasting form may be as much as 25% and there is an accompanying sharp reduction in fertility. Clinical diagnosis is not effective and in one study, diagnosis by routine urine testing at 5–12 days post partum was considerably more efficient (15.6% detected) than diagnosis by the herdsman (4.35% detected). In a British study of 219 herds the annual mean rate of reported clinical ketosis was 0.5 per 100 adult cows but the rate of subclinical ketosis, as defined by high blood concentrations of BHBA and non-esterified fatty acids, was substantially higher.12,13

Potential milk production is reduced by 1–9%.17,20 Surveys of large populations show a declining prevalence of ketosis-positive cows after a peak in the period immediately after calving, and a positive relationship between hyperketonemia and high milk yield.15,49 Infertility may appear as an ovarian abnormality, delayed onset of estrus or as endometritis resulting in an increase in calving to conception interval and reduced conception rate at first insemination.

CLINICAL PATHOLOGY

Hypoglycemia, ketonemia and ketonuria are characteristic of the disease.

Glucose

Blood glucose levels are reduced from the normal of approximately 50 mg/dL to 20–40 mg/dL. Ketosis secondary to other diseases is usually accompanied by blood glucose levels above 40 mg/dL and often above normal. Conversion factors are shown in Table 29.7.

Blood ketones

Most commonly, plasma or serum β-hydroxybutyrate (BHBA) measured in SI units is used for analysis of ketonemia. BHBA is the predominant circulating ketone body. Plasma concentrations of BHBA significantly correlate with plasma concentrations of acetoacetate but acetoacetate is unstable in samples whereas BHBA is relatively stable.2 Normal cows have plasma BHBA concentrations less than 1000 nmol/L, cows with subclinical ketosis have concentrations greater than 1400 nmol/L, and cows with clinical ketosis have concentrations often in excess of 2500 nmol/L. Plasma BHBA shows some diurnal variation in cows fed twice daily with peak concentrations occurring approximately 4 h after feeding and higher concentrations in the morning than in the afternoon. This is not seen in cows fed a total mixed ration ad libitum.7,35

Plasma BHBA is not a cost effective or convenient analysis for routine analysis and cow side monitoring and the content of acetone or BHBA in urine and milk are used for these purposes. Concentrations of BHBA and acetocetate in urine and milk are less than those in blood and the correlation coefficients for blood and milk BHBA and blood and milk acetocetate are 0.66 and 0.62, respectively.52

Milk and urine cowside tests

Cowside tests have the advantage of being inexpensive, giving immediate results, and they can be used as frequently as necessary. A minor source of error is that the concentration of ketone bodies in these fluids will depend not only on the ketone level of the blood but also on the amount of urine excreted or on the milk yield. Milk is less variable, easier to collect and may give fewer false negatives with subclinical ketosis.

Milk and urine ketone levels have been traditionally detected by the reaction of acetone and acetoacetate with sodium nitroprusside and can be interpreted in a semi-quantitative manner based on the intensity of the reaction. Several products are available commercially as test powders or strips are commonly accompanied by a color chart that allows a classification in grades such as negative, trace, small, moderate, large, based on the intensity of the color of the reaction.

Conventional wisdom is that milk powder tests are not sensitive for detection of subclinical ketosis (report too many false negatives) and urine tests are not sufficiently specific (report too many false positives).33

Milk testing. The sensitivity and specificity of the nitroprusside powder test with milk in various studies is reported as 28–90% and 96–100%, respectively.16,53,54 More recently, a milk strip test detecting the presence of BHBA in milk is available and graded on the concentration of BHBA in μmol/L. In different studies it has a reported sensitivity and specificity of 73–96% and 69–96%, respectively.35–57 These variations are, in part, due to different plasma BHBA reference values (1200 and

1400 μmol/L) for designation of subclinical ketosis and different cut points used in urine BHBA. Somatic cell counts greater than 1 million cells/mL will cause an elevation in reading of both the BHBA strip test and the nitroprusside tests.

Urine testing. A nitroprusside tablet has a reported sensitivity and specificity of 100% and 59%, respectively, compared with serum BHBA concentrations above 1400 μmol/L and a nitroprusside strip test a reported sensitivity and specificity of 78% and 96% with a urine cut point corresponding to ‘small’ on the color chart or 49% and 99% with a urine cut point corresponding to ‘moderate’ on the color chart.55 BHBA test strips when used with urine has a reported sensitivity and specificity of 73% and 96%, respectively at a urine cut point of 100 μmol/L BHBA and 27% and 99% at a urine cut point of 200 μmol/L BHBA.53

One author has suggested that the nitroprusside urine strip test or the BHBA milk strip test are best for screening individual cows for ketosis in herds with average prevalence but that the nitroprusside powder test would have limited application.

Milk fat to protein ratio. Milk fat concentration tends to increase and milk protein concentration tends to decrease during postpartum negative energy balance. A fat to protein ratio >1.5 in first day teat milk is indicative of a lack of energy supply in the feed and of risk for ketosis.55

Clinical chemistry and hematology. White and differential cell counts are variable and not of diagnostic value for ketosis.

There are usually elevations of liver enzymes but liver function tests are within the normal range. Liver biopsy is the only accurate method to determine the degree of liver damage.58 Plasma concentrations of non-esterified fatty acids are elevated as are cholesterol concentrations and bilirubin. Bilirubin is not a sufficiently sensitive indicator to assess the extent of fat mobilization and liver function.55 Liver glycogen levels are low and the glucose tolerance curve may be normal. Volatile fatty acid levels in the rumen are much higher in ketotic than in normal cows and the ruminal levels of butyric acid are markedly increased relative to acetic and propionic acids. There is a small but significant fall in serum calcium levels (down to about 9 mg/dL (2.25 mmol/L)), due probably to increased loss of base in the urine to compensate for the acidosis.

DIFFERENTIAL DIAGNOSIS

Cattle
The clinical picture is usually too indefinite, especially in cattle, to enable a diagnosis to be made solely on clinical grounds. General consideration of the history, with particular reference to the time of calving, the duration of pregnancy in ewes and the feeding program, and biochemical examination to detect the presence of hypoglycemia, ketonemia, and ketonuria are necessary to establish a diagnosis.

Wasting form
- Abomasal displacement
- Traumatic reticulitis
- Primary indigestion
- Cystitis and pyelonephritis
- Diabetes mellitus.

Nervous form
- Rabies
- Hypomagnesemia
- Bovine spongiform encephalopathy.

TREATMENT
In cattle, a number of effective treatments are available but in some affected animals, the response is only transient; in rare cases, the disease may persist and cause death or necessitate slaughter of the animals. Most of these cases are secondary and failure to respond satisfactorily to treatment is due to the primary disease.

The rational treatment in ketosis is to relieve the need for glucose formation from tissues and allow ketone body utilization to continue normally. Theoretically, the simplest means of doing this is by the administration of glucose replacement therapy. The effect of the administration of glucose is complex but it allows the reversal of ketogenesis and the establishment of normal patterns of energy metabolism.52 Ideally, treatment should be at an early stage of the disease to minimize loss and with subclinical ketosis this requires biochemical testing.52

Replacement therapy
Glucose (dextrose)
The IV injection of 500 mL of a 50% solution of glucose results in transient hyperglycemia, increased insulin and decreased glucagon secretion, and reduced plasma concentration of non-esterified fatty acids. It effects a marked improvement in most cows but relapses occur commonly unless repeated treatments are used. This is probably due to the transience of the hyperglycemia or insufficient dosing – the dose required varies directly with the amount of lactose being lost in the milk. A significant proportion of the administered glucose is lost to urinary excretion. SC injections prolong the response but are not recommended as they cause discomfort, and large unsightly swellings, which often become infected, may result. IP injections of 20% solution of dextrose may be used alternatively but are also accompanied by risk of infection.

Other sugars
Other sugars, especially fructose, either alone or as a mixture of glucose and fructose (invert sugar), and xylitol, have been used in an effort to prolong the response but idiosyncrasies to some preparations, in the form of polypnea, muscle tremor, weakness and collapse, can occur while the injection is being given.

Propylene glycol and glycerine/glycerol
To overcome the necessity for repeated injections, propylene glycol can be administered as a drench. The traditional does is 225 g twice daily for 2 days, followed by 110 g daily for 2 days to cattle, but higher volumes are also used. Propylene glycol (200–700 g daily), or salts of propionic acid, can be administered in the feed and give good results. Administration in feed is preferred by some because this method avoids dangers of aspiration with drenching; however, cows not used to its inclusion in the feed may show feed refusal. It is recommended that for best results, dosing with these preparations be preceded by an IV injection of glucose.

Parenteral infusions of glucose solutions and the feeding of glycerol depress the fat content of milk, and the net saving in energy may favorably influence response to these drugs. Glycerol and propylene glycol are not as efficient as glucose because conversion to glucose does utilize oxaloacetate. Propylene glycol is absorbed directly from the rumen and acts to reduce ketogenesis by increasing mitochondrial citrate concentrations; its metabolism to glucose occurs via conversion to pyruvate with subsequent production of oxaloacetate via pyruvate carboxylase.12

Other glucose precursors
Because of its glucogenic effect, sodium propionate is theoretically a suitable treatment but when administered in 110–225 g doses daily, the response in cattle is often very slow. Lactates are also highly glucogenic but both calcium and sodium lactate (1 kg initially, followed by 0.5 kg for 7 days) and sodium acetate (110–500 g/d) have given less satisfactory results than those obtained with sodium propionate. Ammonium lactate (200 g for 5 days) has, however, been used extensively with reported good results.

Lactose, in whey, or in granular form in the diet, can increase dry matter intake but increases ruminal butyrate and plasma BHBA concentrations.59

Necropsy findings
The disease is not usually fatal in cattle but fatty degeneration of the liver and secondary changes in the anterior pituitary gland and adrenal cortex may be present.
Hormonal therapy

Glucocorticoids. The efficiency of glucocorticoids in the treatment of bovine ketosis has been demonstrated in both experimental and field cases. Hyperglycemia occurs within 24 h of administration and appears to result from a partitioning of glucose in the body rather than from gluconeogenesis. Historically, many preparations have been used successfully but current drugs are more potent, require lower dosage, and have fewer side-effects. A hyperglycemic state is produced for 4-6 days in ketotic cows given 10 mg of dexamethasone 21-isonicotinate and other preparations such as dexamethasone sodium phosphate (40 mg) and flumethasone (5 mg) are also used. Label regulations vary between countries and in general, the recommendations of the manufacturer with regard to use and dosage should be followed. Profound hypokalemia with high case fatality is a potential sequela to prolonged repeated therapy of ketosis with isoflupredone acetate. Response of cows with primary ketosis to treatment with corticosteroids and IV glucose is superior, with fewer relapses, than therapy with corticosteroids or glucose alone.

Insulin facilitates cellular uptake of glucose, suppresses fatty acid metabolism and stimulates hepatic gluconeogenesis. It is administered in conjunction with either glucose or a glucocorticoid and may be of particular value in early-onset cases of ketosis that are unresponsive to glucose or corticosteroid therapy but is not commonly used. The dose of propranolol zinc insulin is 200-300 IU per animal administered SC every 24-48 h as required.

Anabolic steroids have also been used for treatment of lactational ketosis and ketosis in late pregnant cows that are overfat, stressed, or have twin fetuses. Experimentally, 60 mg and 120 mg of trenbolone acetate are effective as single injections but no extensive field trials are recorded and the drug is banned for use in food animals in most countries.

Miscellaneous treatments. Vitamin B\textsubscript{12} and cobalt are indicated in regions where cobalt deficiency is a risk factor for ketosis. They are sometimes administered to cattle with ketosis in regions where cobalt deficiency does not occur but their therapeutic value is not proven. Cysteamine (a biological precursor of coenzyme A) and also sodium fumarate have been used to treat cases of the disease. Reported results were initially good but the treatment has not been generally adopted. The recommended dose rate of cysteamine is 750 mg IV for three doses at 1-3 day intervals.

Glucagon although ketogenic is strongly gluconeogenic and glycogenolytic and glucagon concentrations are decreased in the blood of fat cows at calving and cows with ketonemia. It could be of value in prevention and therapy but it would require a prolonged delivery system as it has a very short physiologic half life and its effects following a single injection are short-lived.

CONTROL

The control of clinical ketosis is integrally related to the adequate nutrition of the cow in the dry and lactating period. This encompasses details such as:

- Dry matter intake
- Fiber digestibility
- Particle size distribution
- Energy density
- Fat incorporation in early lactation rations
- Protein content
- Feeding systems
- Rumen size
- Other factors better covered in texts on nutrition.

It is difficult to make general recommendations for the control of the disease because of the many conditions under which it occurs, its probable multiple etiology, and feeding systems that vary from those that feed components separately to those that feed total mixed rations. Cows should neither have been starved nor be overfat at calving. Careful estimation of diets by reference to feed value tables is recommended and detailed recommendations on diet and management are available with the caveat that planned rations can deviate from feed bunk rations and feed bunk dry matter and actual dry matter intake may not be the same. Too low a feeding frequency and the feeding of concentrates separate from roughage rather than as a total mixed ration can lead to an increase in rates of ketosis.

In the USA, dry cows are typically divided into two groups; ‘far off’ and ‘close up’ cows. ‘Far off’ cows are generally fed to National Research Council (NRC) dry cow feeding guidelines and ‘close up’ cows are given a ration that is halfway between the dry cow and early lactation ration starting 3 weeks before estimated calving and aiming to maximize dry matter intake and provide adequate energy. Practical recommendations based on British feeding standards and units are also available.

In high-producing cows being fed stored feeds, poor quality roughage commonly leads to acetonemia. Wet ensilage containing much butyrate, and moldy or old and dusty hay, are the main offenders. In concentrates, it is the change of source which creates off-feed effects and precipitates attacks of acetonemia.

Cows that are housed should get some exercise each day and in herds where the disease is a particular problem during the stabilizing period, the cattle should be turned out to pasture as soon as possible in the spring.

The ration should contain adequate amounts of cobalt, phosphorus and iodine. If there is a high incidence in a herd receiving large quantities of ensilage, reduction of the amount fed for a trial period is indicated.

Energy supplements

Propylene glycol is used for the prevention of clinical and subclinical ketosis. Traditionally, propylene glycol has been drenched to cattle in early lactation at doses varying from 350 to 1000 mL daily for 10 days after calving. There is a linear effect of dose on plasma glucose. Propylene glycol can also added to feed and is frequently present in commercial feed product but a bolus dose of propylene glycol is more effective in raising blood glucose than incorporation in feed. A dose of 1 L per day given as an oral drench for 9 days prior to parturition has also been shown efficacious. At doses above 500 mL administered by drench or present in feed some cows may develop rapid and shallow respiration, ataxia, salivation, and somnolence.

Glycerol can be substituted for propylene glycol at equivalent dose rates. A preliminary report of a small experimental study with larger doses of glycerol showed that glycerol given orally at a dose of 1, 2, or 3 L elevated blood glucose concentrations to 16, 20, and 25% of pretreatment values at 0.5 h after treatment and that these concentrations remained elevated for 8 h. Staggering, depression and diuresis were observed in some cows given the 2 or 3 L dose but this could be prevented by administering the glycerol in a large (37 L) volume of water. It concluded that a dose of 1 L was effective in increasing milk production and reducing urinary ketones. Glycerol, fed as a constant component in the transition dairy cow diet is not effective, and possibly may be ketogenic when fed continually.

Glycerol should only be used as drench in hypoglycemic cows and not fed as a component of the diet.

Propionic acid and its salts

Propionic acid absorbed across the rumen wall is transported to the liver where it is converted to glucose via gluconeogenesis to result in an increase in serum blood glucose levels. Older literature reports that 110 g/d fed daily for 6 weeks, commencing at calving, has given good results in reducing the incidence of clinical bovine ketosis and improving production, but is not palatable and has the risk of reducing
feed intake. In controlled trials, feeding energy supplements containing propionic acid and/or its salts for 3 weeks prepartum and 3 weeks post partum had a beneficial effect on milk production but a variable effect on reducing subclinical ketosis.\(^7,73\)

Ionophores
Ionophores alter bacterial flora of the rumen, leading to decreases in Gram-positive bacteria, protozoa, and fungi and increases in Gram-negative bacteria. The net effect of these changes in bacterial flora is increased propionate production and a decrease in acetate and butyrate production providing increased gluconeogenic precursors. Field trials with monensin have demonstrated a reduction in plasma BHBA and a reduced prevalence of clinical ketosis.\(^7,74,75\) It can be administered as a slow release capsule to cattle 2–4 weeks before calving. The capsule contains 32 g of monensin and releases approximately 335 mg monensin a day for 95 days. Ionophores are not labeled for inclusion in lactating cow rations in some countries.

Niacin
Niacin is antipolypytic and induces increases in blood glucose and insulin but there is conflicting evidence that niacin given in the feed has a beneficial effect on subclinical ketosis in cattle.\(^5,20,27\) It has been suggested that it should be supplement from 2 weeks prior to parturition to 12 weeks post partum.\(^7,74\)

**General control**

**Herd monitoring.** Biochemical monitoring of heifers for subclinical ketosis and adequacy of periparturient feeding can be conducted using blood glucose estimations on a sample of cows in their second week of lactation.\(^5\) Blood glucose levels of below 35 mg/dL (1.9 mmol/L) suggest subclinical ketosis. For individual cows, blood glucose estimations should be done at about 14 days after calving. This method of monitoring is expensive. More commonly, testing for ketones in urine or milk of cows in their first or second week of lactation is recommended for early detection of ketosis and early treatment to prevent milk loss and ketosis-associated diseases. One recommendation is to routinely test such cows on a specific day each week.\(^19\) This should be coupled with body condition scoring to monitor the efficacy of the nutritional program. Condition scoring at dry off, mid dry period, calving, calving plus 20–50 days, and two to three subsequent periods in lactation have been suggested.\(^28,67\) Plasma glucose coupled with plasma BHBA are the best predictive model for monitoring energy balance of cattle on a pasture diet with milk acetone the best 'on-farm' predictor. However, the variation in milk acetone is high and frequent sampling is required for accurate estimation.\(^78\)

Automated monitoring by in-line measurements of ketone bodies in milk have been studied and may be of particular value in large dairies. BHBA is proposed as the candidate as it is the more robust in milk, and where cows are fed a TMR, is not subject to significant diurnal variation. It can be measured with a fluorometric method that requires no pretreatment of the milk.\(^7,80\)

**REFERENCES**

ETIOLOGY

Hypoglycemia and hyperketonemia are the primary metabolic disturbances in pregnancy toxemia. The precipitating cause is the energy demand of the conceptus in late pregnancy coupled with a short period of food deprivation in conjunction with a management procedure in late pregnancy such as crutching, shearing, change of environment, or drenching. In pastoral flocks, the fall in the plane of nutrition can result from factors such as inadequate pasture management and improper stocking densities. In pastoral flocks, the occurrence is more common in early-lambing flocks where there is no provision for added feed in years where there is a long winter. In some outbreaks, the ewes have been moved on to better pasture during late pregnancy to prevent the occurrence of ketosis but it occurs because the ewes are unaccustomed to the type of feed and do not eat well. With sheep housed in late pregnancy, the provision of poor quality hay may predispose pregnancy toxemia. A change in feed type and the feeding of moldy feed or feed contaminated with manure can also lead to decreased intake, especially with goats. Competition for inadequate trough space can also be important. Goats exhibit greater dominant/submissive characteristics than sheep and this can result in lower food intake in submissive goats in groups that are hand fed. In all management systems, failure to identify and separate ewes bearing twins and triplets and to feed them separately from ewes bearing single lambs and a general failure to increase the nutritional plane of pregnant sheep in the last 6 weeks of pregnancy are predisposing factors.

Fat ewe pregnancy toxemia

This occurs without a stress induction in ewes that are very well fed and are in an overfed condition in late pregnancy. Fat ewes will experience a voluntary fall in food intake in late pregnancy, due to the reduction of the rumen volume by the pressure of intra-abdominal fat and the developing fetus. This can occur especially if there is reliance at this time on high water content feeds such as silage or root crops. Traditionally, a lack of exercise is also believed to predispose this type of pregnancy toxemia. Commonly there is concurrent hypocalemia.

Starvation pregnancy toxemia

This occurs in ewes that are excessively thin. It is relatively uncommon but occurs in extensive grazing systems where there is prolonged drought and no alternative feed supply and can be seen in any production system where there is mismanagement.

Secondary pregnancy toxemia

This usually occurs as a sporadic disease as the result of the effect of an intercurrent disease such as foot rot or foot abscesses, which affects food intake. Heavy worm infestation, e.g. with Haemonchus contortus, would add a similar drain on glucose metabolism and increase the chances of development of the disease.

Stress-induced pregnancy toxemia

This is the least common cause of the disease, one where stress is the initiator. Examples are the close shepherding or housing of late-pregnant sheep of breeds not used to being housed, the transport of late pregnant sheep and outbreaks that occur following a period of flock attack by dogs.

Pregnancy toxemia occurs in ewes in the last 6 weeks of pregnancy with the peak incidence in the last 2 weeks of pregnancy. It occurs primarily in ewes carrying triplet or twin lambs.

Occurrence

Pregnancy toxemia occurs whenever sheep are raised but it is primarily a disease of sheep raised in intensive farming systems, either grazing or housed during the winter. In part, this is because the breeds of sheep used in intensive farming are more likely to bear twins or triplets. In contrast, sheep breeds in extensive grazing systems commonly bear single lambs and significant outbreaks of pregnancy toxemia are uncommon except where there is drought or poor pasture management. The attack rate in a flock varies with the nature and severity of the nutritional deprivation and the proportion of the flock at risk. It can be very high in starvation pregnancy toxemia, whereas fat ewe pregnancy toxemia is generally of sporadic occurrence. In outbreaks that follow management procedures or other stressors, clinical disease is not manifest until 48 hours later and new cases will develop over several days. Intercurrent disease in late pregnant ewes, such as foot rot or foot abscess, may predispose pregnancy toxemia.

The natural incidence in intensively farmed sheep is approximately 2% of pregnant ewes but where there are severe

The disease also occurs in goats during late pregnancy with the same initiating causes. The following classification of pregnancy toxemia is according to cause as the determination of the management cause is critical to control and prevention. These are further described below.

- Primary pregnancy toxemia
- Fat ewe pregnancy toxemia
- Starvation pregnancy toxemia
- Secondary pregnancy toxemia
- Stress-induced pregnancy toxemia.

EPIDEMIOLOGY

Primary pregnancy toxemia

This is the most common manifestation and results in most flocks from a combination of a fall in the plane of nutrition during the latter half of pregnancy often coupled with a short period of food deprivation in conjunction with a management procedure in late pregnancy such as crutching, shearing, change of environment, or drenching. In pastoral flocks, the fall in the plane of nutrition can result from factors such as inadequate pasture management and improper stocking densities. In pastoral flocks, the occurrence is more common in early-lambing flocks where there is no provision for added feed in years where there is a long winter. In some outbreaks, the ewes have been moved on to better pasture during late pregnancy to prevent the occurrence of ketosis but it occurs because the ewes are unaccustomed to the type of feed and do not eat well. With sheep housed in late pregnancy, the provision of poor quality hay may predispose pregnancy toxemia. A change in feed type and the feeding of moldy feed or feed contaminated with manure can also lead to decreased intake, especially with goats. Competition for inadequate trough space can also be important. Goats exhibit greater dominant/submissive characteristics than sheep and this can result in lower food intake in submissive goats in groups that are hand fed. In all management systems, failure to identify and separate ewes bearing twins and triplets and to feed them separately from ewes bearing single lambs and a general failure to increase the nutritional plane of pregnant sheep in the last 6 weeks of pregnancy are predisposing factors.

Fat ewe pregnancy toxemia

This occurs without a stress induction in ewes that are very well fed and are in an overfed condition in late pregnancy. Fat ewes will experience a voluntary fall in food intake in late pregnancy, due to the reduction of the rumen volume by the pressure of intra-abdominal fat and the developing fetus. This can occur especially if there is reliance at this time on high water content feeds such as silage or root crops. Traditionally, a lack of exercise is also believed to predispose this type of pregnancy toxemia. Commonly there is concurrent hypocalemia.

Starvation pregnancy toxemia

This occurs in ewes that are excessively thin. It is relatively uncommon but occurs in extensive grazing systems where there is prolonged drought and no alternative feed supply and can be seen in any production system where there is mismanagement.

Secondary pregnancy toxemia

This usually occurs as a sporadic disease as the result of the effect of an intercurrent disease such as foot rot or foot abscesses, which affects food intake. Heavy worm infestation, e.g. with Haemonchus contortus, would add a similar drain on glucose metabolism and increase the chances of development of the disease.

Stress-induced pregnancy toxemia

This is the least common cause of the disease, one where stress is the initiator. Examples are the close shepherding or housing of late-pregnant sheep of breeds not used to being housed, the transport of late pregnant sheep and outbreaks that occur following a period of flock attack by dogs.

Pregnancy toxemia occurs in ewes in the last 6 weeks of pregnancy with the peak incidence in the last 2 weeks of pregnancy. It occurs primarily in ewes carrying triplet or twin lambs.

Occurrence

Pregnancy toxemia occurs whenever sheep are raised but it is primarily a disease of sheep raised in intensive farming systems, either grazing or housed during the winter. In part, this is because the breeds of sheep used in intensive farming are more likely to bear twins or triplets. In contrast, sheep breeds in extensive grazing systems commonly bear single lambs and significant outbreaks of pregnancy toxemia are uncommon except where there is drought or poor pasture management. The attack rate in a flock varies with the nature and severity of the nutritional deprivation and the proportion of the flock at risk. It can be very high in starvation pregnancy toxemia, whereas fat ewe pregnancy toxemia is generally of sporadic occurrence. In outbreaks that follow management procedures or other stressors, clinical disease is not manifest until 48 hours later and new cases will develop over several days. Intercurrent disease in late pregnant ewes, such as foot rot or foot abscess, may predispose pregnancy toxemia.

The natural incidence in intensively farmed sheep is approximately 2% of pregnant ewes but where there are severe
management deficiencies of the disease, the disease may affect the majority of late pregnant ewes. In a study of sheep diseases in Canada, 19% of flocks were reported to have the disease. The case-fatality rate is high unless treatment is initiated early in the clinical course. Even with early treatment case-fatality can be high.

**Experimental reproduction**

Hypoglycemia and ketosis can be experimentally produced in pregnant sheep by under-nourishment but the resultant syndrome has biochemical and clinical differences to spontaneously occurring pregnancy toxemia. For example, loss of appetite is an early sign in spontaneous occurring disease whereas starved experimental animals, even though hypoglycemic and ketotic, will eat feed when offered and there is debate that hypoglycemia is the primary precipitating cause of the clinical signs in the naturally occurring disease.

There is a great deal of variation between sheep in the ease with which the hypoglycemia and ketosis can be produced experimentally, and in the variation in incidence of the naturally occurring disease in conditions which appear to be conducive to its development.

It is probable that the difference between sheep depends upon the metabolic efficiency of the liver.

**Animal risk factors**

**Pregnancy**

The disease occurs only in ewes in the last 6 weeks of pregnancy, usually during the last month, with the peak incidence in the last 2 weeks of pregnancy. It occurs primarily in ewes carrying triplet or twin lambs, although ewes bearing a single, large lamb may also be affected.

**Parity**

The disease is uncommon in maiden ewes because of their low fecundity and increases in prevalence up to parity three.

**Breed**

Breed differences largely reflect differences in fecundity and differences in management systems. Thus, the disease is more common in British lowland breeds and their crosses than the Merino. British hill-breeds are traditionally believed more resistant to the development of pregnancy toxemia in the face of nutritional deprivation of the ewe but resistance is achieved at the expense of lamb birth weight and has the penalty of higher neonatal mortality. There are however differences in the susceptibility of individual sheep that appear to be related to differences in rates of hepatic gluconeogenesis.

**Economic significance**

The economic effect of the disease is considerable. Without treatment, the case-fatality rate can approach 100% and in individual flocks, the disease can reach a level of incidence sufficient to be classed as an outbreak. Treated ewes that recover may have dystocia and die during parturition or develop retained placenta and metritis. Flocks that experience pregnancy toxemia also have a significantly higher than normal mortality in neonatal lambs and often a severe decrease in wool quality. Flocks that experience pregnancy toxemia are predisposed to the subsequent occurrence of hypermagnesemia in the lactating period.

**PATHOGENESIS**

Pregnancy toxemia results from inadequate energy intake in late pregnancy in ewes with more than one fetus. Approximately 60% of fetal growth takes place in the last 6 weeks of pregnancy. Ewes that are predisposed to the disease have an ineffective gluconeogenic response to the continued, preferential demands for glucose by the growing fetuses resulting in hypoglycemia, lipid mobilization and the accumulation of ketone bodies and cortisol. The reason for this predisposition is not known. The subsequent disease and metabolic changes are associated with excessive lipid mobilization. Elevated concentrations of β-hydroxybutyrate further suppress endogenous glucose production and exaggerates the development of ketosis and the negative feedback of hyperketonemia on glucose production can result in a vicious circle. The disease manifests with an encephalopathy, believed to be a hypoglycemic encephalopathy resulting from hypoglycemia in the early stages of the disease. The encephalopathy and the disease are frequently not reversible unless treated in the early stages. The onset of clinical signs is always preceded by hypoglycemia and hyperketonemia, although the onset of signs is not related to minimum blood glucose or maximum ketone levels and hypoglycemia may not be the initial precipitating cause of the syndrome. In affected ewes, there is an abnormally high level of cortisol in plasma and it has been suggested that adrenal steroid diabetes contributes to the pathogenesis.

The increase of plasma concentrations of non-esterified fatty acids results in a depression of cellular and humoral immune responses in the experimentally produced disease but the clinical significance of this to naturally occurring disease is not clear. Renal dysfunction is also apparent in the terminal stages of ovine ketosis, and contributes to the development of clinical signs and the fatal outcome.

Those ewes which are carrying only one lamb and have been well fed prior to a short period of undernutrition may develop a subacute syndrome both clinically and biochemically.

**CLINICAL FINDINGS**

**Ovine ketosis**

The earliest signs of ovine ketosis are separation from the group, failure to come up for feeding in pastoral animals or standing near the trough with the group of sheep but not eating, in housed animals, altered mental state and apparent blindness, which is manifested by an alert bearing but a disinclination to move.

The ewe will stand still when approached by attendants or dogs and will turn and face them but make no attempt to escape. It is easily captured but more difficult to restrain than normal sheep. If it is forced to move, it blunders into objects and when an obstacle is encountered, presses against it with its head. Many affected ewes stand in water troughs all day and lap the water. Constipation is usual, the feces are dry and scanty and there is grinding of the teeth.

In later stages, marked drowsiness develops and episodes of more severe nervous signs occur but they may be infrequent and are easily missed. In these episodes, tremors of the muscles of the head cause twitching of the lips, champing of the jaws and salivation, and these are accompanied by a cog-wheel type of clonic contraction of the cervical muscles causing dorsiflexion or lateral deviation of the head, followed by circling. The muscle tremor usually spreads to involve the whole body and the ewe falls with tonic-clonic convulsions. The ewe lies quietly after each convolution and rises normally afterwards but is still blind.

In the periods between convulsions there is marked drowsiness which may be accompanied by head pressing, the assumption of abnormal postures including unusual positions of the limbs and elevation of the chin – the 'stargazing' posture – and incoordination and falling when attempting to walk. A smell of ketones may be detectable on the breath of the ewe.

Affected ewes usually become recumbent in 3-4 days and remain in a state of profound depression or coma for a further 3-4 days, although the clinical course is shorter in fat ewes with pregnancy toxemia. Terminally there may be a fetid diarrhea.

Fetal death occurs commonly and is followed by transient recovery of the ewe, but the toxemia caused by the decomposing fetus soon causes a relapse.

Affected ewes commonly have difficulty in lambing. Recovery may ensue if the ewe lambs or the lambs are removed by caesarean section in the early stages of the disease. In an affected flock, the disease
usually takes the form of a prolonged outbreak; a few ewes become affected each day over a period of several weeks. Recovered ewes may subsequently show a wool break.

CLINICAL PATHOLOGY
Hypoglycemia, ketonemia, and ketonuria are characteristic of the disease. The initial changes are similar to ketosis in cattle but the sequel is not. Hypoglycemia can be used as a diagnostic aid in the early stages of the disease but is of limited value later in the course as by the time that sheep become recumbent, blood glucose levels may be normal or grossly elevated. This may be the result of fetal death which has been shown to remove the suppressing effect of the fetus on hepatic neoglucogenesis.

Ketonemia and ketonuria are constant and serum β-hydroxybutyrate concentrations are in excess of 3000 μmol/L.13 Sheep develop a severe metabolic acidosis, renal failure with a terminal uremia, and become dehydrated. Liver function tests show liver dysfunction.16 Elevation of plasma cortisol occurs in pregnancy toxemia and concentrations above 10 ng/mL are indicative of pregnancy toxemia,17 but pregnancy toxemia and clinical hypocalcemia can both cause sufficient stress to promote such an elevation.

NECROPSY FINDINGS
Pregnancy toxemia in ewes is almost always fatal without treatment intervention. At necropsy, there is severe fatty degeneration of the liver and there is usually evidence of constipation, but some have fetid light colored diarrheic feces. A large single but more commonly twin or greater number of fetuses are present. Fetuses may have died before the ewe and show autolysis.

Histopathologically there is also a poorly defined renal lesion and there may be evidence of neuronal necrosis.18 The lambs may be dead and in varying stages of decomposition. Hepatic glycogen levels are usually very low. Concentrations of β-hydroxybutyrate in the aqueous humor or the CSF >2500 or 500 μmol/L respectively, are supportive of a diagnosis of pregnancy toxemia.13

Differential Diagnosis

Sheep
Pregnancy toxemia is usually suspected in late pregnant ewes which show nervous signs and die within 2-7 days and there may be a history of exertion, stress or sudden deprivation of food. Hypocalcemia can occur under similar circumstances but:
1. The onset is within 12 h of the stress.
2. A considerable proportion of the flock will be affected at the same time.

3. The disease is manifest with myasthenia.
4. It has a much shorter course of 12-24 h.
5. Affected animals respond well to treatment with solutions of calcium salts.
   - Listeriosis
   - Cerebral abscess
   - Acidosis
   - Uterine torsion or impeding abortion
   - Rabies.

TREATMENT
Treatment in sheep
Sheep treated very early in the course of the disease generally respond favorably, but response to therapy is poor once sheep have become recumbent and the IV administration of 50% dextrose at this time may hasten death. Therapy requires the correction of fluid, electrolyte, and acid-base disturbances in addition to replacement therapy with glucose.

Parenteral therapy
Ideally, individual sheep should be examined biochemically and the corrective therapy based accordingly, with fluids, electrolytes and glucose (dextrose) given over a prolonged period of time. One recommendation for glucose therapy is the administration of 5-7 g of glucose IV 6-8 times a day in conjunction with 20–40 units of zinc protamine insulin given IM every other day for 3 days. In many sheep-raising areas, intensive laboratory monitoring and therapy is not possible because of access, expense, or the number of sheep involved in an outbreak. In the absence of biochemical monitoring, therapy with glucose should be accompanied by the IV injection of isotonic sodium bicarbonate or lactated Ringer's solution and the administration of further fluids by a stomach tube.

Standard doses of corticosteroids have little therapeutic effect in sheep and therefore treatment with these drugs is not recommended although they are commonly used. Very large doses are effective in ewes still able to stand but the success probably rests in the removal of the glucose drain by the induction of premature parturition. Treatment with recombinant bovine somatotrophin (0.15 mg/kg body weight) in conjunction with dextrose and electrolytes may result in a shorter duration of treatment, improve ewe survival and result in a greater viability of lambs born4,19,20 but reported results are not impressive.

Oral therapy
Traditionally, propylene glycol or glycerine (110 g/d) given by mouth is used to support parenteral glucose therapy. Less intensive therapy includes the use of propylene glycol or glycerine alone which has given excellent results for some workers but poor results for others.

Success is reported with the oral drenching, every 4-8 h, of 160 mL of a solution containing 45 g glucose, 8.5 g sodium chloride, 6.17 g glycine and electrolytes, which is available commercially as a concentrated oral rehydration solution for calves with diarrhea.21 This therapy is now commonly used in the UK.22 Drenching of non-pregnant sheep with this solution is followed by higher blood concentrations of glucose than those achieved following drenching with glycerol or propylene glycol. Reported recovery rates in pregnancy toxemia are 90% in early cases and 55% in advanced cases.21 Vasopressin has been used to induce closure of the esophageal groove in conjunction with the oral administration of glucose. Treatment with insulin in addition to treatment with oral glucose precursors and electrolytes showed a significantly higher survival rate (87%) compared with treatment with oral glucose precursors and electrolytes alone.23

Caesarean section
Caesarean section can be used as an alternate to replacement therapy. Provided ewes are in the early stages of the disease, removal of the lambs by caesarean section is probably the therapy that has the greatest success rate. The demand for glucose by the lambs is immediately removed and both the ewe and the lambs have a high chance of survival providing the caesarean section is conducted before there is irreversible brain damage in the ewe and providing the lambs are close to term. If the ewe is in the recumbent stage then her chance of survival is low. Cesarian section can still offer the chance for survival of the lambs but also less viable at this stage and may be dead. Ultrasound to determine if the lambs are alive, aids in the decision for caesarean section.

Induction of parturition
Induction of parturition is a further option but should only be used if the ewe is in the early stage of the disease as lambs will be delivered no earlier than 36 h after therapy, and often later. If the ewe is judged unlikely to survive this period, caesarean section is a better option. Induction with corticosteroids has been effected with dexamethasone 21-isonicotinate or the sodium phosphate form at a dose rate of 16–25 mg per ewe but dexamethasone trimethylacetate appears to be ineffective. Lambs will be born 48–72 h after injection.

Induction of parturition in normal sheep is reported with 10 mg of betamethasone or 2.5 mg of flumethasone but there are no reports of their efficacy in sheep with pregnancy toxemia.

CONTROL
When clinical cases occur, the rest of the flock should be examined daily for any evidence of ketosis and affected animals
treated immediately with propylene glycol or glycerol or oral glucose/glycine/ electrolyte solutions. Supplementary feeding of the flock should be commenced immediately, with particular attention given to an increase in carbohydrate intake. Cereal grain starting at 0.5 lb/head per day and increasing to 2 lb/head per day (0.25–1 kg/head per day) for large frame breeds is recommended.

Prevention
Ensure that the plane of nutrition is rising in the second half of pregnancy, even if it means restricting the diet in the early stages. Ewes that are in condition score 2.5–3.0 on a 1.0–5.0 scale at 90 days of gestation and are in an ideal situation to respond to increased feeding in the latter part of gestation. If necessary, ewes with higher condition scores at the end of the first month of pregnancy can be fed to lose 0.5 condition score during the period to the third month of pregnancy without any significant effect on the ewe or lamb size or viability. Many small farm sheep producers have sheep in too high a condition score early in pregnancy.

The last 2 months are particularly important in the prevention of pregnancy toxemia as 70% of the lamb’s birth weight is gained during the last 6 weeks of pregnancy. During this period, the provision of cereal grain or a concentrate containing 10% protein at the rate of 0.25 kg/d, increasing to 1 kg/d in the last 2 weeks, has provided good protection. During this period, the ewe should gain an increase of body weight of 10% for ewes with single lambs and 18% in ewes carrying twins. For the flock this represents a flock body condition score that maintains or gains to 3.0–3.5 during this period. Higher body condition scores can result in higher birth weight of lambs but other than in stud flocks these are not economic and the standard commercial flock runs the risk of fat ewe pregnancy toxemia with higher targeted body condition scores.

At the beginning of the fourth month of pregnancy, the flock can be conditioned scored and divided into three groups; those with acceptable condition scores, those with sub-optimal condition scores, and those that are fat and the groups fed accordingly. Response should be evaluated by condition scoring at 2 weekly intervals through the fourth and fifth month of pregnancy. Maiden ewes should be fed as a separate group in order to provide for the requirement for growth in addition to the requirement for pregnancy. Attention should also be given to broken-mouthed ewes to ensure that they are maintaining an adequate body condition.

There are managemental difficulties in any nutritional program for sheep because of the way they are husbanded. Ideally, sheep should be divided into a number of sub-flocks and fed depending on whether there are one, two or three, or no fetuses present. Ultrasound offers a method for this selection.

When feeding sheep, account needs to be taken of those ewes (and does) who are timid and for this, or other reasons, slow feeders. If supplementary feeding is practiced in a confined space, with insufficient trough space for all the flock to eat at one time, and if the feed fed is in small amounts and highly edible, a proportion of ewes will get little or no feed.

Before embarking on a nutritional support program, it is advisable to estimate cost effectiveness. In sheep breeds with low twinning rates that are well managed, it is often more profitable to do nothing and to let the disease occur in the very occasional sheep and treat it accordingly.

Sudden changes in type of feed should be avoided and extra feed provided during bad weather. Shelter sheds should be available, and in purely pastoral areas, lambing should not be planned before the pasture is well grown. A high incidence is often encountered in small, well-fed flocks where the ewes get insufficient exercise. In such circumstances the ewes should be walked 30 min daily and, if pasture is available, only concentrate should be fed so that they will be encouraged to forage for themselves.

Flock monitoring for latent pregnancy toxemia during the last 6 weeks of pregnancy can be conducted using serum β-hydroxybutyrate as an indicator with concentrations of 800 μmol/L indicating adequate energy intake, 800–1600 μmol/L inadequate energy intake and levels greater than 1600 μmol/L indicating severe undernourishment. Boiled samples have been used to reduce the cost of analysis. Serum glucose and β-hydroxybutyrate concentrations have been found to vary significantly between flocks within the normal range.

FATTY LIVER IN CATTLE (FAT COW SYNDROME, HEPATIC LIPIDOSIS, PREGNANCY TOXEMIA IN CATTLE)
Fatty liver or hepatic lipidosis is a major metabolic disease of dairy cows in early lactation and is associated with decreased health status and reproductive performance.

Synopsis
Etiology Mobilization of excessive body fat to liver during periods of negative energy balance at time of parturition or in early lactation of dairy cows and late pregnancy of beef cows.
Epidemiology High-producing dairy cows overfed during dry period may develop fatty liver syndrome just before or after calving precipitated by any factor or disease which interferes with feed intake. Occurs in well-conditioned beef cattle in late pregnancy when energy intake suddenly decreased. Moderate and subclinical degrees of fatty infiltration may adversely affect reproductive performance of dairy cows.
Signs Inappetence to anorexia, ruminal atony, lethargic, inactive, ketonuria, fat body condition, weakness and recumbency if worsens. Recover if continue to eat and appetite improves.
Clinical pathology Increase in serum hepatic enzyme levels, increase in ketone bodies, increased fat in liver biopsy.
Necropsy findings Fatty infiltration of liver.
Diagnostic confirmation Liver biopsy.
Differential diagnosis list
- Left-sided displacement of abomasum
- Right-sided displacement of abomasum
- Milk fever
- Parturition syndrome
- Abomasal impaction
- Vagus indigestion
- Peritonitis.
Treatment Fluid and electrolyte therapy including glucose IV. Propylene glycol orally. Provision of palatable feed.
Control Avoid overfeeding during late lactation and dry period. Avoid situations which reduce feed intake at time of parturition.
ETIOLOGY
Fatty liver is caused by the mobilization of excessive quantities of fat from body depots to the liver. It develops when the hepatic uptake of lipids exceeds the oxidation and secretion of lipids by the liver. Excess lipids are stored as triacylglycerol in the liver and are associated with decreased metabolic functions of the liver. It occurs because of a sudden demand of energy in the immediate postpartum period in well-conditioned lactating dairy cows. It also occurs because of a sudden deprivation of feed in fat pregnant beef cattle, and is especially severe in those bearing twins. The disease is an exaggeration of what is a common occurrence in high-producing dairy cows which are in a state of negative energy balance in early lactation. A substantial drop in voluntary dry matter intake (VMDI) is initiated in late pregnancy and continues into early lactation. This decrease has traditionally been interpreted as caused by physical constraints which role may be overemphasized. The decline in intake coincides with changes in reproduction status, fat mass and metabolic changes in support of lactation and metabolic signals may have an equally important role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, insulin, gut peptides, cytokines, and neuropeptides. Body fat, especially subcutaneous is mobilized and deposited primarily in liver but also muscle and kidney. Whether or not the cow is truly fat at parturition may not be important in determining the degree of fat mobilization, but the degree of negative energy balance in early lactation is critical.

EPIDEMIOLOGY
Occurrence and incidence. Fatty infiltration of the liver is common in high-producing dairy cattle from a few weeks before and after parturition and is associated with several periparturient diseases, and an increase in the calving-to-conception interval. In dairy cows, fatty liver occurs primarily in the first 4 weeks after calving when up to 50% of all cows have some accumulation of triacylglycerol in the liver. A severe form of fatty infiltration of the liver immediately before or after parturition is known as the fatty liver or fat cow syndrome or pregnancy toxemia of cattle which can be highly fatal. In beef cattle, the disease occurs most commonly in late pregnancy when the nutrient intake is decreased in cattle which were previously well fed and in good body condition. The prevalence of fatty liver (more than 50 mg triacylglycerol/1 g wet liver tissue) in a sample of commercial dairy herds was 54.1%.

In a field study, the percentage of cattle dying or being culled because of disease was affected by the amount of hepatic triglyceride: 15%, 31%, and 42% for cattle with mild, moderate, and severe hepatic lipodiosis, respectively. Outbreaks of the disease have occurred in dairy herds in which up to 25% of all cows were affected with a case-fatality rate of 90%.

Cattle have been classified into three groups on the basis of liver fat content determined histologically 1 week after parturition. Less than 20% lipid corresponds to less than 50 mg/g liver by weight, 20-40% lipid, 50-100 mg/g liver, and greater than 40% represents more than 100 mg/g liver. These concentrations correspond to mild, moderate, and severe cases of fatty infiltration. Cows with less than 20% lipid in the liver at 1 week after calving are considered normal, and those with more than 20% are considered to have a fatty liver. About 30% of high-yielding dairy cows in the UK are considered to have a fatty liver 1 week after calving. Clinical evidence of hepatic disease may not occur consistently until liver lipid concentrations are in the range of 35-45% or more.

Risk factors
Host factors
Fatty infiltration of the liver is part of a generalized fat mobilization syndrome which occurs in early lactation, particularly in high-yielding dairy cows, as milk production outstrips appetite and body reserves are used to meet the energy deficit. Diseases which occur commonly in early lactation predispose to fatty liver include ketosis, left-side displacement of the abomasum, mastitis, retained fetal membranes, milk fever, and the downer cow syndrome. Any disease of early lactation which affects appetite and voluntary intake can contribute to fatty liver.

The deficit occurs because dietary intake cannot meet the energy requirements for the high yield. Peak yields of milk are reached 4-7 weeks after calving, but the highest levels of voluntary feed intake are not reached until 8-10 weeks after calving. As a result of the energy deficit, the cow mobilizes body reserves for milk production and may lose a large amount of body weight.

In about 30% of high-producing cows, the infiltration is severe and is associated with reversible but significant effects on liver structure and function. In some populations of cows, the incidence of fatty liver is much lower and insignificant.

The body condition score at calving can have a direct effect on the health, milk yield, and fertility of cows. It represents the cumulative effects of the dry period, the body condition score at drying off and the loss of body condition during the dry period. The risk of retained placenta may be greater for cows underconditioned at drying, whereas cows that lost more body condition during the dry period may be more affected by both retained placenta and metritis; the two effects are independent of each other. The risk of ketosis is increased in cows overconditioned at calving, which may be due to a long dry period. Cows calving in a higher body condition score produced more milk, fat, and protein in the first 90 days of lactation and the effect was most pronounced on milk fat content. Cows with a higher body condition score at calving were less prone to anestrus but did not conceive more successfully to first service. A reduction of 6 open days in primiparous cows was estimated for each additional unit of body condition score at calving. Multiparous cows which lost more body condition during the dry period are more prone to inactive ovaries and are more likely to be open 150 days after calving in the next lactation.

Dairy cows with abnormally long, dry periods also have a tendency to become obese and develop the fatty liver syndrome of parturition. The feeding of dairy cows in large groups as in loose housing systems has been associated with an increase in the incidence of the disease. The disease has occurred in pregnant heifers within 31 days after being turned to grass.

The disease can occur in non-lactating dairy cows by the imposition of a partial starvation diet in late pregnancy in an attempt to reduce the body weight of cows which are considered to be too fat. Changing the diet of pregnant beef cows from silage to straw in an attempt to reduce their body weight and the incidence of dystocia has resulted in outbreaks of the disease.

In beef cattle in North America, the severe form of the disease, pregnancy toxemia, is seen most commonly in the last 6 weeks of pregnancy in cows which are fat and pregnant with twins. The affected cows are usually well fed until late pregnancy when an unexpected shortage of feed occurs, or the cows are too fat and cannot consume sufficient low-energy feed to meet the demands of pregnancy. Under usual circumstances, the disease in beef cattle occurs sporadically; the morbidity is about 1% but the mortality is usually 100%.

Pregnancy toxemia of cattle has occurred in pregnant beef cattle in Australia and the UK. First-calf heifers were more commonly affected than older cows and most were in late pregnancy (7-9 months) or had just recently calved. Cows pregnant with twins are particularly susceptible.
**Genetics of lipid mobilization**

Cows generally mobilize body lipid reserves in early lactation and regain these reserves during subsequent pregnancy. Lipid mobilized from body reserves makes a substantial contribution to the energetic cost of milk production in early lactation. It is usually assumed that this mobilization of body energy reserves is entirely a response to a deficit in feed energy intake relative to milk energy output. This implies that increasing the energy content of the feed being offered would decrease body energy mobilization in early lactation. A number of studies indicate that this is not always the case. A recent proposal indicates that both mobilization of body reserves in early lactation, and the subsequent gain in body reserves during pregnancy, are to a large extent genetically driven. Thus, body energy mobilization is not a response but rather a natural component of the reproductive cycle. Ignoring this preprogrammed body mobilization has important consequences for the prediction of energy requirements and the intake necessary to meet these requirements. Most methods used to predict energy requirements are based on estimates of milk production and maintenance. They do not explicitly allow for any genetically driven body energy metabolism. Prediction of the cow's energy requirements can be substantially improved, particularly in early lactation, by incorporating genetically driven body energy mobilization.

Genetically driven body lipid change is defined as that which would occur in cows kept in an environment that was in no way constraining. It then follows that environmentally driven body lipid change is defined as that which occurs in response to an environment that is constraining. A simple method to predict the genetically driven pattern of body lipid change through pregnancy and lactation in dairy cattle has been described. The rationale and evidence for genetically driven body lipid change have their basis in evolutionary considerations and in the hemorrhagic changes in lipid metabolism through the reproductive cycle. The inputs required to predict body lipid changes are body lipid mass at calving (kg) and the date of conception (days in milk). Body lipid mass can be derived from body condition score and live weight.

**Relationship between body lipid reserves and the reproductive cycle**

Based on consideration of the cyclic nature of reproductive priorities and strategies for dealing with environmental constraints, a conceptual framework describing the relationship between body lipid reserves and the reproductive cycle in dairy cattle has been developed. Female reproductive performance is affected by mobilization of body energy reserves. In dairy cattle, an increase rate of body energy mobilization is associated with an increase in the duration of post-calving anestrus. Also, very thin cows show a delay in post-calving return to estrus and conception rates are affected by these factors.

**Environmental and dietary factors**

In North America, the introduction of the system of challenge feeding of dairy cows was associated with an increased incidence of the disease. The overall effect of the system is to provide excess energy in the diet during late pregnancy or during the dry period generally. The diets fed may contain a high percentage of the cereal grains, corn ensilage, or brewer's grains. In this system, high-energy rations are fed beginning a few weeks before parturition. The total daily amount of feed is increased by regular increments to reach a high level at parturition and peak levels to coincide with the peak in the lactation curve several weeks after parturition. This resulted in some excessively fat cows at the time of parturition, when energy demands are high. The disease has also occurred in dairy cows which were fed excessive amounts of high-energy rations throughout the dry period. In dairy herds, the fatty liver syndrome has also been associated with an increase in the incidence of milk fever, ketosis, and left-sided displacement of the abomasum, all of which are much more difficult to treat successfully because of the fatty liver.

Overfeeding during the dry period predisposes cows to accumulate fat in adipose tissue during the prepartum period. Before parturition, adipose tissue from overfed cows has higher rates of esterification than the adipose tissue of cows fed a restricted energy intake. In the fatty liver of these overfed cows, the rate of gluconeogenesis is not optimal, which results in prolonged lipolysis, particularly during the first few weeks after parturition. The increased lipolysis after parturition leads to a major increase in the hepatic triglyceride concentration and to a shift in hepatic fatty acid composition. Unrestricted feed intake during the dry period impairs postpartum oxidation and synthesis of fatty acids in the liver of dairy cows.

In Australia, only beef cattle have been involved in pregnancy toxemia; the fat and the obese are most commonly affected. The disease occurred most notably when there was a shift to autumn calving (February to April) when feed supplies were low because of low, late summer rainfall. The cows were in good to fat body condition because of lush pastures in the spring and early summer, but by autumn when the calving season approached, the feed supplies were low and the nutritive value of the pasture inadequate. The lack of feed combined with the expensive nature of supplementary feeding resulted in an inadequate level of nutrition during late pregnancy. Similarly, the control of internal parasitism, especially ostertagiasis, is not intensively practiced. The morbidity is usually from 1 to 3% but may be as high as 10% and the disease is usually fatal.

**PATHOGENESIS**

Fatty liver is associated with a negative energy balance which is essentially universal in dairy cow in the first few weeks of lactation. Most cows adapt to the negative energy balance through an intricate mechanism of metabolic adaptation. Fatty liver develops because of failure of these adaptive mechanisms. Under normal physiological conditions, the total amount of fat increases in the liver beginning a few weeks before calving, rises to an average of about 20% (of wet weight basis) 1 week after calving and declines slowly to the normal level of less than 5% by 26 weeks after calving. However, the levels vary from almost none to 70% among cows 1 week after calving. Fat mobilization begins about 2–3 weeks before calving and is probably induced by a changing hormonal environment prior to calving rather than an energy deficit. After calving, there is a larger increase in fat accumulation. The changes in the liver in dairy cows are functional and reversible and related to the metabolic demands of late pregnancy and early lactation. In experimentally induced fatty liver in periparturient dairy cows the capacity for hepatic glucogenesis before parturition is much lower than in cows without fatty liver. The low glucogenic capacity leads successively to low blood glucose concentrations, low insulin levels and high rates of mobilization of fatty acid, causing severe hepatic lipodosis. In subclinical fatty liver in cows, lower plasma glucose and higher mean plasma NEFA concentrations were closely related to the amount of triglyceride in the liver, and cows with increasing levels of triglyceride in the liver are less capable of maintaining concentrations of glucose and NEFAs within a small margin. Also insulin loses its regulatory control on the glucose concentration and the accumulation of triglyceride in the liver of the early lactating cow.

Fatty liver develops when the uptake of lipids exceeds the oxidation and secretion of lipids by the liver. Excess lipids are stored as triacylglycerol in the liver and are associated with decreased metabolic functions of the liver. Non-esterified
Lipoproteins consist of lipids and apoproteins. Lipoprotein lipid concentrations are quickly altered by conditions such as time of feeding, whereas apoprotein concentrations are relatively stable, thereby providing apoprotein concentrations and enzyme activity as diagnostic markers for fatty liver and related diseases. Apolipoproteins (apo) include apoB-100, apoA-I, apoC-III, lecithin:cholesterol acyltransferase, haptoglobin and serum amyloid A (apoAA). Haptoglobins and apoA-II, usually categorized as acute phase proteins, are intimately related to the lipid metabolism.

The apolipoproteins are decreased in many cases of fatty liver, ketosis, retained placenta, milk fever, and the downer cow syndrome.

During the periparturient period, plasma concentrations of steroid hormones are considerably altered to adapt to the transition from the pregnant, non-lactating state to the non-pregnant, lactating state. The hormonal alteration, particularly of estradiol (E2) and glucocorticoids, is thought to be an additional factor for fatty liver development.

The hormonal alteration, particularly of estradiol (E2) and glucocorticoids, is thought to be an additional factor for fatty liver development.

Lipoproteins consist of lipids and apoproteins. Lipoprotein lipid concentrations are quickly altered by conditions such as time of feeding, whereas apoprotein concentrations are relatively stable, thereby providing apoprotein concentrations and enzyme activity as diagnostic markers for fatty liver and related diseases. Apolipoproteins (apo) include apoB-100, apoA-I, apoC-III, lecithin:cholesterol acyltransferase, haptoglobin and serum amyloid A (apoAA). Haptoglobins and apoA-II, usually categorized as acute phase proteins, are intimately related to the lipid metabolism.

The apolipoproteins are decreased in many cases of fatty liver, ketosis, retained placenta, milk fever, and the downer cow syndrome.

During the periparturient period, plasma concentrations of steroid hormones are considerably altered to adapt to the transition from the pregnant, non-lactating state to the non-pregnant, lactating state. The hormonal alteration, particularly of estradiol (E2) and glucocorticoids, is thought to be an additional factor for fatty liver development.
days if they continue to eat even small amounts of hay.

In fat beef cattle shortly before calving, affected cows are aggressive, restless, excited, and uncoordinated with a stumbling gait, and sometimes have difficulty in rising and they fall easily. The feces are scant and firm and there is tachycardia. When the disease occurs 2 months before calving, the cows are depressed for 10-14 days and do not eat. Eventually they become sternal recumbent. The respirations are rapid, there may be an expiratory grunt, and the nasal discharge is clear but there may be flaking of the epithelium of the muzzle. The feces are usually scant but terminally, there is often a febrile yellow diarrhea. The disease is highly fatal; the course is 10-14 days and terminally there may be coma with cows dying quietly.

In dairy cattle, there is a relationship between the occurrence of a subclinical fatty liver within the first four weeks after calving and inferior reproductive performance due to a delay in the onset of normal estrus cycles and a reduction in conception rate which results in an increase in the average days between calving and conception. There may be differences in reproductive performance between cows with mild and moderate fatty liver early after calving. However, an examination of the postpartum hormone profiles of cows with fatty liver did not reveal the pathogenetic mechanism of the reduced fertility. The fat cow syndrome may also be associated with an increased incidence of parturient paresis and unresponsive treatment for ketosis in early lactation.

**CLINICAL PATHOLOGY**

**Serum biochemistry**

The biochemical changes associated with fatty liver syndrome in cows have been described based on blood and liver samples taken from cows during abdominal surgery, transcutaneous liver biopsy, or at the abattoir immediately after slaughter.

The serum biochemical abnormalities will depend on the severity of the fatty liver. There is a significant trend toward increasing values with increasing amounts of liver fat, although there may be considerable overlap in the distribution of individual test values in a population of animals with suspected fatty liver.

The serum biochemical abnormalities and liver tissue of 95 anorectic, ketotic, lactating Holstein heifers and cows with suspected varying degrees of fatty liver were studied retrospectively. Only 50% of the animals required treatment for ketosis, and only 50% had serum biochemical evidence of liver diseases, as determined by the presence of a test value of two-fold or greater than the upper limit of the reference range for at least two of the four serum tests: gamma-glutamyl transferase (GGT), aspartate aminotransferase (AST), and sorbitol dehydrogenase (SDH) activities and bile concentrations. Although cattle with severe fatty liver had significantly higher serum bilirubin concentrations and AST and SDH than cattle with less severe fatty liver, the specificity of abnormally high SDH or bilirubin concentrations for severe fatty liver was only 8%. Abnormally high serum AST was 83% sensitive and 62% specific for severe fatty liver. Serum glucose and total carbon dioxide concentrations were significantly lower in cattle with severe fatty liver than in those with mild or moderate fatty liver. Low serum glucose or total carbon dioxide concentrations were rare in cattle without severe fatty liver. Thus the use of a single biochemical or histopathologic criterion to define severity of disease or degree of liver compromise in anorectic, ketotic cows results in misidentification of many animals. It cannot be assumed that the same degree of fatty liver is of identical importance in cattle whose fatty liver developed under different circumstances or over a different time period.

**Milk ketones**

Several cowside milk ketone tests are available for the detection of subclinical ketosis in postpartum dairy cows. The Pink test liquid and the Ketolac test strip are highly sensitive for subclinical ketosis when used with milk. The routine testing of cows postpartum for subclinical ketosis would provide a screening test for cows in the early stages of fatty liver.

**Liver biopsy and analysis**

A liver biopsy can be used to determine the severity of the fatty liver and the concentration of triglyceride and is the most reliable method of accurately estimating the degree of fatty infiltration of the liver.

The triglyceride concentration of liver in normal cows ranges from 10% to 15% on a wet weight (WW) basis. Estimation of the lipid content of bovine liver samples obtained by biopsy may be made by biochemical or histological methods. Both methods provide reasonable estimates of liver fat content over a wide range of values. The lipid content of bovine liver is highly correlated with its specific gravity and the submergence of needle biopsy specimens into water, and copper sulfate solutions with specific gravities of 1.025 and 1.055 can be used as a test to estimate lipid content. For routine clinical diagnosis, three solutions of specific gravities of 1.025, 1.055, and 1.055 can be used. Liver samples which float in all three solutions contain greater than 34% lipid, those that sink in water but float in 1.025 and 1.055 specific gravity solutions contain less than 34% but greater than 25% lipid, whereas those that float only in 1.055 specific gravity solutions contain less than 25% but greater than 13% lipid. Samples which sink in all three solutions contain less than 13% lipid. Some limited evidence indicates that cows with liver lipid concentrations above 34% are severely affected and can be expected to have clinical manifestations of hepatic insufficiency. Those with liver lipid levels between 34% and 25% are moderately affected and might have some clinical evidence of hepatic insufficiency. Those between 25% and 13% are mildly affected, which is the range of most postpartum dairy cows without any evidence of disease. Liver lipid concentrations below 13% are inconsequential.

**Ultrasoundography of liver**

Ultrasoundography of the liver has been used to evaluate fatty infiltration in dairy cattle and has the highest sensitivity, specificity, accuracy, and positive and negative predictive values. In the normal cow, the hepatic ultrasonogram consists of numerous weak echoes distributed homogeneously over the entire area of the liver. The echo beam gradually attenuates as it passes through the normal liver tissue. The portal and hepatic veins can be seen within the normal echotexture, and the parenchymal edges are normally visible. In the fatty liver, there is a diffuse nature and echogenicity are roughly proportional to the volume of fat vacuoles and the amount of triglyceride in the liver.

**Hemogram**

In cattle with subclinical fatty liver, there may be a leukopenia, neutropenia, and lymphopenia.

**NECROPSY FINDINGS**

In severe fatal cases, the liver is grossly enlarged, pale yellow, friable, and greasy. Mild and moderate cases are usually not fatal unless accompanied by another fatal disease such as peracute mastitis. The degree of fatty infiltration in these is much less obvious. The histological changes include the occurrence of fatty cysts or lipogranulomas, enlarged hepatocytes, compression of hepatic sinusoids, a decreased volume of rough endoplasmic reticulum and evidence of mitochondrial damage. The latter two changes are reflected in reduced albumin levels and increased activities of liver enzymes in the blood. The proportion of the various fatty acids in the liver are altered considerably. Palmitic and oleic acid proportions are higher in fatty liver cows than in normal cows, while stearic acid is lower.
Differential diagnosis
In dairy cows, fatty liver must be differentiated from those diseases which occur commonly immediately following parturition. Left-sided displacement of the abomasum results in a secondary ketosis, inappetence, and pangs over the left abdomen.

Retained placenta and metritis may be accompanied by fever, inappetence to anorexia, ruminal atony and a foul-smelling vaginal discharge. A degree of fatty liver may occur in these cows, making it indistinguishable from the effects of the retained placenta and metritis.

Primary ketosis may occur immediately after parturition or within several days rather than at the most common time, at 6-8 weeks of lactation. Inappetence, ruminal hypotonicity, marked ketonuria and a good response to glucose and propylene glycol are characteristic.

In beef cattle, pregnancy toxemia before parturition must be differentiated from abomasal impaction, vagin indigestion and chronic peritonitis.

TREATMENT
The prognosis for severe fatty liver is unfavorable and there is no specific therapy. In general, cows with the severe fat cow syndrome which are totally anorexic for 3 days or more usually die in spite of intensive therapy. The prognosis for cases with nervous signs is very poor. Liberal quantities of highly palatable feed are necessary to encourage these cows to eat in increasing daily amounts. Water should be provided. Those which continue to eat will recover. Several different therapeutic approaches have been tried based on empirical experience.

Fluid and electrolyte therapy. Intensive therapy directed at correcting the effects of the ketosis and the fatty liver is required. The recommended treatment includes continuous IV infusion of 5% glucose and multiple electrolyte solutions, and the intraruminal administration of rumen juice (5-10 L) from normal cows in an attempt to stimulate the appetite of affected cows. Water and multiple electrolytes (10-30 L) can be administered intraruminally.

Glucagon. The subcutaneous injection of 15 mg/d of glucagon for 14 days beginning at day 8 post partum decreases liver triglyceride concentrations in cows older than 35 years. Glucagon, containing 29 amino acids, is a pancreatic hormone which improves carbohydrate status of cows by stimulating hepatic gluconeogenesis, glycojenolysis, amino acid uptake and ureagenesis. The effect of glucagon on lipid metabolism is both direct and indirect because it directly increases lipolysis in adipose tissue but indirectly decreases lipolysis by increasing concentrations of plasma glucose and insulin. Intravenous infusions of glucagon are not practical for on-farm use.

Glucocorticoids. Prednisolone at 200 mg IM daily for days decreased liver triglyceride concentrations.

Propylene glycol given orally at 1 L/day promotes gluconeogenesis and is used for the treatment of ketosis.

Insulin as zinc protamine at 200-300 SC twice daily promotes the peripheral utilization of glucose.

Outbreaks in a herd. When outbreaks of fat cow syndrome occur in pregnant beef cattle, all remaining cows should be sorted into groups according to body conditions and fed accordingly. Excessively fat cows should be fed the best quality hay which is available with a supplement. Fat cows should be exercised by feeding them on the ground and forcing them to walk.

CONTROL
Control and prevention of fatty liver in cattle will depend on decreasing or eliminating most of the potential risk factors for the disease. The early recognition and treatment of diseases which affect the voluntary dietary intake in late pregnancy and immediately after parturition is necessary to minimize the mobilization of body fat stores to meet the overall energetic requirements of the cow during the period of negative energy balance, and to maintain or increase hepatic gluconeogenesis. Diseases such as ketosis, displaced abomasum, retained placenta, acute mastitis, milk fever, and the downer cow syndrome must be treated as early as possible to avoid varying degrees of hepatic lipolysis.

Dry matter intake and energy balance in the transition period
The literature on dry matter intake and energy balance in the transition period of the dairy cow has been reviewed.

The transition from late gestation to early lactation in the dairy cow is a critical period in the lactation-gestation cycle. During this period, feed intake is at the lowest level in the production cycle. In addition to the drop in feed intake there is a concurrent transition from late gestation to lactation with huge increases in energy demands. This leads to a negative energy balance which can result in ketosis or fatty liver. Voluntary dry matter intake may decrease 25% and 52% during the final 14 days of gestation for first and second parity animals and aged (third and fourth or greater) cows. A negative energy balance can occur before parturition, and is more likely to occur in heifers than cows because heifers have a lower DMI and the additional need for energy requirement for growth. The fall in DMI is the usual cause of a negative energy balance rather than an increase in energy requirements for fetal growth.

Metabolic adaptations during the transition period
The primary goal of nutritional management of dairy cows during the transition period should be to support the metabolic adaptations which occur. The hallmark of the transition period of dairy cattle is the dramatic change in nutrient demands that necessitate exquisite coordination of metabolism to meet requirements for energy, amino acids, and calcium by the mammary gland after calving. Estimates of the demand for glucose, amino acids, fatty acids, and net energy by the gravid uterus at 250 days of gestation and the lactating mammary gland at 4 days post partum indicate approximately a tripling of demand for glucose, a doubling of demand for amino acids, and approximately a five-fold increase in demand for fatty acids during this period. In addition, the requirement for calcium increases approximately four-fold on the day of parturition. The literature on the integration of metabolism and intake regulation in periparturient animals has been reviewed.

Glucose metabolism
The primary homeorhetic adaptation of glucose metabolism to lactation is the concurrent increase in hepatic gluconeogenesis and decrease in oxidation of glucose by peripheral tissues to direct glucose to the mammary gland for lactose synthesis. The major substrates for hepatic gluconeogenesis are propionate from ruminal fermentation, lactate from Cori cycling, amino acids from protein catabolism or net portal-drained visceral absorption and glycerol released during lipolysis in adipose tissue.

Lipid metabolism
The primary homeorhetic adaptation of lipid metabolism to lactation is the mobilization of body fat stores to meet the overall energetic requirements of the cow during a period of negative energy balance in early lactation. Body fat is mobilized into the blood stream in the form of NEFA which are used to make upwards of 40% of milk fat during the first days of lactation. Skeletal muscle uses some NEFA for fuel, particularly as it decreases its reliance on glucose as a fuel during early lactation. Given that NEFA concentrations increase in response to increased energy needs accompanied by inadequate feed intake, DMI and plasma NEFA concentrations usually are inversely related. The liver takes up NEFA in proportion to their supply but the liver
typically does not have sufficient capacity to completely dispose of NEFA through export into blood or catabolism for energy. Therefore, cows are predisposed to accumulate NEFA as triglycerides within liver when large amounts of NEFA are released from adipose tissue into the circulation.  

**Nutritional management to support metabolic adaptations during the transition period**

**Grouping strategies**
The primary goal of nutritional management strategies of dairy cows during the transition period should be to support the metabolic adaptations just described. Industry-standard nutritional management of dairy cows during the dry period consists of a two-group nutritional scheme. The NRC Nutrient Requirements of Dairy Cattle, 7th ed., 2001 recommends that a diet containing approximately 1.25 Mcal/kg of NE\textsubscript{E} be fed from dry off until approximately 21 days before calving, and that a diet containing 1.54–1.62 Mcal/kg of NE\textsubscript{E} be fed during the last 3 weeks before calving. The primary rationale for feeding a lower energy diet during the early part of the dry period is to minimize body condition score gain during the dry period. During the last 3–4 weeks prepartum, a diet higher in energy and protein concentration than current NRC recommendations should be fed so that adequate nutrient intake occurs within the limits of the reduced voluntary dry matter intake.  

Supplying excessive energy to dairy cows during the early dry period may have detrimental carryover effects during the subsequent early lactation. Managing cows to achieve a BCS of approximately 3.0 at drying off rather than the traditional 3.5 is now recommended.  

**Strategies to meet glucose demands and decrease NEFA supply during the transition period**

**Carbohydrate formulation of the prepartum diet.** Feeding diets containing higher proportions of non-fiber carbohydrate (NCF) promotes ruminal microbial adaptation to NFC levels typical of diets fed during lactation and provide increased amounts of propionate to support hepatic gluconeogenesis and microbial protein (providing the diet contains sufficient ruminically degradable protein) to support protein requirements for maintenance, pregnancy, and mammmogenesis.

**Direct supplementation with gluconeogenic precursors.** Propylene glycol is a gluconeogenic precursor which has been used as an oral drench in the treatment of ketosis. Decreased concentrations of plasma NEFA and BHBA follow oral administration of propylene glycol. The administration of an oral drench of propylene glycol for 2 days beginning at calving decreased concentrations of NEFA in plasma and increased milk yield during early lactation. However, in general, the lack of consistent production responses does not support a recommendation for routine use. Propionate supplements added to the diet to supply substrate for hepatic gluconeogenesis have also been used but with inconsistent results.

Glycerol given orally is an effective treatment for lactational ketosis in dairy cattle. Feeding glycerol to dairy cows from 14 days prepartum to 21 days in milk did not have the gluconeogenic effect attributed to it when given orally as a drench to individual cows.  

Monensin provided in controlled release capsules (CRC) administered 2–4 weeks prepartum has been shown to decrease the incidence of ‘energy associated diseases’ subclinical ketosis and left-side displaced abomasum by 40%, and a 25% reduction in retained placenta. The capsule delivers 335 mg/dL of monensin for 95 days. The common mechanism for reduction of the incidences of these ‘energy associated diseases’ is likely to be improved energy metabolism during the transition period. The net effect of monensin within the rumen is to increase ruminal propionate production at the expense of ruminal acetate and methane production so that propionate supply is increased and the overall energetic efficiency of ruminal fermentation is increased.  

**Added fat in transition diets.** It has been proposed that dietary fat may partially decrease concentrations of NEFA and prevent the occurrence of ketosis. Dietary long-chain fatty acids are absorbed into the lymphatic system and do not pass first through the liver. The fat can provide energy for peripheral tissues and the mammary gland and the increased energy availability would in turn decrease mobilization of body fat and decrease NEFA concentrations. However, available evidence indicates that added fat fed to cows during the prepartum period does not decrease plasma NEFA concentrations.  

**Effects of specific fatty acids on NEFA supply.** A substantial amount of research has examined the metabolic roles of individual fatty acids in transition cow nutrition and metabolism. Feeding trans-10, cis-12 conjugated linoleic acid or trans-10, cis-12 conjugated linoleic acid experimentally may decrease the negative energy balance but the ultimate metabolic effects in transition cows are as yet uncertain.

Because of the large economic losses associated with pregnancy toxemia in cattle, every economic effort must be made to prevent the disease. The principal method of control is to prevent pregnant cattle from becoming fat during the last trimester of pregnancy, particularly during the dry period in dairy cattle. During pregnancy, mature cattle should receive sufficient feed to meet the needs for maintenance and pregnancy and the total daily nutrient intake must increase throughout the last trimester to meet the needs of the fetus. However, this increase is usually difficult to control without some cows getting fat and others losing weight. Sorting cows into groups on the basis of size and condition and feeding accordingly is recommended. Metabolic profiles may be used as a means of assessing energy status and correspondingly the likelihood of occurrence or otherwise of acetonemia or pregnancy toxemia. Both blood glucose and BHBA levels can be used.

**Body condition scoring of dairy cows** at strategic times can be used to monitor the nutritional status of the herd and minimize the incidence and severity of fatty liver syndrome. The scoring should be done throughout the production cycle as part of a herd health program. Scoring done at calving, at 21–40 days, and 90–110 days postpartum can be used to monitor the nutritional status of the herd. Scoring done at 100–60 days before drying off provides an opportunity for management to make appropriate adjustments in the feeding program so that optimal body condition goals are achieved. The optimum body condition score of a cow at calving which will result in the most economical amount of milk has not yet been determined. On a scale of 5, the suggested optimum score at calving has ranged from 3 to 4. The optimum score will probably depend on the characteristics of the individual herd which include type of cow, type of feedstuffs available, season of the year, environmental temperature, and the people doing the actual body condition scoring.

**REVIEW LITERATURE**

Clinical pathology
Hyperlipidemia (triglyceride >500 mg/dL, 5 mmol/L).

Necropsy findings
Widespread lipodosis, swollen liver, hepatic rupture.

Treatment
Enteral or parenteral feeding. Treat underlying disease.

Control
Maintain optimal body condition. Prevent disease and nutritional stress including changes in diet and prolonged transportation.

ETIOLOGY

The disease hyperlipemia is associated with hyperlipidemia (an abnormal concentration of lipids in blood). The disease is due to a derangement in fat metabolism secondary to nutritional stress.1

EPIDEMIOLOGY

Occurrence
The disease occurs worldwide. Although its occurrence is sporadic, multiple cases can occur on a farm. The annual incidence of the disease in ponies in southeastern Australia is 5%,2 but less than 2% in donkeys in the UK.3 The case-fatality rate is 40–80%.4 Incidence varies with season and locality; the disease in ponies in Europe occurs most commonly during late gestation (January–March), while in southern Australia, the disease is more common in ponies during early lactation (November–January).

Animal risk factors
The disease does not occur in full sized horses and is recognized in Shetland and other ponies, donkeys and miniature donkeys, and American Miniature Horses.4–6 The disease is most common in females (90% of cases), uncommon in pony stallions and geldings, and rare in foals.1,5,7 Most affected ponies are more than 4 years old and the peak incidence occurs in 9-year-olds.8 In donkeys, the incidence of disease increases with age.3

Pregnancy and lactation increase the risk of the disease in ponies1,2 but not in donkeys.3 The disease in Miniature Horses is always associated with underlying disease, such as colic which is apparently an important risk factor.4,5 Underlying disease is identified in 50% of cases in ponies, however many cases occur in pregnant or lactating mares without evidence of other disease.2,3 Overweight ponies and donkeys are at increased risk, and the onset of disease is often preceded by some sort of stress, typically transport, lactation, food deprivation, or a combination of these factors.2,3 Characteristically the disease occurs in fat, middle-aged, pregnant, or lactating ponies that experience a decrease in feed intake. However, the disease is not restricted to this demographic and thin ponies can develop the disease.

Hypertriglyceridemia is detected in horses with evidence of systemic inflammatory response syndrome (severe illness associated with decreased feed intake). There is no opacity of the plasma or serum and the hypertriglyceridemia has not been demonstrated to worsen the outcome of the underlying disease.9

PATHOGENESIS

The combination of the innate insulin resistance of ponies and a nutritional stressor, such as disease, pregnancy, lactation, or food deprivation, results in excessive mobilization of fatty acids from adipose tissue at a rate that exceeds the gluconeogenic and ketogenic capacity of the liver. Adipocytes of ponies, in response to norepinephrine, release fatty acids at a rate 6.5 times greater than those of horses,10 possibly providing at least a partial explanation for the difference in likelihood of differing breeds developing the disease. Lipolysis is mediated by β3-adrenergic receptors in ponies and horses.11 The induction of excessive fat mobilization in ponies is likely associated with the well-characterized insulin resistance of this breed, especially in obese individuals.11,12 There is no difference between ponies and horses in the extent to which lipolysis is inhibited by insulin.11 The effect of insulin resistance on glucose uptake from the blood might be exacerbated in sick ponies by the increase in serum cortisol concentrations associated with stress or disease.12

Equids have little propensity to produce ketones and so the excess fatty acids are re-esterified in the liver to triglycerides and released into the circulation as very low-density lipoproteins (VLDL). The fundamental defect in the disease is in the regulation of free fatty acid release from fat stores due to a defect in control of hormone-sensitive lipase, the enzyme responsible for hydrolysis of triglycerides to free fatty acids and glycerol in adipose tissue. Unchecked activity of this enzyme results in mobilization of fatty acids in hyperlipemic ponies that is 40 times the rate in normal ponies. There is no dysfunction of lipoprotein lipase, the enzyme mediating uptake of plasma free fatty acids by extra-hepatic tissues, and its activity can be 300% of that of unaffected ponies.13

Hypertlipidemia causes widespread lipodosis and organ dysfunction.1 Hepatic lipodosis compromises liver function resulting in accumulation of toxic metabolites and derangement in coagulation.

CLINICAL FINDINGS

The clinical course varies between 3 and 22 days but is generally 6–8 days. The unchecked disease progresses from mild depression and inappetence, through profound depression, weakness and jaundice, to convulsions or acute death in 4–7 days. Depression, weight loss, and...
jaundice is variable. Many animals show anappetence are the initial signs in 90% of
cases. Inappetence progresses to anorexia
and the depression which is followed by
somnolence and hepatic coma. Compulsive
walking or mania develop in 30% of
cases. Signs of mild colic, including flank
watching, stretching and rolling, are
evident in 60% of cases. The incidence of
jaundice is variable. Many animals show a
willingness to drink but are unable to
draw water into the mouth and swallow.
Others continually lap at water. The tem-
perature is normal or moderately elevated
and heart rate and respiratory rates are
increased above normal. Diarrhea is an
almost constant feature in the terminal
stages.

Visual examination of the plasma or
serum phase of a blood sample collected
from an affected animal reveals cloudy,
milky, mildly opalescent plasma.

CLINICAL PATHOLOGY

There is usually leukocytosis with
neutrophilia. Hyperlipidemia is a consistent
feature of the disease. Serum triglyceride
concentrations will be at least 5 mmol/L
(500 mg/dL) and may be 20 times that
of normal. Serum cholesterol and free
fatty acid concentrations are also increased,
although less so than triglycerides. The
plasma triglyceride concentration is of
minimal prognostic use in ponies, but most American Miniature horses with
triglyceride concentrations above
1200 mg/dL (12 mmol/L) die.5,8,13

Plasma glucose concentration is
usually low. Ketonemia and ketonuria do
not occur. Biochemical evidence of liver
disease is characteristic of the advanced
disease. Serum activity of GGT may be
elevated before clinical signs of disease are
apparent. Serum creatinine and urea
nitrogen concentrations increase as renal
function declines. Blood clotting time
increases. Metabolic acidosis develops
terminally. Hematological and bio-
chemical variables may also be affected by
any underlying disease.

Diagnostic confirmation of hyper-
lipemia is achieved by demonstration of
hyperlipidemia (plasma triglyceride con-
centrations above 5 mmol/L [500 mg/dL])
in a horse with appropriate clinical signs.

NECROPSY FINDINGS

Extensive fatty change is present in most
internal organs, but especially in the liver,
which is yellow to orange, swollen, and
friable. Liver rupture with intra-abdominal
hemorrhage may be present. Tissue pallor
due to lipid accumulation is also prominent
in the kidney, heart, skeletal muscle and
adrenal cortex. Serosal hemorraghes of
the viscera reflect disseminated intra-
vascular coagulation. The necropsy should
either include an examination for lesions
which might predispose the animal to
hyperlipidemia, such as pancreatic damage
or laminitis. Histologically, widespread
microvascular thrombosis as well as intra-
cellular lipid in various tissues are evident.

Samples for postmortem
confirmation of diagnosis

Formalin-fixed liver, kidney, heart, adrenal,
skeletal muscle, and pancreas for light
microscopic examination.

DIFFERENTIAL DIAGNOSIS

- Parasitism
- Anemia
- Liver disease including pyrrolizidine
  toxicosis
- Serum hepatitis
- Aflatoxicosis

Hyperlipemia should be considered in any
pony with a history of weight loss,
inappetence, and progressive somnolence,
especially in late pregnancy or early
lactation.

TREATMENT

The principles of treatment are:
- Treatment of the underlying or inciting
disease
- Restoration and maintenance of a
  positive energy balance
- Correction of any defects in hydration,
  acid-base and electrolyte status
- Reduction of the hyperlipidemia.

Every effort should be made to determine
if there is an underlying disease, and it
should be treated aggressively. Parasitism
is a common inciting disease, as are
equine Cushing's disease and neoplasia (lymphosarcoma, gastric squamous cell
carcinoma) in older ponies.

The negative energy balance must be
corrected. A mature, non-pregnant, and
non-lactating 200 kg (440 lb) pony has
energy requirements (digestible energy
intake) of 9.3 Mcal/d (38 mJ/d) whereas a
lactating pony has energy requirements of
13.7 Mcal/d (57.2 ml/d).14 Affected animals
should be encouraged to eat and must be
supplemented either orally or intravenously
if they will not eat a sufficient quantity.
Supplements, either oral or intravenous, are
unlikely to meet all the animal's energy
requirements, but normalization and stabil-
zation of blood glucose concentrations, and
the apparent consequent changes in
hormonal milieu, inhibit lipolysis and
enhance clearance of triglycerides from
plasma and hepatic and renal tissues.

Oral supplementation using commercial
equine or human enteral nutrition prepara-
tions has been successful for treatment of
the disease in American Miniature
horses and donkeys.5 If these products are
not available, a homemade gruel consisting
of alfalfa pellets and cottage cheese can
be used.6 These preparations are admin-
istered every 6h through a nasogastric
tube. Alternatively, glucose can be given
orally (1 g/kg, as 5% solution every 6 h,
about 5 L to a 250 kg pony) or intra-
venously (5% solution, 100 mL/kg per day
as a continuous intravenous infusion). As
noted above, this dose of glucose will not
meet the energy needs of the pony but
might be sufficient, along with treatment of
the underlying disease and supportive
care, to restore normal fat metabolism.
Provision of parenteral nutrition is feasible
and apparently effective, but expensive
and technically demanding thereby
restricting its use to veterinary hospitals.

Mares in late pregnancy should be
aborted and lactating mares should have
the foal removed.

Dehydration and abnormalities in
electrolyte and acid-base status should be
corrected by oral or IV administration of
isotonic fluids (lactated Ringer's solution)
and, if necessary, sodium bicarbonate.

Encephalopathy associated with liver
failure should be treated with oral neo-
mycin (20 mg/kg, every 6 h) or lactulose
(1 mL/kg, every 6 h).

Hyperlipidemia should be reduced by
minimizing free fatty acid production by
disposable tissue and enhancing triglyceride
removal from plasma. Free fatty acid pro-
duction is minimized by insulin adequate
energy intake and normal plasma glucose
concentrations. Use of insulin and heparin
has been recommended for reduction of
plasma free fatty acids concentration.
However, the efficacy of these treatments
is not clear and the emphasis should be
placed on provision of adequate energy
intake rather than administration of these
hormones. Insulin (protamine zinc insulin)
is administered at 0.1 to 0.3 IU/kg SC
every 12-24 h. Blood glucose concen-
trations should be monitored and the
insulin dose may need to be adjusted.
Heparin (40-100 IU/kg SC every 6-12 h)
can be given to increase lipoprotein lipase
activity and promote the clearance of
triglycerides from plasma. It should be
noted that lipoprotein lipase activity is not
deficient in affected ponies5,8,10 and therefore
the administration of heparin to ponies
with hyperlipemia is not recommended.
Severely affected ponies may have an
increase in clotting time that could be
evacipated by heparin.

Corticosteroids and adrenocorticotropine
hormone are contraindicated in treatment of
this disease.

CONTROL

A mature, non-pregnant and non-lactating
200 kg (440 lb) pony has energy require-
ments of 9.3 Mcal/d (38 ml/d) whereas a lactating pony has energy requirements of 13.7 Mcal/d (57.2 ml/d) and every effort should be made to meet these requirements. This might require dietary supplementation during periods of nutritional stress, such as drought, late pregnancy, peak lactation, or transportation. Ponies should be maintained in optimal body condition, and nutritional stress avoided. A parasite and disease control program should be instituted. Transport of pregnant and lactating ponies should be avoided.

**REVIEW LITERATURE**

**REFERENCES**

**STEATITIS**

Generalized fat necrosis and steatitis occur rarely in foals. The cause is unknown. There are widespread inflammatory changes in adipose tissue which are characterized clinically by firm plaque-like swellings under the skin. Panniculitis, an unusual form of steatitis limited to the subcutaneous tissues has been reported in an aged pony mare. Generalized steatitis has also been reported in an adult pony mare. The affected animal had lost weight in spite of having a normal appetite. Soft swellings 2-4 cm in diameter may be present under the skin of the abdominal wall and over the back. Hard plaque-like swellings may also be present over the upper cervical area. Polyneuritis and dyspnea may be present and ventral abdominal edema and fever may be present. Biopsy of some of the SC swelling reveals histopathological evidence of fat necrosis with mineralization. At necropsy, the SC fat is hard, dry, and yellow-white with areas of necrosis forming abscess-like lesions up to 3 cm deep and 10 cm in diameter. The fat lining the abdominal wall may contain firm yellow-white and red tissue nodules up to 3 cm in diameter. Generalized steatitis with fat necrosis ('yellow fat disease') has been recognized in many species at various ages and is thought to be related to a dietary deficiency of vitamin E and selenium along with an intake of polysaturated fatty acids.

**REFERENCES**

**NEONATAL HYPOGLYCEMIA**

**Synopsis**

**Etiology** Insufficient milk ingestion by newborn pigs in their first few days of life or piglets affected with any disease which interferes with milk intake or that have enteropathy and are unable to digest milk.

**Epidemiology** Most common in piglets under 3 days old. Sows have insufficient milk. Morbidity 30–70%, mortality 100%. Occurs in twin or triplet lambs exposed to hypothermia. Occurs rarely in calves with diarrhea. Occurs in premature foals.

**Clinical pathology** Hypoglycemia.

**Necropsy findings** No gross lesions. Stomach may be empty.

**Diagnostic confirmation** Response to treatment with glucose.

**Differential diagnosis list**

**Piglets**
- Coliform septicemia
- Transmissible gastroenteritis
- Viral encephalomyelitis
- Other septicemias.

**Lambs**
- Watery mouth disease
- Hypothermia.

**Calves**
- Coliform septicemia
- Bacterial meningitis
- Dehydration and acidosis associated with enterotoxigenic colibacillosis.

**Treatment** IV or IP glucose solutions.

**Control** Insure adequate colostrum and milk intake for newborn piglets, lambs, and calves.

**ETIOLOGY**

An inadequate intake of milk is the primary cause of hypoglycemia in piglets. This may be due to failure of the sow's milk supply or to failure of the piglet to suck. Failure to suck may be due to such diseases as coliform septicemia, TGE, streptococcal infections, mycocalia congenita, and hemolytic disease of the newborn. Piglets under 4 days old rapidly develop hypoglycemia under fasting conditions; older pigs do not.

In piglets affected with transmissible gastroenteritis (TGE), there is decreased digestion of lactose, reduced absorption of glucose following the severe and diffuse intestinal villous atrophy and, combined with the low-energy reserves of the newborn piglet, severe hypoglycemia can occur. Hypoglycemia may occur in newborn calves with acute severe diarrhea and when they are deprived of milk or a source of carbohydrates for more than a few days.

Hypoglycemia occurs in newborn pigs before hypothermia after 12 h of age.

**EPIDEMIOLOGY**

Newborn pigs encounter several challenges to their survival during the initial hours of life. One is the inherent problem of glucose homeostasis with the first day of life being the most critical period. Liver glycogen is rapidly depleted postnatally (12–24 h) for the maintenance of blood glucose. Little insulation against heat loss is provided by the sparse hair coat and the 1–2% total body fat at birth. There is only a small amount of carcass fat and no brown fat, and consequently the piglet is dependent almost exclusively on carbohydrate metabolism for subsistence. Therefore, maintenance of the physiologically critical energy metabolism, glucose, depends on the ability of the neonatal pig to compete with its littermates for regular nourishment from its dam.

Neonatal hypoglycemia in piglets occurs primarily during the first 3 days after birth. The disease has been recorded mainly from North America and the UK. Most affected piglets die if left untreated; the morbidity is usually 30–70% and may be as high as 100% in individual litters. Apart from deaths due to hypoglycemia, many piglets are too weak to avoid the sow and are killed byoverlaying. Piglets which fail to ingest sufficient colostrum or milk because of a failure of the sow's milk supply or because of an inability of the piglet to suck normally are the most common primary circumstances. A secondary determinant occurs when piglets affected with an enteritis, such as transmissible gastroenteritis, are unable to properly digest the lactose in milk and absorb sufficient glucose.

Hypoglycemia occurs in twin and triplet lambs which may be immature or undersized and are subjected to cold exposure and hypothermia. About 50% of the total lipid present in the newborn lamb is in the adipose tissue in the form of brown fat which is used by the lamb for non-shivering thermogenesis during the first 24 h following birth. However, the lipid content of newborn lambs can vary from 1.5 to 4.5% of birth weight and...
small lambs have low levels. Neonatal viability of lambs decreases as birth weight decreases, which may be related to their low lipid content in relation to body size. Additional factors include mismothering and complete absence of the ewe in lambs only a few days of age.

**Hypoglycemia in calves** has been recorded as a concurrent disease with diarrhea. The hypoglycemia may be secondary to the interference with absorption and digestion caused by the diarrhea. The signs are characteristic but the hypoglycemia does not respond to glucose therapy as quickly, if at all, as in other species. However, hypoglycemia in diarrheic calves is not considered to be a significant problem if affected calves receive a supply of milk or milk replacer during the convalescent period.

**Hypoglycemia occurs in foals** which are born prematurely and unable to suck the mare, those with septicemias, and those exposed to hypothermia.

**PATHOGENESIS**
The piglet is born with liver glycogen levels which may be as high as 200 mg/g WW, while muscle glycogen may reach 120 mg/g WW. The blood glucose level at birth is low at 30–60 mg/dL (1.66–3.33 mmol/L) and increases rapidly after feeding on colostrum to 95 mg/dL (5.25 mmol/L). Satisfactory gluconeogenesis does not develop in piglets until the 7th day after birth, and during this period glycogen stores are likely to be rapidly exhausted if the intake of milk is restricted. The blood glucose level is then extremely unstable and dependent entirely upon dietary sources. The first week of life is thus the danger period. Deprivation of food after this produces only loss of weight and has no effect on blood glucose levels. This particular susceptibility to hypoglycemia in the early postnatal period seems to be characteristic of the pig and may play a major role in causing losses in piglets by contributing to the effects of various infectious and non-infectious agents.

Signs appear first when blood glucose levels fall to about 50 mg/dL (2.775 mmol/L), although further depression to levels as low as 7 mg/dL (0.388 mmol/L) has been observed. Even in such extreme cases, complete recovery is possible after the administration of glucose. The hypoglycemic comatose state induced in piglets by fasting occurs as blood glucose values fall below 40 mg/dL (2.2 mmol/L). Experimental hypoglycemia produced by the injection of insulin causes a clinical syndrome similar to that of the naturally occurring disease.

In piglets with TGE, the blood glucose levels decreased from a normal of 119 mg/dL (6.6 mmol/L) to 36 mg/dL (2.0 mmol/L). This hypoglycemia coincides with the onset of lethargy followed by a comatose state in a few hours.

**CLINICAL FINDINGS**
The disease is most characteristic in piglets under a few days of age. Incoordination is apparent first and the piglet has progressive difficulty in maintaining balance until recumbency becomes permanent. There is shivering, dullness, and anorexia, and often a typical weak squeal. A characteristic feature is the subnormal rectal temperature and the cold, clammy skin which also evidences marked pallor and ruffling of the hair. The pallor is related to the failing circulation. The heart rate becomes increasingly feeble and slow and may fall as low as 80/min. In many cases, there are few additional signs but convulsions are recorded as a common occurrence by some observers. These vary from aimless movements of the head and forelimbs to severe tetanic convulsions. In the latter, there are violent galloping movements, particularly with the hindlegs, opisthotonos, and champing of the jaws. Tortuous movements and rigidity of the neck and trunk also occur. Terminally, coma develops and death follows 24–36 h after the onset of signs. The clinical findings are similar in other species with weakness, incoordination, hypothermia, eventual recumbency, and coma being characteristic. The nervous signs are most common in the piglet and not seen in the other species.

**CLINICAL PATHOLOGY**
Blood glucose levels of less than 50 mg/dL (2.8 mmol/L) in piglets are considered to indicate clinical hypoglycemia. The hypoglycemic comatose state induced in piglets by fasting occurs as blood glucose values fall below 40 mg/dL (2.2 mmol/L). Significant rises in blood non-protein nitrogen and urea nitrogen are often observed but appear to be related to catabolism rather than to renal dysfunction.

In calves with acute severe diarrhea, the blood glucose may fall to below 40 mg/dL (2.2 mmol/L) in 30–50% of cases.

**NECROPSY FINDINGS**
There are no visible lesions. Absence of curd in the stomach is good contributory evidence of lack of intake of milk but in many cases, it will be obvious that some milk was consumed. Hepatic glycogen levels are usually negligible.

**TREATMENT**
Piclets with primary hypoglycemia should be given glucose (15 mL of 20% solution) IP, repeated every 4–6 h until the animal will suck a foster dam or drink an artificial diet. Protection from cold is important and an environmental temperature of 27–32°C (80–90°F) will improve the survival rate of piglets. The combined use of oral fluid therapy and the IP administration of 5% dextrose at a rate of 25 mL/kg body weight to piglets affected with hypoglycemia associated with TGE did not correct the hypoglycemia. A newborn piglet weighing 1250 g requires 170 kcal (711 kJ) per day when maintained at 30°C (88°F); 30 mL of a 5% dextrose solution would provide approximately 1.5 g of glucose, which would yield only 5.6 kcal (23 kJ) per dose. It would be difficult to provide the energy requirements by parenteral administration of 5% dextrose because the amount of fluid injected per day should not exceed 8% of their body weight.

**Differential Diagnosis**

Unless blood glucose levels are estimated, the predominantly nervous signs may lead to an error in diagnosis. However, hypoglycemia and a good response to treatment with glucose may occur when the hypoglycemia is secondary to another disease. A definite diagnosis of neonatal hypoglycemia must depend on elimination of other diseases as primary causes.

**Piclets**

**Coliform septisemia and enterotoxigenic colibacillosis** are characterized by weakness, recumbency, collapse and dehydration. Viral encephalomyelitis and pseudorabies cause an almost identical clinical picture but are not restricted in occurrence to pigs less than 1 week old.

**Bacterial meningoencephalitis,** including streptococcal septisemia and listeriosis, may also affect pigs of this age. Necropsy examination should make definition of viral and bacterial infections a relatively easy task.

**Lambs**

**Wate ry mouth disease** is characterized by weakness, drooling from the mouth, hypothermia, distended fluid abdomen and hypoglycemia.

**Foals**

**Premature foals** born several days before term, are weak and unable to stand and suck, and are hypoglycemic.

**Septicemias** occur in foals born at term and are characterized by depression, failure to suck, inactivity, fever, dehydration, petechiation, and death in several hours if not treated intensively.
Piglets should be carefully observed during the first week of life for early signs of any disease and treatment instituted promptly. Maintenance of a stable environmental temperature at 32°C (90°F) may delay the onset of the disease, or in marginal circumstances prevent its occurrence.

Lambs require between 180 and 210 mL colostrum/kg body weight during the first 18 h after birth in order to provide sufficient energy for heat production. The administration of colostrum at a rate of 30 mL/kg body weight within a few minutes after birth, directly into the stomach using a catheter and syringe, is recommended to boost the energy supply of the small lamb. Ewes which are well fed during late pregnancy produce more colostrum than their lambs need, those with singletons have enough for a second lamb, but in most underfed ewes, the lamb requirements for colostrum exceed the ewe's production. Colostrum can be readily obtained by milking those ewes with excess production. The effects of feeding ewe colostrum, cow colostrum, or ewe milk replacer, on plasma glucose in newborn lambs have been compared. Both ewe and cow colostrum resulted in a two-fold increase in plasma glucose within 1–3 h; the milk replacer caused marked hyperglicemia.

ETIOLOGY In North America, diets low in phosphorus or unsupplemented with phosphorus are usually associated with the disease in dairy cattle. In New Zealand, one form of the disease may be related to copper and selenium nutrition.

ETIOLOGY

In North America, diets low in phosphorus or unsupplemented with phosphorus are usually associated with the disease in dairy cattle. In New Zealand, one form of the disease may be related to copper and selenium nutrition.

ETIOLOGY

In North America, diets low in phosphorus or unsupplemented with phosphorus are usually associated with the disease in dairy cattle. In New Zealand, one form of the disease may be related to copper and selenium nutrition.

ETIOLOGY

In North America, diets low in phosphorus or unsupplemented with phosphorus are usually associated with the disease in dairy cattle. In New Zealand, one form of the disease may be related to copper and selenium nutrition.
selenium may be important because they are commonly deficient in feedstuffs. Both copper and selenium may also provide some protection against the effects of orally acquired hemolytic agents in cruciferous plants. The clinical findings are those of acute hemolytic anemia and in fatal cases, death is due to anemic anoxia.

CLINICAL FINDINGS

Hemoglobinuria, inappetence, and weakness develop suddenly and there is a severe depression of the milk yield, although in some less acute cases, the cow continues to eat and milk normally for 24 h after discoloration of the urine is evident. Dehydration develops quickly, the mucous membranes are pallid, and the cardiac impulse and jugular pulse are much augmented. A moderate temperature rise (40°C; 103.5°F) often occurs. The feces are usually dry and firm. Dyspnea may be obvious and tachycardia is common. Jaundice may be apparent in the late stages. Pica may be observed in the other animals in the group. The course of the acute disease extends from 3 to 5 days; the cow becomes weak and staggery and finally recumbent. Gangrene and sloughing of the tip of the tail or the digits has been observed occasionally. Death may occur within a few days. In non-fatal cases, convalescence requires about 3 weeks and recovering animals often show pica. Ketosis commonly occurs coincidentally.

In a herd where the disease occurs, there may be additional signs of phosphorus deficiency, although when the deficiency is marginal the general condition of the herd may be excellent. A similar acute syndrome to that described earlier, and less severe cases of anemia, may occur sporadically in animals on lush spring pasture.

CLINICAL PATHOLOGY

In marginal phosphorus-deficient areas, normal non-lactating animals in an affected herd may have serum inorganic phosphorus levels within the normal range. Lactating cows in an affected herd may have moderately low levels of 2–3 mg/dL (0.65–0.97 mmol/L) and affected animals extremely low levels of 0.4–1.5 mg/dL (0.13–0.48 mmol/L). Erythrocyte counts and hemoglobin levels are also greatly reduced. Heinz bodies may be present in erythrocytes in the New Zealand disease. The urine is dark red-brown to black in color and usually moderately turbid. No red cells are present in the urine. A low copper status of the blood and liver of affected cows and the pasture grazed is also recorded.

Necropsy findings

The blood is thin and icterus is widespread throughout the body. The liver is swollen, and fatty infiltration and degeneration are evident. Discolored urine is present in the bladder.

DIFFERENTIAL DIAGNOSIS

Postparturient hemoglobinuria is characterized by an acute hemolytic anemia in cows calved within the preceding 4 weeks. Other causes of acute hemolytic anemia are not confined to the post-calving period. Laboratory examination is usually necessary to confirm the diagnosis and to eliminate hematuria as a cause of the discoloration of the urine. The differential diagnosis of red urine in cattle is summarized in Table 20.3.

TREATMENT

A transfusion of whole blood is indicated in severe cases. A delay of 12 h often seems to lead to an irreversible state. A minimum of 5 L of blood to a 450 kg cow is recommended. This will usually suffice for up to 48 h by which time an additional transfusion may be necessary if the cow is weak and the mucous membranes pale. Following successful blood transfusions, fluid therapy is recommended as both supportive therapy and to minimize the danger of hemoglobinuric nephrosis. The administration of phosphorus to acutely ill animals should include the IV administration of 60 g of sodium acid phosphate in 300 mL of distilled water and a similar dose SC, followed by further SC injections at 12-hourly intervals on three occasions and similar daily doses by mouth. Oral dosing with bone meal (120 g twice daily) or dicalcium phosphate or a suitable source of calcium and phosphorus daily for 5 days is recommended followed by inclusion in the ration. Hematinics during convalescence are recommended. Ketosis is a common complication of the disease and additional treatment for it may be required.

CONTROL

An adequate intake of phosphorus according to the requirements for maintenance and milk production should be insured, particularly in early lactation. A decrease in the incidence of the disease is reported after copper supplementation of cattle in a copper-deficient area.

RHABDOMYOLYSIS OF HORSES

Rhabdomyolysis occurs in horses as a manifestation of a variety of diseases and usually, but not always, in response to exercise. Metabolic diseases including polysaccharide storage myopathy, mitochondrial myopathy, glycolgen branching enzyme deficiency in foals, or vitamin E/selenium deficiency in foals and rarely adults, and malignant hyperthermia in halothane-anesthetized horses of a particular genotype all have rhabdomyolysis as a prominent feature of their presentation. Rhabdomyolysis also occurs sporadically in response to unaccustomed exercise of horses of any breed or usage, or as a recurrent disease in Thoroughbred and Standardbred race horses. A familial syndrome of recurrent exertional rhabdomyolysis is recognized in Thoroughbred race horses. A syndrome of idiopathic rhabdomyolysis occurs in horses at pasture in Europe. There is a specific syndrome involving primarily muscles of mastication.

Acute exertional rhabdomyolysis is a rapidly evolving disease of horses manifest as signs of acute muscle damage. The sporadic disease occurs on a single occasion whereas the recurrent disease occurs repeatedly in susceptible horses. Clinical manifestations of the disease during acute episodes are identical regardless of the cause or nature (sporadic versus recurrent) of the disease.

REFERENCE

SPORADIC ACUTE EXERTIONAL RHABDOMYOLYSIS IN HORSES

(AZOTURIA, TYING-UP)

The disease discussed here is that of sporadic acute exertional rhabdomyolysis that occurs as a single event in a horse and does not have a tendency to recur. The recurrent disease is discussed elsewhere.

ETIOLOGY

The etiology of most cases of sporadic acute exertional rhabdomyolysis is unknown although suggested causes include: hypothyroidism, sodium or potassium deficiency, viral infection, high carbohydrate diets, and abnormalities in metabolic function. The most common cause is performing exercise of unaccustomed intensity or duration, which can result in metabolic exhaustion and hyperthermia. However, the disease is not
always associated with severe exertion or hyperthermia, and it can occur with or without exercise as slow work or turn out to pasture after stabling. An important contributing factor is a prolonged period (days to weeks) of rest in a horse previously accustomed to regular exercise. The disease occurs in young horses as a result of vitamin E/selemens deficiency although this is an uncommon cause in adult horses.1

Rhabdomyolysis not associated with exercise occurs during general anesthesia maintained by inhalation of halothane in horses of a specific genotype or in horses at pasture in Europe. Rhabdomyolysis also occurs in horses with Streptococcus equi infection (strangles).

Recurrent exertional rhabdomyolysis is a recognized syndrome in Thoroughbred horses and is dealt with separately. It is likely that most cases of sporadic exertional rhabdomyolysis are a result of a combination of predisposing factors with the disease precipitated by a bout of exercise. The difficulty in detecting the presence of predisposing factors contributes to the sporadic nature of the disease.

**EPIDEMIOLOGY**

The sporadic disease is almost always associated with exercise that is either enforced, as with horses in training or competition, or spontaneous, as with young horses turned out to pasture after a prolonged period of stabling. Clinical signs occur in horses within minutes to hours of the cessation of exercise, although signs can be apparent in horses during prolonged exercise. The epidemiology of the sporadic disease has not been well defined, in contrast to that of recurrent exertional rhabdomyolysis.

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis is difficult because studies to date have mostly not differentiated between the recurrent exertional rhabdomyolysis of Thoroughbreds, polysaccharide storage myopathy of Quarterhorses and related breeds, and the sporadic disease in other breeds. The incidence or 1 year period prevalence of exertional rhabdomyolysis is 1.5% in ponies in Australia; 4.9% in Thoroughbred racehorses in the USA, Australia, and Great Britain; 6.1% in National Hunt Thoroughbreds in Great Britain; and up to 13.5% in polo ponies in the USA and Great Britain.2-5 Polo, racing, rodeo, Western, and show jumping are all associated with a high period prevalence (≥5% per annum) of exertional rhabdomyolysis.2

Risk factors for exertional rhabdomyolysis include exercise, breed and use, and sex. Overall, horses that exercise are approximately 10 times more likely to develop the disease than are sedentary horses, and among breed/use groups, polo horses are approximately 3 times more likely to develop the disease than are horses used for racing.2 Horses used for racing are more likely to have episodes of the disease than are horses used for pleasure riding or 'other' uses,2 although racing and breed (Thoroughbred or Standardbred) are confounding factors. Female race horses are three times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) race horses.2,6 and young, female Thoroughbreds are at greatest risk.2,3,4 Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males.5 Female polo ponies are not more likely to develop the disease.6 Thoroughbred racehorses and polo ponies, but not National Hunt horses, with a nervous or 'flighty' temperament are more likely to experience episodes of the disease.4,6,7 Other apparent risk factors include a rest day before hard exercise,6 feeding >4.5 kg of grain per day,7 lameness,8 playing polo at a level for which the horse is not fit,9 and playing early in the season.7

The disease occurs repeatedly in 74% of affected Thoroughbred race horses in Great Britain10 and in 20% of affected polo ponies.6

The disease is of considerable economic impact because of its frequent occurrence in athletic horses, recurrent nature, and need to rest affected horses. On average, affected Thoroughbred race horses cannot train for 6 days after an episode, and approximately two-thirds of affected horses are unable to race because of the disease.3,6 Polo ponies lose an average of 7 days of training after an episode of exertional rhabdomyolysis.4 The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred race horses in Australia is attributable to exertional rhabdomyolysis.7

**PATHOGENESIS**

The disease is due to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase, aspartate aminotransferase and carbonic anhydrase, and myoglobin. The proximate cause of myocyte death is uncertain, but it is not related to accumulation of lactic acid,9 as previously supposed. Proposed mechanisms include oxidant injury to cells as a result of increased oxidant formation during exercise or inadequate antioxidant activity.9,10 Apart from horses deficient in vitamin E and/or selenium, which are rare, there is no indication that oxidant injury is a common cause of rhabdomyolysis in horses.9

Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function.11 Necrosis of myocytes caused pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

Release of cellular constituents results in electrolyte abnormalities, primarily a hypochloremic metabolic alkalosis, a systemic inflammatory response, and pigmentation. Severely affected horses can have a metabolic acidosis. Myoglobin, and possibly other cell constituents, are nephrotoxic and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function cause a stilted, short stepping gait.

**CLINICAL FINDINGS**

The clinical findings are variable and range from poor performance to recumbency and death. Signs can be mild and resolve spontaneously within 24 h or be severe and progressive.

The most common presentation is of a horse that does not perform to expectation and displays a stiff or short stepping gait that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, paw, and frequently shift its weight. More severely affected horses can be unable to continue to exercise, have hard and painful muscles (usually gluteal muscles), sweat excessively, tremble or have widespread muscle fasciculations, be apprehensive, refuse to walk, and have elevated heart and respiratory rates. Affected horses may be hyperthermic, especially soon after exercise. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent.

**CLINICAL PATHOLOGY**

Mildly or inapparently affected horses have moderate increases in serum creatine kinase (CK) (20 000–50 000 IU/L), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) activity. Severely affected horses have large increases in CK (>100 000 IU/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5–6 and 24 h after exercise, respectively12,13 and in the absence of further muscle damage serum AST might not return to normal levels for 7–10 days. The half-life of CK activity in serum is approximately
serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

**DIFFERENTIAL DIAGNOSIS**

- Ear tick (Otothius megninii) induced muscle cramping
- Polysaccharide storage myopathy of Quarter horses
- Ionophore intoxication (monensin, lasalocid, salinomycin, narasin, maduramicin)
- Equine lower motor neurone disease (acute form)
- Gastric acid toxicity
- Hyperkalemic periodic paralysis
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis.

**TREATMENT**

The treatment chosen depends on the severity of the disease. The general principles are rest, correction of dehydration and electrolyte abnormalities, prevention of complications including nephrosis and lamiinitis, and provision of analgesia.

**Mildly affected horses** (heart rate <60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (22 mg/kg, orally or IV every 12 h for 2–4 d). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

**Severely affected horses** (heart rate >60 bpm, rectal temperature >39°C (102°F), 8–10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic fluids, such as lactated Ringer's solution, should be administered IV to severely affected horses to correct any hypovolemia and to insure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4–6 L every 2–3 h). Although it has been recommended that urine should be alkalinized by administration of mannitol and sodium bicarbonate (1.3% solution IV, or 50–100 g of sodium bicarbonate orally every 12 h) to minimize the nephrotoxicity of myoglobin, this therapy is not effective in humans at risk of myoglobinuric nephrosis.**A**ffected horses should not be given diuretics (e.g. furosemide).

**Phenylbutazone** (2.2–4.4 mg/kg, IV or orally, every 12–24 h), **flunixin meglumine** (1 mg/kg IV every 8 h) or **ketoprofen** (2.2 mg/kg IV every 12 h) should be given to provide analgesia.

**Mild sedation** (acetylpromazine 0.02–0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01 to 0.02 mg/kg) may decrease muscle pain and anxiety. Tranquilizers with vasodilatory activity, such as acetylpromazine (acepromazine), should only be given to horses that are well hydrated. **Muscle relaxants**, such as methocarbamol, are often used but have no demonstrated efficacy.

**Recumbent horses** should be deeply bedded and repositioned by rolling every 2–4 h. Severely affected horses should not be forced to stand.

**CONTROL**

Prevention of the sporadic, idiopathic disease centers on insuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium and electrolytes, and have a regular and consistent program of exercise. Despite lack of clear evidence for a widespread role for vitamin E or selenium deficiency in exertional rhabdomyolysis, horses are often supplemented with 11U/kg vitamin E and 2.5 μg/kg selenium daily in the feed. Care should be taken not to induce selenium toxicosis.

**Sodium bicarbonate** (up to 0.5 to 1.0 g/kg body weight daily in the ration) and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented. Phenytoin has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6–8 mg/kg, orally, every 12 h, and the dose adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months. Dimethylglycine, dantrolene, alrenogest, and progesterone are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

The feeding of high fat, low soluble carbohydrate diets is useful in the prevention of recurrent exertional rhabdomyolysis in Thoroughbred horses and polysaccharide storage myopathy in Quarter horses. The usefulness of this practice in preventing sporadic, idiopathic exertional rhabdomyolysis has not been demonstrated.

**REFERENCES**

Degeneration of the masseter muscles causes dysphagia and trismus in adult horses. The disease is associated with abnormally low serum or blood concentrations of vitamin E or selenium in some affected horses. Muscles of locomotion and cardiac muscle can be affected in addition to disease of the masseter muscle. Clinical signs include dysphagia, trismus, weight loss, gait abnormalities, atrophy of the masseter muscles, teeth grinding or quidding of feed, and unexpected death. Horses with extensive involvement of other muscles can have myoglobinuria. Signs of dysphagia and trismus are related to dysfunction of the masseter muscle. Gait abnormalities are related to disease in muscles of locomotion and unexpected death is probably due to the cardiac lesions. Serum activity of creatine kinase and aspartate aminotransferase is elevated in acute cases. Necropsy examination reveals diffuse swelling, muscle pallor, and white streaking of masseter muscle in acutely affected animals. Lesions are also detected in muscles of locomotion and myocardium in some horses. Chronic cases have atrophy of affected muscle. Histological changes include swelling, fragmentation and loss of striations of myocytes in acute cases and degenerating fibers replaced by fibrosis in chronic cases. Treatment is symptomatic and affected horses can require enteral or parenteral delivery of nutrients. Vitamin E and selenium status should be determined and administered if indicated. Prevention should focus on ensuring that horses in geographic regions in which vitamin E or selenium are deficient in feeds are supplemented with these micronutrients.

ATYPICAL MYOPATHY (MYOglobINuria) IN GRAZING HORSES
A syndrome of acute myoglobinuria occurring in horses at pasture is reported from Great Britain and Europe, and is suspected to occur in North America and Australia. Occurrence of the disease is sporadic but usually affects more than one animal in a band of horses. Localized outbreaks involving large numbers of horses are reported. The case fatality rate is usually very high, approaching 100%. The disease occurs more commonly in the autumn or winter although cases have been reported from most months of the year. There does not appear to be a breed or sex predilection to development of the disease. Younger horses might be at greater risk of the disease but this could simply reflect the age distribution of horses at pasture in areas in which the disease occurs. Atypical myopathy occurs almost exclusively in horses at pasture and is not associated with enforced exercise.

Clinical signs are those characteristic of acute rhabdomyolysis and include an abrupt onset of stiffness and reluctance to move. Progression to lateral recumbency is rapid, occurring within hours of the initial onset of signs. Recumbency is often the first indication of this disease observed in horses at pasture. Horses forced to stand have tremors and difficulty walking. Lumbar and gluteal muscles can be firm. Affected horses are tachycardic and tachypneic. Respiratory distress, presumably secondary to degeneration of intercostal muscle and diaphragm, is common in recumbent horses in the terminal stages of the disease. There is discolored urine (pigmenturia). Affected horses die within 24–72 h of onset of clinical signs. Serum biochemical abnormalities include massively increased serum activities of creatine kinase, lactate dehydrogenase, and aspartate aminotransferase. Serum concentrations of troponin T, a marker of myocardial damage, are above normal in most affected horses. Serum concentrations of vitamin E and/or selenium and red cell activity of glutathione peroxidase are not consistently abnormally low.

Necropsy examination does not reliably reveal gross evidence of muscle disease although there can be swelling, edema and localized hemorrhage into muscles. There are hemorrhagic or pale areas in the ventricular myocardium of some horses. Histologic examination reveals the presence of widespread degeneration of myocytes, without inflammation, in muscles of locomotion and respiration. Within a muscle group some fibers are severely affected while other neighboring fibers are apparently normal. The ventricular myocardium has lesions of muscle degeneration in some horses. Myoglobinuric nephrosis is a consistent finding in horses that die spontaneously or are euthanized in the terminal stages of the disease.

Definitive diagnosis is based on the presence of clinical signs of muscle disease, large elevations in serum activity of muscle derived enzymes and necropsy examination.

Treatment is supportive and largely ineffectual and should follow the guidelines provided under acute rhabdomyolysis. There are no documented effective control measures although ensuring normal vitamin E and selenium status is advisable.

REFERENCES

LOW MILK FAT SYNDROME
The secretion of a normal volume of milk but with its milk fat reduced, often to less than 50% of normal, is a significant cause of wastage in high-producing cows. It occurs most commonly in cows on low-fiber diets, for example, lush, irrigated pasture or grain rations that are ground very finely or fed as pellets. It is assumed that a decreased formation of acetate in the rumen is the cause of a depletion of fatty acid precursors and the fall in butterfat. Treatment is achieved by administration of sodium bicarbonate or magnesium oxide, which increase fiber digestibility and hence the propionate:acetate ratio. Magnesium oxide also increases the activity of lipoprotein lipase in the mammary gland and increases uptake of triglycerides by the mammary gland from the plasma.

EQUINE PARS INTERMEDIA DYSFUNCTION (ADENOMA OF THE PARS INTERMEDIA OF THE PITUITARY, EQUINE CUSHING’S DISEASE)
A slowly progressive disease of older horses caused by non-malignant hypertrophy and hyperplasia of melanotropes of the pars intermedia of the pituitary gland and characterized by polyuria, polydipsia, hirsutism, and laminitis.

ETIOLOGY
The disease appears to be attributable to degeneration of the periventricular hypothalamic dopaminergic neurons with subsequent development of a non-malignant functional tumor comprised of
melanotropes of the pars intermedia of the pituitary gland. Cushing's syndrome caused by adrenocortical tumors is exceedingly rare in horses.

EPIEDEIOLoGY
The disease occurs worldwide in all breeds of horses and ponies. It is sporadic, non-infectious, and non-contagious. The prevalence of the disease is approximately 0.1%. The case-fatality rate is high (approaching 100%) after a prolonged course because of the advanced age of most affected horses, the severity of the disease and the cost of palliative treatment.

There is no apparent sex or breed predisposition, although the disease might be more common in ponies. Affected animals are usually at least 7 years old, and the average age at presentation is 20 years.

PATHOGENESIS
There is a loss of inhibitory effect of dopamine with subsequent hypertrophy and hyperplasia of melanotropes of the pars intermedia of the pituitary gland which results in unchecked secretion of pro-opiomelanocortin and compression of the neurohypophysis, hypothalamus and optic chiasma. Production of pro-opiomelanocortin by melanotropes is not under the negative feedback control of glucocorticoids and as a result affected horses produce large quantities of pro-opiomelanocortin, melanoocyte stimulating hormone, β-endorphin, and smaller but still excessive quantities of adrenocorticotropic hormone (ACTH). Production of ACTH results in loss of the normal circadian rhythm in serum cortisol concentration and hyperadrenocorticism, and secondary diabetes mellitus. The space-occupying effects of the tumor can cause blindness because of compression of the optic chiasma, and diabetes insipidus, because of neurohypophyseal dysfunction.

CLINICAL FINDINGS
Affected horses exhibit one or more of hirsutism, hyperhidrosis, polyuria, polydipsia, polyphagia, and a docile demeanour. There is often central obesity, characterized by excessive fat deposition in the crest of the neck and in the supraorbital fossae. Rarely, affected horses are blind or have seizures. Hirsutism, the presence of a long, often curly hair coat that is not shed during the warmer months, is a relatively consistent and specific finding in affected horses. Laminitis is a frequent finding in horses with equine pars intermedia dysfunction, and as many as 70% of horses with idiopathic laminitis (i.e. not clearly associated with an inducing disease such as colic or diarrhea) have evidence of pars intermedia dysfunction. Affected horses are often infertile and heal poorly.

CLINICAL PATHOLOGY
There is often mild neutrophilia and lymphopenia. Serum biochemical analysis may demonstrate hyperglycemia and an increase in alkaline phosphatase activity. Resting serum cortisol concentrations of affected and normal horses are similar and not useful in diagnosis. Glucosuria is often present.

DIAGNOSTIC CONFIRMATION
Antemortem diagnosis is achieved on the basis of clinical signs and one of several diagnostic tests. It is important that testing be based on the presence of clinical signs compatible with the disease in order to minimize the frequency of false positive diagnoses. Laboratory tests for the disease are not infallible and the results of these tests should be viewed only in the context of the horse's clinical signs. Further complicating diagnosis of equine pars intermedia dysfunction is the slow and progressive onset of the disorder. It is therefore likely that attempting a definitive dichotomous answer (disease present or disease absent) based on laboratory testing is unreasonable—some mildly affected horses will test normal while some apparently healthy horses with histologically normal pituitary glands will test positive. Laboratory tests used to diagnose pars intermedia dysfunction include measurement of serum or plasma cortisol, ACTH, glucose, or insulin concentrations, the ACTH stimulation test, the thyrotropin-releasing hormone stimulation test, measurement of urinary and salivary cortisol concentrations and combinations of these tests. The most widely accepted laboratory tests are the overnight dexamethasone suppression test and measurement of serum ACTH concentration. Other tests have been suggested, but either their sensitivity and specificity have not been determined, or they involve measurement of multiple variables or of hormones for which assays are not readily commercially available. Measurement of basal serum insulin concentration is not a useful diagnostic test for equine pars intermedia dysfunction. Measurement of urine or salivary cortisol concentrations has been suggested as a means of diagnosing equine pars intermedia dysfunction, but neither has been validated in a sufficient number of horses to permit assessment of their clinical utility. Diagnosis with a high degree of accuracy is achieved by the overnight dexamethasone suppression test. After collection of a serum sample for measurement of cortisol, dexamethasone (40 μg/kg IM) is administered at about 5 p.m. A second blood sample is collected 15 h later, with the option to collect a third sample 19 h after dexamethasone administration. Normal horses will have a serum cortisol concentration of less than 1 μg/dL (28 nmol/L) in the second and third blood samples, whereas affected horses will not show a significant reduction in serum cortisol concentration from that of the initial sample. The sensitivity and specificity of this test are apparently high with both reported to be approximately 100%. However, recent studies of healthy horses demonstrate that there is considerable seasonal variation in the dexamethasone suppression test, with all of 39 healthy aged ponies and horses having normal tests in January (winter) but 10 of the same 39 (26%) having abnormal tests in September (autumn). These results suggest that these diagnostic tests should be interpreted with caution when conducted in the autumn.

Diagnosis with a high degree of accuracy is achieved by the overnight dexamethasone suppression test. After collection of a serum sample for measurement of cortisol, dexamethasone (40 μg/kg IM) is administered at about 5 p.m. A second blood sample is collected 15 h later, with the option to collect a third sample 19 h after dexamethasone administration. Normal horses will have a serum cortisol concentration of less than 1 μg/dL (28 nmol/L) in the second and third blood samples, whereas affected horses will not show a significant reduction in serum cortisol concentration from that of the initial sample. The sensitivity and specificity of this test are apparently high with both reported to be approximately 100%. However, recent studies of healthy horses demonstrate that there is considerable seasonal variation in the dexamethasone suppression test, with all of 39 healthy aged ponies and horses having normal tests in January (winter) but 10 of the same 39 (26%) having abnormal tests in September (autumn). These results suggest that these diagnostic tests should be interpreted with caution when conducted in the autumn.

Measurement of serum or plasma adrenocorticotropin (ACTH) concentration has been proposed as an accurate laboratory indicator of equine pars intermedia dysfunction. The upper ACTH concentration from normal horses is 35–55 pg/mL. However, there is considerable seasonal variation in aged normal horses, with all of 39 horses having plasma ACTH concentration <35 pg/mL in January (winter), and May (late spring) but in only three of the same 39 horses in September (autumn). These results demonstrate the need for caution when assessing the diagnostic importance of plasma ACTH concentrations in aged horses.

The combined dexamethasone suppression/TRH stimulation test has reported sensitivity and specificity of 88% and 79%, respectively. The test is performed by administering 40 mg/kg of dexamethasone phosphate (or similar dexamethasone salt) intravenously between 8 a.m. and 10 a.m. Cortisol concentration in serum is then measured 3 h later and thyroid releasing hormone (TRH, 1 mg) administered intravenously. Serum cortisol concentration is measured 30 min after TRH administration. Serum cortisol concentrations of healthy horses 30 min after TRH administration are unchanged from those at the time of TRH administration, while serum cortisol concentrations in horses with equine pars intermedia dysfunction increase by >66% of the baseline value.

NECROPSY FINDINGS
The pituitary gland is usually enlarged due to the increased numbers of melanocorticotropes cells comprising an adenoma of the pars intermedia. The adrenal cortices are
usually of normal width but may be thickened in some cases. With the appropriate clinical history, the observation of a well-defined nodule within the pituitary gland is usually sufficient for confirmation of the diagnosis, but histology and immunohistochemical testing of the mass can be performed. There is only fair (kappa = 34%) agreement among pathologists for histologic diagnosis of the disease.  

DIFFERENTIAL DIAGNOSIS
- Insulin resistance
- Diabetes insipidus
- Both of these diseases are exceedingly rare in horses
- Obesity
- Psychogenic polydipsia or salt eating
- Chronic renal failure.

TREATMENT
Treatment is palliative. There is no effective treatment of the pars intermedia adenoma and the aim of treatment is to reduce secretion of the products of the melanotropes through the use of dopamine agonists or serotonin antagonists. Treatment must be continued for the life of the horse.

The treatment of choice is administration of pergolide, a dopamine agonist, at 1.7-5.5 μg/kg orally every 24 h. The recommended starting dose is 3.0 μg/kg once daily for 2 months, at which time clinical and laboratory (plasma ACTH concentration, dexamethasone suppression test) signs of the disease should be evaluated. This treatment is superior to cyproheptadine in terms of reducing plasma ACTH concentrations and improving clinical signs of disease, although this is not a uniformly reported observation. Cyproheptadine, a serotonin antagonist, is administered at 0.25 mg/kg orally every 24 h for 1 month. If an acceptable response is achieved then this dose is continued, if not, then the dose is increased to 0.25 mg/kg every 12 h.

Symptomatic treatment should include clipping of the hair coat in spring, treatment of laminitis and wounds, and prevention of injuries and infection.

CONTROL
None.

DISORDERS OF THYROID FUNCTION (HYPOTHYROIDISM, HYPERTHYROIDISM, CONGENITAL HYPOTHYROIDISM, THYROID ADEMA)

Disorders of thyroid function due to abnormalities in the thyroid gland, pituitary gland or hypothalamus are uncommon in the domestic species and are best documented for the horse. Thyroid disorders secondary to excessive or inadequate intake of iodine, or selenium deficiency are discussed under those headings.

ETIOLOGY
Disorders of thyroid function result in hypothyroidism or hyperthyroidism. Hypothyroidism can result from diseases of the thyroid gland (primary hypothyroidism), pituitary gland (secondary hypothyroidism due to reduced secretion of thyroid stimulating hormone), or hypothalamus (tertiary hypothyroidism, decreased thyrotropin [thyroid releasing hormone] secretion). Autoimmune thyroiditis has not been described in horses. Lymphocytic thyroiditis occurs in goats. Consumption of propylthiouracil (4 mg/kg body weight orally once daily for 4-6 weeks) induces hypothyroidism in adult horses. Administration of trimethoprim-sulfadiazine (30 mg/kg orally q. 24 h for 8 weeks), which can induce hypothyroidism in humans and dogs, does not impair thyroid function of most horses.

Hereditary congenital hypothyroidism secondary to defects in thyroglobulin production occurs in sheep, goats, and Afrikaner cattle. The disease is inherited as an autosomal recessive trait. The cause of congenital hypothyroidism in foals is uncertain, although ingestion of nitrates by the pregnant dam is strongly suspected. Partial thyroidectomy of equine fetuses results in birth of foals with clinical and pathological characteristics similar to the spontaneous disease.

Hyperthyroidism in horses is attributable to functional adenocarcinoma or adenoma of the thyroid gland, but most thyroid tumors, are not functional.

EPIDEMIOLOGY
The frequency with which hypothyroidism occurs in adult horses is unknown. It is relatively common practice to administer thyroid hormone or iodinated casein to fat horses, those with laminitis, rhabdomyolysis, or anhidrosis, or to enhance fertility, but documentation of abnormal thyroid function in these animals is rare. None of 79 clinically normal brood mares had an abnormal response to thyroid stimulating hormone administration, indicating that hypothyroidism is uncommon. Importantly, horses with non-thyroid related illness often have low concentrations of thyroid hormones in blood without evidence of thyroid dysfunction – this is referred to as the euthyroid sick or non-thyroidal illness syndrome and is not indicative of thyroid disease.

Abnormalities of the thyroid gland were detected in 12% of 1972 goats examined in India.1 Of thyroid glands examined from 1000 goats in India, 2.4% had colloid goiter, 39% parenchymatous goiter, 1.8% lymphocytic thyroiditis, and 2.1% were fibrotic.

Congenital hypothyroidism in foals occurs in western Canada and the western and northern USA. One survey of necropsy records of almost 3000 equine fetuses and neonatal foals in western Canada found that 2.7% had histologic evidence of thyroid and musculoskeletal abnormalities consistent with congenital hypothyroidism.14 Congenital hypothyroidism occurs in Dutch goats, Merino sheep, and Afrikaner cattle. Hypothyroidism is reported in an East Friesian ram.

Hyperthyroidism is a sporadic disease of older horses for which other risk factors are not identified.17 Thyroid tumors are common in older horses with ~50% having adenomas evident on histologic examination of the thyroid gland.11 The clinical course of such tumors is benign, although their size can be quite impressive. Thyroid adenocarcinoma is much less common but has a malignant course.

CLINICAL FINDINGS
Clinical characteristics of hypothyroidism in adult horses are poorly defined, largely because of the difficulty of confirming the diagnosis and the pharmacological effect of exogenous thyroid hormones. Clinical abnormalities anecdotally attributed to hypothyroidism include exercise intolerance, infertility, weight gain, mal-distribution of body fat, agalactia, anhidrosis, and laminitis, among others. Definitive association of these clinical syndromes with abnormalities of thyroid function is lacking.

Thyroidectomy of horses causes a reduction in resting heart rate and body temperature, docility, decreased food intake, increased cold sensitivity, dull hair
coat, and delayed shedding of hair. Blood and plasma volumes of horses increased after removal of the thyroid glands. Effects of thyroidectomy were reversed by administration of thyroxine, with the exception of blood and plasma volume which did not return to euthyroid values. Thyroidectomized horses did not become obese or develop laminitis.

Induced hypothyroidism in goats is evident as a loss of body weight, facial edema, weakness, profound depression, and loss of libido.

Coat, and delayed shedding of hair. Blood and plasma volumes of horses increased after removal of the thyroid glands. Effects of thyroidectomy were reversed by administration of thyroxine, with the exception of blood and plasma volume which did not return to euthyroid values. Thyroidectomized horses did not become obese or develop laminitis.

Induced hypothyroidism in goats is evident as a loss of body weight, facial edema, weakness, profound depression, and loss of libido.

**Congenitally hypothyroid** foals have a prolonged gestation but are born with a short silky hair coat, soft pliable ears, difficulty in standing, lax joints, and poorly ossified bones. The foals are referred to as dysmature. Characteristic musculoskeletal abnormalities include inferior (mandibular) prognathism, poorly ossified bones. The foals are referred to as dysmature. Characteristic musculoskeletal abnormalities include inferior (mandibular) prognathism, poorly ossified bones. The foals are referred to as dysmature.

Horses with hyperthyroidism are tachycardic, celiacx, and have hyper-active behavior. There is usually detectable enlargement of the thyroid gland. Thyroid adenomas are evident as unilateral, non-painful, enlargement of the thyroid gland of older (>15 years) horses. Thyroid adenocarcinoma presents as metastatic disease with both local and distant spread. Some affected horses have signs of hyperthyroidism, although this is unusual.

**CLINICAL PATHOLOGY**

Hematologic abnormalities in hypothyroid horses are not well documented. Induced-hyperthyroidism in horses causes increases in serum concentrations of very low density lipoprotein, triglycerides, and cholesterol, and decreased concentrations of non-esterified fatty acids. Induced hypothyroidism in goats caused hypoglycemia, hypercholesterolemia, and anemia. Hypothyroidism in a ram caused hypercholesterolemia.

**Thyroid hormone assays**

Assays are available for measurement of serum concentrations of T3, T4, free T4 (radioimmunoassay or equilibrium dialysis), and TSH. Values of each of these analytes varies depending on the method of analysis, physiologic status of the animal, and administration of other compounds (Table 29.8). Serum concentrations of thyroid hormones is high at birth and declines with age. There are statistically significant diurnal variations in serum concentrations of T3 and T4 in adult horses with lowest concentrations observed during the early morning hours, likely coincident with the time at which metabolic rate is lowest (Table 29.8).

**Feed restriction** for 3–5 days lowers serum concentrations of T3, T4, and fT4 in horses by 24–42%. Administration of phenylbutazone decreases concentrations of fT4 (measured by equilibrium dialysis) and T4 by 4 days of treatment, and can persist for up to 10 days after discontinuation of phenylbutazone.

The decrease in T4 is suggested to be attributable to displacement of T4 from protein binding sites by phenylbutazone, but this does not explain the decrease in fT4. The clinical significance of phenylbutazone-induced decreases in thyroid hormones is uncertain, but should be considered when assessing thyroid function in horses. Because of the number of analytical and physiologic factors that affect serum thyroid hormone concentrations, values considered normal vary considerably, as illustrated by the finding that 44 of 79 clinically normal non-pregnant broodmares had serum T4 concentrations below the reference range, although responses to

| Table 29.8. Serum or plasma concentrations of thyroid hormones in horses at different ages and stages | Serum or plasma concentrations of thyroid hormones in horses at different ages and stages |
|---|---|---|---|---|
| Age | T3 | fT4 | TSH |
| Birth (<10 h) | 991 ng/dL | 28.8 μg/dL | 12.1 ng/dL | 
| 1–3 days | 940 ng/dL | 28.0 μg/dL | 12.1 ng/dL |

| Induced hypothyroidism (PTU) | 4 (1–10) nmoL/L | 4.5 (1.5–13) pmol/L (RIA) | 
| Induced hypothyroidism (PTU) | 8 (1–20) pmol/L (ED) | 
| Euthyroid sick horses | 2 (2–24) nmoL/L | 5 (2–13) pmol/L (RIA) | 
| Euthyroid sick horses | 19 (4–48) pmol/L (ED) | 

fT4 = free T4; TSH = thyroid stimulating hormone. Mean ± SD or median (95% confidence interval). To convert μg/dL to nmol/L for T4 or fT4, multiply by 12.87.

To convert ng/dL to nmol/L for T3 or T4, multiply by 0.0154.

fT4 determined by radioimmunoassay (RIA) or equilibrium dialysis (ED).
TRH were normal.12 This example illustrates the need to determine reference ranges based on the methodology used and with well defined definition of the physiological state of the animals being tested.

Diagnosis of hypothyroidism is aided by demonstration of inappropriate responses of the thyroid gland to administration of TRH or TRH, although the use of these tests depends on determining the increase in serum T3 and/or T4 that is expected in normal horses and in horses with thyroid disease. Of 79 clinically normal mares, all had some increase in T3 and 77 had an increase in T4 2 hours after IV administration of 1 mg of TRH intravenously.13 The mean increase in serum T3 concentration was 4.5 times that of resting values (from 0.62 ng/mL to 2.44 ng/mL), whereas serum T4 concentration increased to a mean of 2.1 times that of resting value (from 14.7 ng/mL to 28.6 ng/mL).12 While responses to administration of TSH are reported, responses, other than complete lack of response, indicative of abnormal thyroid function have not been determined and the utility of the test has been questioned.27

The TSH response test involves administration of 51U of TSH intravenously. Blood samples are collected before, 30 min and 2 and 4 h after administration.29 Serum concentrations of T3 and T4 in healthy horses double after administration of TSH. An alternative involves administration of 5 IU intramuscularly and collection of blood before and 3 and 6 h after a TSH administration.30 TSH is currently unavailable.

The TRH response test requires administration of 0.5–1 mg of TRH intravenously. Blood samples are collected before, 30 min and 2 and 4 h after administration.29 Serum concentrations of T3 and T4 in healthy horses double after administration of TRH. An alternative involves administration of 5 IU intramuscularly and collection of blood before and 3 and 6 h after a TSH administration.30 TSH is currently unavailable.

Diagnosis of hypothyroidism in horses should be based on the presence of compatible clinical signs, low serum concentrations of thyroid hormones (T3, T4, fT4); elevated concentrations of thyroid stimulating hormone, lack of an increase in serum concentrations of thyroid hormones in response to administration of thyroid releasing hormone (TRH), and increased TSH concentration in serum in response to TRH administration. Diagnosis of hypothyroidism should not be based solely on clinical signs, or on the measurement of resting (unstimulated) serum T3 or T4 concentrations. At a minimum, appropriate clinical signs and documentation of an abnormal response to stimulation testing (TSH or TRH) are essential for diagnosis of hypothyroidism in horses. Measurements of fT4 concentrations determined by equilibrium dialysis are useful in determining thyroid function in sick horses in which T3 and T4 concentrations are low as fT4 concentrations will be normal in horses without thyroid disease.13

Foals with congenital hypothyroidism have abnormally low concentrations of T3 and T4, and less than expected increases in serum concentrations of these hormones in response to TSH administration.33 Horses with hyperthyroidism have markedly elevated concentrations of T3 and T4.4,17 Concentrations of T4 do not decline in response to administration of T3.17 T3 (2.5 mg) is administered intramuscularly twice daily for 3 days and serum concentrations of T3 and T4 measured. T4 concentrations in serum of healthy horses decline by approximately 80% whereas those of horses with hyperthyroidism do not decline.

**NECROPSY FINDINGS**

Findings on necropsy examination of hypothyroid horses have not been reported. Foals with congenital hypothyroidism have histologic evidence of thyroid hyperplasia, but no gross signs of goiter.

**TREATMENT**

Treatment of confirmed hypothyroidism in horses is achieved by administration of levo-thyroxine (20 μg/kg PO q24 h).34 Serum T3 concentrations peak in 1 h and then decline while concentrations of T4 peak in 2 h and persist for 24 h.34 The clinical status of the horse should be monitored during treatment and serum concentrations of T3 and T4 measured every several months. Iodinated casein, which is no longer readily available in the USA, is administered at 5 g/450 kg body weight orally once daily. Administration of thyroxine or iodinated casein for treatment of low serum thyroid hormone concentrations in horses with non-thyroidal illness syndrome (euthyroid sick syndrome) should be done judiciously.

A response to thyroxine administration is not necessarily confirmation of hypothyroidism as thyroxine can have marked effects in horses with normal thyroid function. Administration of thyroxine (up to 96 mg/470 kg, orally once daily) increases serum concentrations of T4 and, to a lesser extent, fT4, and decreases concentrations of TSH.35 The increases in T4 are associated with a loss of body weight, decreases in serum concentrations of triglycerides, cholesterol, and very low density lipoproteins, and an increase in whole body insulin sensitivity.36 Thyroxine should be administered with caution to horses with normal thyroid function.

**CONTROL**

There are no recognized control measures for hypothyroidism in adult horses. Minimizing intake of nitrates by pregnant mares appears warranted, but definitive proof of the efficacy of this practice is lacking. Pregnant mares should not be fed fodder or supplements that interfere with thyroid function.

The inherited disorder in sheep, cattle, and goats can be prevented by selective breeding.

Introduction
The following criteria are suggested for the assessment of the importance of nutrition in the etiology of a disease state in a single animal or in a group of animals:

- Is there evidence from an examination of the diet that a deficiency of a specific nutrient or nutrients may be occurring?
- Is there evidence from an examination of the animals that a deficiency of the suspected essential nutrient or nutrients could cause the observed disease?
- Does supplementation of the diet with the essential nutrient or nutrients prevent or cure the condition?

The difficulties encountered in satisfying these criteria and making an accurate and reliable diagnosis of a nutritional deficiency have increased as investigations have progressed into the area of trace elements and vitamins. The amounts of such substances as selenium present in feedstuffs and body tissues are exceedingly small and their estimation difficult and expensive. Because of these difficulties it is becoming more acceptable to describe individual syndromes as responsive diseases, i.e. which satisfy only the third of the above criteria. The practice leaves much to be desired but has the advantage that applicable control measures are more readily available.

EVIDENCE OF EXISTENCE OF DEFICIENCY

General evidence will include either evidence of deficiency in the diet, or abnormal absorption, utilization or requirement of the nutrient under consideration. Special evidence may be obtained by chemical or biological examination of the feed.

Diet

The diet for a considerable period prior to the occurrence of the disease must be considered because body stores of most dietary factors may delay the appearance of clinical signs. Specific deficiencies are likely to be associated with particular soil types, and in many instances soil and geological maps may predict the probable occurrence of a nutritional disease. Diseases of plants may also indicate specific soil deficiencies, e.g. 'reclamation disease' of oats indicates a copper deficiency in the soil. Domination of the pasture by particular plant species may also be important, e.g. subterranean clover selectively absorbs copper, legumes selectively absorb molybdenum, and Astragalus spp. are selector plants for selenium.

Farming practices may have a marked bearing on the presence or absence of specific nutrients in livestock feed. For example, heavy applications of nitrogen fertilizer can reduce the copper, cobalt, molybdenum, and manganese content of the pasture. On the other hand, many applications of lime reduce plant copper, cobalt, zinc, and manganese levels, but increase the molybdenum content. Effects such as these are sufficiently severe to suggest that animals grazing the pasture might suffer trace element deficiency. Modern hay-making methods, with their emphasis on the artificial drying of immature forage, tend to conserve vitamin A but may result in a gross deficiency of vitamin D. Soil and pasture improvement by exaggeration of the depletion of nutrients, particularly trace elements, from marginally deficient soil may give rise to overt deficiency disease. Thus, local knowledge of farming and feeding practices in a particular area is of primary importance in the diagnosis of nutritional deficiency states.

Abnormal absorption
Even though a diet may contain adequate amounts of a particular nutrient, some other factor, by decreasing the absorption of the nutrient, may reduce the value of the dietary supply. For instance, excess phosphate reduces calcium absorption, excess calcium reduces the absorption of iodine, and absence of bile salts prevents proper absorption of the fat-soluble vitamins. Chronic enteritis reduces the absorption of most dietary essentials. The list of antagonisms that exist between elements grows all the time, most of them being interferences with absorption. For example, excess calcium in the diet interferes with the absorption of fluoride, lead, zinc, and cadmium, so that it may cause nutritional deficiencies of these elements, but it also reduces their toxic effects when they are present in the diet in excessive amounts.

Abnormal utilization of ingested nutrients
This may also have an effect on the development of conditioned deficiency diseases. For example, molybdenum and sulfate reduce copper storage, vitamin E has a sparing effect on vitamin A, and thiamine reduces the dietary requirements of essential fatty acids.

Abnormal requirement
Stimulation of the growth rate of animals by improved nutrition or other practices may increase their requirement of specific nutrients to the point where deficiency disease occurs. There seems to be little doubt that there is a genetic variation in mineral metabolism and it has even been suggested that it may be possible to breed sheep to ‘fit’ actual deficiency conditions, but the significance of the inherited component of an animal’s nutritional requirement is unknown and probably small. It should not be overlooked, however, when policies of upgrading livestock in deficient areas are initiated.

EVIDENCE OF A DEFICIENCY ASSOCIATED WITH THE DISEASE
Evidence is usually available from experimental work to indicate the clinical signs and necropsy findings one can expect to be produced by each deficiency. Several modifying factors may confuse the issue. Deficiencies under natural circumstances are unlikely to be single and the clinical and necropsy findings will be complicated by those caused by deficiencies of other factors or by intercurrent infections. In addition, most of the syndromes are both variable and insidious in onset and the minimal nature of the necropsy lesions in many nutritional deficiency diseases adds further difficulty to the making of a diagnosis.

Special clinical and laboratory examinations of the animals are valuable aids to diagnosis in many instances. However, the ranges of blood or tissue concentrations of minerals and vitamins, or their biochemical markers, in normal animals and those values which indicate deficiency have not been well-established. In other words, the cut-off values above which animals are normal and below which they are abnormal or deficient have not been adequately determined in naturally occurring nutritional deficiencies. Experimentally induced nutritional deficiencies provide an indication of the changes that occur in the concentrations of a particular nutrient marker, but variations due to age, genotype, production cycle, length of time on the inadequate diet, previous body stores of the element and other stressors commonly complicates the results and render them difficult to interpret accurately and with repetitability.

In most cases, nutritional deficiencies affect a proportion of the herd or the flock at the same time and the clinicopathological examination should include both normal and clinically affected animals. Comparison of the laboratory results of normal and abnormal animals allows for more accurate and reliable interpretation and the making of a diagnosis.

EVIDENCE BASED ON CURE OR PREVENTION BY CORRECTION OF THE DEFICIENCY
The best test of the diagnosis in suspected nutritional deficiency is to observe the effects of specific nutrient additions to the ration. Confounding factors are frequently encountered. Spontaneous recoveries may occur and adequate controls are essential. Curative responses may be poor because of an inadequate dose rate, because of advanced tissue damage, or because the abnormality may have been only a pre-disposing factor or secondary to a complicating factor that is still present. Another common cause of confusion in therapeutic trials is the impurity of the preparations used, particularly when trace elements are involved. Finally, the preparations used may have intrinsic pharmacological activity and produce some amelioration of the disease without a deficiency having been present.

Monitoring of nutritional status
The feeds and feeding program have a major influence on reproductive performance, growth rate, and milk production and must be monitored regularly. The veterinarian must be aware of any changes in the feeding program that have occurred since the last farm visit or that are intended in the near future. On breeding farms, there are several different age groups of animals at different levels of growth and production. This requires close surveillance to avoid undernutrition or overnutrition. Scoring of the body condition of dairy cattle, beef cows, sheep, and pigs is becoming commonplace as an indicator of the adequacy of the diet. Veterinary clinical nutrition is now a veterinary medical specialty that should provide new and useful information for the practitioner working with a particular species or class of food animals. The American College of Veterinary Nutrition also provides consultants in veterinary nutrition who can be called on for advice in solving nutritional problems. An experienced and competent nutritionist should be consulted to assist with complex nutritional problems.

Nutritional management in dairy herds
Advising farms about nutrition is a key activity for dairy cattle practitioners. Feed costs constitute approximately 60% of the total cost of producing milk, and even minor improvements in feeding efficiency can be profitable. Some dairy practitioners function as the nutritional specialists for the dairy farms they serve. They may collect feed samples for nutrient analysis, formulate rations, and advise the farmer regarding crop and harvesting conditions. These veterinarians often devote a considerable amount of their professional time to nutritional management.

It is common for farms to employ a professional nutritionist or to use a nutritionist employed by a feed company or local cooperative. These professional nutritionists generally formulate the rations and submit feed samples for nutrient analysis. On these herds, the veterinarian can have an important role in ensuring that the diet described on paper is adequately formulated and delivered to the cows. Routine scheduled activities such as measuring the dry matter of forages, hand mixing total mixed rations (TMR) for one cow and comparing it with the machine-mixed TMR (TMR test mix), and scoring the feed bunk to assess feed sorting and dry matter intake are important procedures that help to ensure the successful delivery of a nutritional program. Assessing pasture conditions by periodic inspection of pasture is an important component of managing the nutritional program of herds that use management-intensive grazing. These quality control activities should be conducted routinely as part of the health and production management program.

There is probably no aspect of a dairy enterprise that has a wider impact than the feeding program. Dairy farm feeding
programs have direct effects on production and growth and set the stage for future productive potentials. Many health problems on a dairy relate in some way to the feeding program. Feed costs on the average dairy account for more than 60% of total operating expenses in the USA. A significant part of the average dairy’s labor force devotes its time to planting, growing, harvesting, mixing, and feeding rations to a variety of animals. Investments in equipment used in feeding programs are an important part of the dairy’s debt load. Small changes in feeding programs may bring about large changes in productivity, health, income, feed costs, labor allocation, and debt load. The total savings from small changes can be substantial. Without considering improved production or health effects, one study has shown that routine nutritional consultation by veterinarians can save 14% of total feed costs on dairies.

For all these reasons, veterinarians who intend to serve their dairy clients on a herd basis must become actively involved in the herd’s feeding program. Dairy herds are commonly fed unbalanced, expensive rations. By serving as independent consultants, veterinarians can provide unbiased advice to their clients. Those veterinarians who wish to serve their clients at a herd level constantly find their attention focused on the feeding program. The next recumbent, hypocalcemic cow raises questions about dry cow feeding. The next anestrous, thin cow with smooth ovaries raises questions about early lactation energy levels in the ration and dry matter intake (DMI). The next time the herd average mature equivalent milk production falls by 500 lb, the problem generates the same sense of urgency as a cow with a prolapsed uterus. As a profession, dairy veterinary medicine must come to grips with the fact that it cannot truly serve client needs by practicing therapeutic medicine separately from nutritional consulting. Veterinarians must train themselves to deal with nutrition directly, consistently and knowledgeably.

In recent years, as herd size has increased, many dairies have come to rely on a team of advisors rather than only one or two. A nutritional consultant, local veterinarian, and outside consultant may all be providing advice to a dairy. In these circumstances, communication about the feeding program and resulting performance is critical. It is imperative that the veterinarian be knowledgeable about dairy nutrition and involved in ration formulation. The veterinarian needs to maintain their involvement as part of the advisory team.

Levels of nutritional service

Having decided to be involved in a dairy’s feeding program, the veterinarian and client should first agree on the level of nutrition service that is to be provided. The level varies from herd to herd, depending on the veterinarian’s expertise, the client’s ability and interest, and the role being played by other consultants to the farm. There are essentially four levels of service that might be provided:

Level 1: Problem identification and analysis
At level 1, the veterinarian takes on the task of monitoring the dairy herd for indicators that there might be nutrition-related problems. Many areas need to be monitored: production, milk components, DMI, body scores, disease rates, growth rates, and feed costs. Based on these monitored areas, the veterinarian can call attention to problems as they arise, form and test hypotheses about likely causes, and interact with other farm service personnel as the problems are addressed.

Level 2: Ration analysis
At level 2, the veterinarian evaluates the nutritional adequacy of diets as they are fed to the cows. If problems of balance or economics are identified, they are referred to the appropriate person for reformulation. This level is difficult to sustain over time because, after a while, the person formulating the ration is likely to resent being ‘second-guessed.’ It can work well if the ‘team approach’ is part of the procedure on the dairy.

Level 3: Ration formulation
At level 3, the veterinarian takes on the responsibility of formulating the ration. To operate responsibly at this level, veterinarians need several additional skills. Regardless of region, an important part of the team that would include the nutritionist, as well as by the veterinarian. Good nutrition provides the essential basis for total program consulting can be accomplished with the veterinarian as a part of the team that would include the nutritionist, as well as the veterinarian. Thus, many dairies grow to rely on a team of advisors rather than only one or two. A nutritional consultant, local veterinarian, and outside consultant may all be providing advice to a dairy. In these circumstances, communication about the feeding program and resulting performance is critical. It is imperative that the veterinarian be knowledgeable about dairy nutrition and involved in ration formulation. The veterinarian needs to maintain their involvement as part of the advisory team.

Nutritional management of the beef breeding herd

Good nutrition provides the essential basis for optimum productivity in cattle breeding operations. Despite this, nutritional expertise has not been a traditional strength of many food-animal veterinarians.

Throughout the world, beef-breeding operations are generally range or pasture based. These operations are conducted in diverse environments, with great variation in nutritional management. Even within the USA, the area of pasture or rangeland required to maintain a cow-calf unit may vary from 3 acres or more in the south-west to 1 or 2 acres in more intensive regions. In parts of Australia, the corresponding area may be measured in square miles. However, in general, the area of land, or amount of pasture, necessary for production is related to local economic realities. This, in turn, is related to levels of managerial and resource inputs that can differ with regions, markets, and enterprise priorities. Notwithstanding such caveats, there are a number of principles of good nutritional management that may be universally applied to cattle breeding operations. Regardless of region, an important consideration is that of maintaining or
improving production while reducing costs. In simple terms, financial return from a beef breeding operation is a function of number of calves, their weaning weight, and price. On the cost side of the ledger is the maintenance cost of the breeding females. This varies considerably, both within and between regions. Market price, in general, is usually unmanageable at the farm level. However, both the number of calves born and their weaning weights are strongly influenced by nutrition. For example, good nutritional management helps to ensure that as many females as possible are cycling at the start of the breeding season. This, in turn, helps to ensure that calves are born early with the result that they are older, and heavier, at weaning than later-born calves.

In general, nutrition is the most important limiting factor of beef breeding performance. For veterinarians, understanding the principles underlying the nutritional management of breeding females is necessary. Effective counseling and troubleshooting does not necessarily require a higher degree in nutrition, although it should include sufficient knowledge and wisdom to know when such expertise is needed. A starting point is to have a working knowledge of the different energy measuring systems (total digestible nutrients (TDN), metabolizable energy (ME) and net energy, NE) that are commonly used, their applications for different classes of animals, activities and feedstuffs, and to identify one with which the veterinarian can work best. The Nutrient Requirements of Beef Cattle from the National Research Council (NRC) in the USA is a useful document revised in 2000. This is packaged with a computer program that includes ration formulators as well as a library of feeds and feedstuffs. A number of computer programs are now available for least-cost ration formulation in beef herds.

Nutritional advice for beef feedlots
Feedlots frequently consult a qualified nutritionist to assist in the formulation of cost-effective diets. The veterinarian should communicate regularly with the nutritionist to be aware of the composition of the diets and any changes that are being planned. Because feed is the major portion of the cost per unit of body weight gain, it is imperative that the diet be the lowest-cost diet possible while providing nutrients that allow optimum growth and finishing. Most of the emphasis in feedlot nutrition has been on the development of cost-effective diets that support a maximum growth rate without any deleterious effects. Considerable information is available on the nutrient requirements for feedlot cattle and on the feeds and feeding systems used.

The precise specifications of the diets are the responsibility of the nutritionist, but the feedlot veterinarian frequently is in a position to evaluate the quality of the feed delivery system. This means checking to determine whether cattle are fed on time, whether the feed is mixed properly, and whether the feed intake is intermittent because of inclement weather or muddy ground surfaces. Any deviations should be communicated to the consulting nutritionist.

Nutritional deficiency diseases are uncommon in feedlot cattle, because cattle usually receive a diet that contains the nutrients required for maintenance and promotion of rapid growth. Diets prepared according to the Nutrient Requirements of Beef Cattle should meet all the requirements under most conditions.

Specific nutrient deficiencies are extremely rare, because diets are prepared every few days or daily and it would be highly unusual for a feedlot to use a feedstuff deficient in a specific nutrient for a prolonged period. However, such a situation may occur in a small farm feedlot that prepares its own feedlot diet with little or no attention to the necessity for supplementation of homegrown feeds. Thus, there are only a few nutrition-related diseases that may affect a well-managed feedlot, but these diseases may cause large economic losses when they occur. They include the following:

- Carbohydrate engorgement (grain overload or D-lactic acidosis)
- Feedlot bloat or ruminal tympany
- Feeding errors (i.e. accidental incorporation of an excessive amount of a feed additive, such as monensin or urea, or sudden unintended changes in the ingredient composition of the diet).

Nutritional advice for swine-herds
Veterinarians involved in health management of swine-herds must be well informed about the nutrient requirements of the different age groups of pigs. Since feed constitutes 60–80% of the cost of producing a market pig, every effort must be made to increase the economic efficiency of feed use. Some surveys of well-managed pig farms in Alberta, Canada, found a 20% difference in feed costs, and it is estimated that in the industry the range in feed costs is likely to be near 50%. Reduction of the feed cost of the highest costing farm to that of the lowest costing farm would save that farm more than US$23,000 annually, which is equivalent to a cost reduction in production of $6.80/pig. The trend is to use complete feeds formulated by feed company nutritionists who are familiar with the nutrient composition of local feedstuffs. With complete diets, specific nutrient deficiencies are uncommon.

The major problem is the efficiency of utilization of the different feeds throughout the life cycle of the pig. The nutrient requirements of the pig at various phases of growth from birth to market weight and of breeding stock are well established. The remaining questions appear to be about the levels of feed that should be provided during the different phases of the growth of the pig in order to achieve optimum production and to yield the best carcass. Proper nutrition can greatly increase the efficiency of pig production, because feed represents such a large percentage of the cost involved. The following are some recommended practices for increasing efficiency of feed utilization with pigs:

- Provide well-balanced diets with adequate levels of amino acids, energy, vitamins, and minerals necessary to meet the particular demands of the pig at each stage of its life cycle. The diet depends on the demands, usually characterized as the growth rate or lean deposition. Feed intake is the supply function. Feed intake is limited by appetite, and thus other nutrients are matched to expected energy intake and subsequent growth.
- Use least-cost formulation to the extent that it is feasible. The least-cost energy source in most of the pig-rearing areas is corn, and the most common protein source is soybean meal.
- Restrict the level of a properly balanced diet for sows during gestation to avoid overfeeding. Sows that have lost excessive body weight in the previous lactation need supplemental feed during the dry period to avoid the thin-sow syndrome.
- Ad-lib feeding for growing pigs is usually optimum, unless the genotype deposits excess fat during the latter stages of growth.
- Market pigs as close to optimum slaughter weight as possible to maximize margin over feed costs.
- Avoid feed wastage by using well-designed feeding systems and proper adjustment of those feeders.
- Use pelleting of diets to increase digestibility, especially of small grains, and to decrease feed wastage. However, pelleting also predisposes pigs to gastroesophageal ulcers.

The feed efficiency of the pigs from weaning to market should be monitored regularly. It is often difficult to obtain accurate data on this item for specific groups of pigs, because the amount fed to each group may not be calculable when a
common feeding system is in use. However, the total amount of feed used and the total weight of pigs marketed will give an estimate of feed efficiency.

The National Research Council (NRC) in the USA provides an important service in establishing the nutrient requirements of swine and other species. The 10th revised edition of the Nutrient Requirements of Swine was published in 1998. The 200-page edition incorporates the wealth of new research information that has emerged over the past 10 years since the 8th edition, and addresses new areas such as modelling nutrient requirements and reducing nutrient excretion.

Even though the nutrient requirements of pigs are well known, they do continue to change because of changes in growth and production characteristics of pigs. Pigs with high lean-growth rates require higher levels of amino acids to support their increased rate of body protein deposition. Similarly, high milk-producing sows nursing large litters have increased amino acid requirements.

In the 10th edition, a new approach is used to produce estimates of nutrient requirements that take into consideration not only the pig’s body weight, but also its accretion rate of lean (protein) tissue, gender, health status, and various environmental factors. To accurately estimate nutrient needs of gestating and lactating sows, there is a need to account for body weight, weight gain during gestation, weight loss during lactation, number of pigs in the litter, weight gain of the litter (a reflection of milk yield), and certain environmental factors.

A series of integrated mathematical equations was used to account for the many factors now known to influence nutrient requirements. These equations provide the framework for modeling the biological basis of predicting requirements. The NRC models predict the levels of nutrients (outputs) needed to achieve a certain level of production under a given set of environmental conditions (inputs).

Five principles were used to develop the models. The models: (1) were made for ease of use by people with varying levels of nutritional expertise and with limited information; (2) were developed for continued relevance for several years to come; (3) were intended to be structurally simple, so they could be understood readily by users; (4) were developed to be transparent so that all of the equations could be available to the user and (5) were firmly anchored to empirical data at the whole-animal level rather than being simply based on theoretical values. Three independent models were developed for growth, gestation, and lactation. The growth model estimates amino acid requirements of pigs from weaning to market weight, and the gestation and lactation models estimate energy and amino acid requirements of gestating and lactating sows.

Few revisions were made in the previously published mineral requirements. Based on recent findings, higher dietary requirements for sodium and chloride in the young pig were established. The manganese requirements were increased from 10 to 20 ppm for gestating and lactating sows.

Several changes were made in the feed composition tables. Nutrient composition of feeds was obtained from as many data bases as possible, including from the feed industry and from data sets outside the USA and Canada.

The information on water was expanded considerably, with more detailed information on the factors that influence water intake. There is additional new information on non-nutritive feed additives, such as antimicrobial agents, anthelmintics, microbial supplements, oligosaccharides, enzymes, acidifiers, flavors, odor control agents, antioxidant pellet binders, flow agents, high-mineral supplements, and carcass modifiers.

A new chapter on minimizing nutrient excretion is included in the 10th edition. It addresses environmental issues and the importance of reducing the excretion of nutrients, particularly nitrogen and phosphorus, which can potentially contribute to environmental pollution.

**Nutritional advice for sheep flocks**

The influence of nutrition on the reproductive performance of ewes has been a matter of concern to sheep farmers and sheep production research workers throughout the world. It is clear that the relationship between nutritional provision and nutrient requirements for optimum reproductive performance is seldom ideal because of the wide range of environmental conditions and the seasonality of breeding that most sheep breeds exhibit. Prolonged periods of undernutrition during mid-pregnancy are partly the result of the decline in feed availability and quality over that stage of the reproductive cycle.

Prolonged duration of moderate to severe undernutrition of ewes bearing twins in mid-pregnancy can reduce placental development causing significant reductions in lamb birth weight with increased mortality. Considerable progress has been made in understanding the principles of nutrition of sheep and in defining their nutrient requirements for maintenance, pregnancy, and lactation.

The sensitivity of lamb birth weight, particularly in twins and triplets, to the ewe’s plane of nutrition during late pregnancy is well known. It has been established that mortality rates are high in lambs with birth weights below the breed norm, and that after birth the absolute growth rates are lower in surviving light lambs than in heavier lambs of the same breed. The plane of nutrition and the size of the placenta have been recognized as major determinants of the fetal growth rate. Fetal growth retardation in undernourished ewes has a placental component, and the factors that affect placental growth are relevant here.

The 21-week gestation can be divided into a number of periods to consider the effects of nutrition on reproduction within each period. In the first month of gestation, embryonic loss is the main sequel to inadequate nutrition. During this period, it is generally recommended that the BCS of the ewe be maintained at 2.5–3.5 (scale of 1 to 5) to minimize embryonic and early fetal losses. This is followed by a period of 2 months in which there is rapid growth of the placenta, but during which growth of the fetus in absolute terms is still small. Over this period, it is normal to advocate that losses in body weight should not exceed 5%. Finally, there is the phase from 90 days to parturition, in which gain in the mass of the fetus amounts to 85% of its birth weight; during this period, nutrient intake must be increased.

Placental development in the pregnant ewe begins about 30 days after conception, the number of placentomes associated with each fetus is fixed at this time, and the total weight of the placentomes increases until about 90 days of gestation, after which there is little change. The factors that influence the ultimate size of the placenta and its weight include hormonal and nutritional factors, prolonged environmental heating of pregnant ewes, parity of ewes, and possibly genotype, but the most important determinant is nutrition of the ewe. Moderately severe undernutrition during early pregnancy and midpregnancy significantly reduces placental weight at or near term and causes chronic intrauterine growth retardation.

The size of the placenta is a major determinant of fetal growth. In well-fed ewes, the fetal growth rate before 120 days of gestation is not correlated positively with placental weight, but fetal growth rate in the last 3 to 4 weeks of pregnancy is limited by the size of the placenta. Earlier placental influences on fetal growth are evident, however, when ewes are underfed. Placental weight and fetal growth rate are correlated positively during periods of maternal underfeeding, which starts before 90, at 95, or at 112 days of gestation. During the first 90 days of pregnancy, placental growth is reduced when ewes are moderately underfed. Low-weight fetuses in ewes with placenta weights near the bottom of the
normal range are affected with chronic and progressive hypoxemia and hypoglycemia, which affect fetal metabolism. The consequences are fetal death during late pregnancy, fetal hypoxemia during parturition, premature birth, and a high perinatal mortality rate caused by hypoglycemia and hypothermia.

The extent to which ewes maintained on a fixed ration draw on their own body reserves in an attempt to meet the energy costs of pregnancy is determined by fetal weight. In well-fed ewes, fetal growth rate remains constant until at least 120 days of gestation and decreases thereafter. However, its absolute growth rate increases markedly during the last 8 weeks of gestation, when fetal growth is most rapid, exceeding 100 g/day near birth. The growth rate among fetuses is highly variable, which accounts for birth weights ranging from 2 kg to over 7 kg. When ewes that have been well fed are severely underfed at any stage during the last 40 to 50 days of pregnancy, the fetal growth rate decreases within 3 days, by 30% to 70%. This illustrates that the mobilization of maternal reserves is substantially less than fetal requirements and emphasizes the importance of ensuring a continuous supply of good-quality feed during late pregnancy. The larger the fetal burden, the more susceptible a ewe is to hypoglycemia during underfeeding.

Re-feeding after severe underfeeding can reverse the reduced growth rate of fetuses, but the response depends on the duration of the underfeeding. If the period of underfeeding is 16 days or less, the growth rate increases when ewes are re-fed, but there is no change when re-feeding occurs after 21 days of severe underfeeding. Moderate underfeeding of pregnant ewes for 85 days reduces the fetal growth rate irreversibly, and refeeding them in late pregnancy does not cause the fetal growth rate to increase but does prevent further decreases after 120 days.

The major consequences of prenatal growth retardation are on lamb survival. The neonatal mortality of lambs increases markedly in many environments as the birth weight falls below 3-3.5 kg. Compared with normal lambs, low-birth-weight animals have reduced insulation because of the smaller number of wool fibers, greater relative heat loss because of their larger surface area per unit of body weight, and a reduced capability to maintain heat production because of their lower fat and energy reserves. All these factors increase their susceptibility to environmental stress and reduce their ability to compete with normal-sized siblings. Underfeeding during pregnancy can also reduce available body lipids in lambs by about 47% and also decreases the lactose, lipid, and protein available in colostrum during the first 18 h by about 50%. Newborn lambs have to draw on body reserves of glycogen in order to maintain heat production during the first 18 h after birth, and thus depend heavily on colostrum intake and supplemental feeding to avoid hypoglycemia and hypothermia.

The effects of maternal nutrition on under development and on the production and yield of colostrum and milk in ewes have also been examined. In the last 30 days before birth, there is a marked increase in the rate of mammary tissue growth in the ewe. In well-fed ewes with one or two lambs, large volumes of colostrum accumulate in the mammary glands during the last few days of pregnancy and copious milk secretion begins soon after birth, with averages of 1800 to 2800 mL of colostrum and milk being produced during the first 18 h. Udder growth rates are proportional to fetal growth rates in that the greatest increase inudder weight occurs in the last 30 days of gestation and the weight of udder tissue is 30-40% of the total weight of the litter. Colostrum production is proportional to udder weight, and re-feeding of ewes a few days before lambing fills the udder tissue present but does not increase udder tissue weight. In underfed ewes, prenatal colostrum accumulation is reduced markedly, lactogenesis is delayed, and the total production of colostrum and milk during the first 18 h averages about 1000 mL. Subsequently, in both types of ewe, milk production increases, reaching a peak about 1–2 weeks after birth. Underfeeding ewes beginning at 105 days of gestation can reduce the total yield of colostrum during the first 18 h after birth by decreasing mammary tissue growth. Thus, the prepartum accumulation of colostrum and its sub-sequent rates of secretion are reduced. Improving the ewe’s nutrition from 1 h after birth can increase the secretion rates of colostrum between 10 and 18 h.

The growth rate of lambs during the first few weeks of life is correlated positively with birth weight. Low planes of maternal nutrition during late pregnancy and early lactation are generally associated with low birth weights, milk yields, and postnatal growth rates, and high planes of nutrition with the opposite effects. A marked increase in the plane of maternal nutrition at birth can overcome the inhibitory effects on lactation and lamb growth rate of underfeeding in late pregnancy.

At breeding time, the aim is to achieve a body score of 3.0–3.5, which ensures maximum ovulation rate. For ewes with a BCS of 3.5 at breeding, it is desirable to allow them to lose no more than 5% of their body weight steadily, equivalent to approximately 0.5 to 1 unit of condition score during the second and third months of pregnancy. This mild degree of undernutrition enhances placental growth and establishes the basis for maximum fetal growth in the 4th and 5th months of pregnancy, the period during which the fetus achieves over 80% of its growth. During these final 2 months of pregnancy, there is a limit to the extent to which body fat reserves can be used, because excessive mobilization of depot fats as a consequence of inadequate dietary energy supply leads to pregnancy toxemia. In late gestation, the optimum BCS ranges from 2.5 to 3.0. In contrast, early lactation is a period in which body fat can be safely used to meet some of the high energy demands of lactation. During this period, a loss of BCS of 1.0 (equivalent to 5 kg fat for a 70 kg ewe at mating) is acceptable, and during lactation it ranges from 1.5 to 2.5. The replacement of the body fat that is used before the next breeding cycle is important in achieving a maximum ovulation rate and subsequently optimum reproductive performance.

Winter shearing of pregnant ewes during the final 10 weeks of pregnancy has been shown to cause a significant increase in lamb birth weight. Shearing pregnant sheep at 8 weeks before lambing leads to a chronic increase in energy requirements, which are met by oxidizing body fat depots without risks of clinical ketosis. Fetal growth is enhanced as a result of these metabolic adaptations.

The nutrient requirements for maintenance, breeding, pregnancy, and lactation of ewes have been catalogued, and optimum feeding strategies for the breeding ewe can be formulated. The evaluation of the ewes’ ration during late gestation by monitoring plasma concentrations of the ketone body 3-OH butyrate has been described with accurate guidelines, which have been used as the basis for flock nutritional advice during late gestation.

The achievement of optimum reproductive performance involves changing feeding strategies and adjusting the nutrient value of the diet as necessary throughout the reproductive cycle to meet the needs of the particular stage. The requirements for metabolizable energy begin to increase steadily above maintenance levels beginning at between 8 and 12 weeks of pregnancy and continuing into late pregnancy and lactation. During early lactation, when the energy requirements of prolific ewes exceed those required by the voluntary consumption of all but the highest-quality diets, the body fat reserves are used and then replenished toward the end of lactation, when milk yield declines, and in the period leading up to rebreeding.

In contrast to the ability of the ewe, particularly in early lactation, to use body reserves when the intake of energy fails to
Deficiencies of energy and protein

DEFICIENCIES OF ENERGY AND PROTEIN

DEFICIENCY OF ENERGY

ETIOLOGY

Insufficient quantity or quality of feed is a common nutritional deficiency and practical problem of feeding livestock. The term protein-energy malnutrition is used to describe a form of incomplete starvation in which energy and protein are present in the diet in suboptimal quantities. Protein and energy deficiencies usually occur concurrently in underfed livestock and often cannot be strictly separated.

EPIEDEMOLOGY

A deficiency of energy is the most common nutrient deficiency limiting performance of farm animals. There may be inadequate amounts of feed available, or the feed may be of low quality. Supplies of feed may be inadequate because of overgrazing, drought, snow covering, or it may be too expensive to be fed to the animals. Available feed may be of such low quality and digestibility that animals cannot consume enough to meet energy requirements. In some cases, forage may contain a high concentration of water, which limits total energy intake.

Clinical Findings

The clinical findings of an energy deficiency depend on the age of the animal, whether or not it is pregnant or in lactation, the presence of concurrent deficiencies of other nutrients and environmental influences. In general, an insufficient supply of energy in young animals results in retarded growth and delay in the onset of puberty. In mature animals, there is a marked decline in milk production and a shortened lactation. A prolonged energy deficiency in pregnant beef heifers will result in a failure to produce adequate quantities of colostrum at parturition. In mature animals, there is also a marked loss of body weight, especially during high demands for energy as in late pregnancy and early lactation. There are prolonged periods of anestrus lasting up to several months, which has a marked effect on reproductive performance in the herd. Primigravid females are particularly susceptible to protein-energy malnutrition because of growth and maintenance requirements. A prolonged deficiency of energy during late gestation may result in undersized, weak neonates with a high mortality rate.

Review Literature

REFERENCES

DEFICIENCY OF PROTEIN

A deficiency of protein commonly accompanies a deficiency of energy. However, the effects of the protein deficiency, at least in the early stages, are usually not as severe as those of energy. Insufficient protein intake in young animals results in reduced appetite, lowered feed intake, inferior growth rate, lack of muscle development, and a prolonged time to reach maturity. In mature animals, there is loss of weight and decreased milk production. In both young and mature animals, there is a drop in hemoglobin concentration, packed cell volume, total serum protein, and serum albumin. In the late stages, there is edema associated with the hypoproteinemia. Ruminants do not normally need a dietary supply of essential amino acids, in contrast to pigs which need a natural protein supplement in addition to the major portion of total protein supplied by the cereal grains. The amino acid composition of the dietary protein for ruminants is not critical because the ruminal flora synthesizes the necessary amino acids from lower quality proteins and non-protein sources of nitrogen.

CLINICAL FINDINGS

The clinical findings of an energy deficiency are similar to those of a protein deficiency and the clinical findings of both resemble many other specific nutrient deficiencies and subclinical disease. Protein-energy malnutrition in beef cattle occurs most commonly in late gestation and is characterized clinically by weakness, clinical recumbency, marked loss of body weight, a normal mental attitude, and a desire to eat. Cows with concurrent hypocalcemia will be anorexic. If the condition occurs at the time of parturition, there will be an obvious lack of colostrum. Calves of these cows may attempt to vigorously suck their dams, attempt to eat dry feed, drink surface water or urine andellow continuously. Affected calves and their calves may die within 7–10 days.

Protein-energy malnutrition is less common in dairy cattle because they are usually fed to meet the requirements of maintenance and milk production. Dairy calves fed inferior quality milk replacers during periods of cold weather will lose weight, become inactive, lethargic, and may die within 2–4 weeks. Affected calves may maintain their appetites until just before death. Diarrhea may occur concomitantly and be confused with acute undifferentiated diarrhea due to the enteropathogenic viruses or cryptosporidiosis. Affected calves recover quickly when fed cow’s whole milk.

Protein-energy malnutrition also occurs in sheep and, less commonly, in goats. Excessive dental attrition is a common cause in grazing sheep, which is exacerbated by the excessive ingestion of soil.

DIFFERENTIAL DIAGNOSIS

The diagnosis will depend on an estimation of the concentration of energy and protein in the feed, or a feed analysis, and comparing the results with the estimated nutrient requirements of the affected animals. In some cases, a sample of feed used several weeks earlier may no longer be available or the daily amount of feed intake may not be known. Marginal deficiencies of energy and protein may be detectable with the aid of a metabolic profile test. Specific treatment of livestock affected with protein-energy malnutrition is usually not undertaken because of the high cost and prolonged recovery period. Oral and parenteral fluid and electrolyte therapy can be given as indicated. The provision of high-quality feeds appropriate to the species is recommended.

PREVENTION

The prevention of protein-energy malnutrition requires the provision of the nutrient requirements of the animals according to age, stage of pregnancy and production, the environmental temperature and the cost of the feeds. Body-condition scoring of cattle and sheep can be used as a guide to monitor body condition and nutritional status. Regular analysis of feed supplies will assist in the overall nutritional management program. The published nutrient requirements of domestic animals are only guidelines to estimated requirements since they were determined in experimental animals selected for uniform size and other characteristics. Under practical conditions, all of the common factors that affect requirements must be considered.

Diseases associated with deficiencies of mineral nutrients

An enormous literature exists on the subject of mineral nutrient deficiencies in animals and it is not possible to review it all here. However, some general comments should be made. The era of large-scale deficiencies affecting very large numbers of animals and comprising single elements has now largely passed in developed countries. The diagnostic research work has been done and the guidelines for preventive programs have been outlined and put into action in the field, so that the major breakthroughs have already been made, and what remains is in many ways a tidying-up operation after large-scale control campaigns. The loose edges needing to be refined include correcting overzealous application of minerals, which can produce toxicoses, sorting out the relative importance of the constituent elements in combined deficiencies, which are characterized by incomplete response to provision of single elements, and devising means of detecting marginal deficiencies.

At least 15 mineral elements are nutritionally essential for ruminants. The macrominerals are calcium, phosphorus, potassium, sodium, chlorine, magnesium, and sulfur. The trace elements, or micro-minerals, are copper, selenium, zinc, cobalt, iron, iodine, manganese, and molybdenum. Improving trace element nutrition of grazing livestock, in a way that is cost effective and that meets consumer perceptions and preferences, is a continuing challenge.1

INCIDENCE AND ECONOMIC IMPORTANCE

Despite increasing experimental evidence that anomalies in trace element supply can influence growth, reproductive performance, or immunocompetence of livestock, few data exist from which the incidence and economic significance of such problems can reliably be assessed. Most published reports of the more readily recognized trace element-related diseases continue to provide insufficient quantitative information to assess their incidence and true economic impact. Despite these deficiencies in information, the FAO/WHO Animal Health Yearbooks indicate that, of the countries providing information on animal diseases, 80% report nutritional diseases of moderate or high incidence, and trace element deficiencies or toxicities are involved in more than half of those whose causes were identified. In the UK, it has been estimated that, despite the activities of its nutritional and veterinary advisory services and extensive policies of ration supplementation, characteristic clinical signs of copper deficiency develop annually in about 0.9% of the cattle population. In light of recently described evidence that copper deficiency can predispose to increased mortality due to infectious diseases in lambs, the
economic losses from copper deficiency may be grossly underestimated.

**DIAGNOSTIC METHODS AND STRATEGIES**

In developed countries with highly developed animal industries, the emphasis is on disease prevention rather than therapy, and elimination or economical control of trace element deficiencies is a matter of education rather than research. However, because copper, cobalt, selenium, and iodine deficiencies can affect reproductive performance, appetite, early postnatal growth, and immunocompetence on a herd or flock basis, increasing emphasis is being placed on diagnostic methods that will identify a developing risk long before specific clinical manifestations appear. In addition, it is not good enough to merely define the distribution of animal populations with an abnormal trace element status indicated by blood or tissue analysis, or to detect a deficiency of the trace element in the diet. The only feasible way of monitoring the preclinical stages of trace element deficiency is the identification of a biochemical indicator which reflects changes in the activity of the enzyme involved or the concentration in tissues of its substrate or products. The demand is growing for techniques that will predict when the likely pathological outcome of such anomalies justifies the introduction of protective measures. For example, recent observations indicate that a high proportion of grazing cattle become hypocupremic if maintained on forage, but fail to develop characteristic clinical signs of deficiency and, furthermore, only a small percentage of these animals exhibit any physiological response to the administration of copper. This illustrates the lack of understanding of the variables involved in the development of clinical manifestations of copper deficiency and whether they are induced by a simple dietary deficiency of copper or by specific copper antagonists present in the diet. A relatively new and interesting area of development is the observation of genetic variation in diet requirements for copper among different breeds of sheep and that sheep can be selected for a high or low concentration of plasma copper, which in turn will have profound physiological consequences in the low group. There is now evidence that heredity is involved in the utilization of trace elements by animals. A small amount is necessary, but a larger amount may be toxic, and there is a need to determine the optimal economic balance.

Thus, it is likely that trace element deficiencies are widespread, but their incidence and importance are probably underestimated because subclinical forms of deficiency can occur and go unnoticed for prolonged periods.

**DEFICIENCIES IN DEVELOPING COUNTRIES**

In developing countries, the trace element problem is confounded by the common deficiencies of energy, protein, phosphorus, and water, which affect postnatal growth and reproductive performance. Undernutrition is commonly accepted as the most important limitation to herbivore livestock production in tropical countries. However, mineral deficiencies or imbalances in soils and forages have long been held responsible for low production and reproduction problems among grazing tropical cattle. Cattle grazing forages in areas severely deficient in phosphorus, cobalt, or copper are even more limited by lack of these elements than either that of energy or protein.

**PATHOPHYSIOLOGY OF TRACE ELEMENT DEFICIENCY**

The physiological basis of trace element deficiency is complex. Some elements are involved in a single enzyme, some in many more, and a lack of one element may affect one or more metabolic processes. Furthermore, there are wide variations in how individual animals respond clinically to lowered blood or tissue levels of a trace element. For example, two animals in a herd or flock with the same copper levels in their blood may be in different bodily condition. The susceptibility to clinical disease may be a function of the stage of physiological development at which they occur, genetic differences within a species, and interrelationships with other trace elements. There is now good evidence to show that the amounts of dietary copper adequate for some breeds of sheep were deficient for others, and even toxic to others.

A dietary deficiency does not necessarily lead to clinical disease. Several factors predispose the animal to clinical disease and they include:

- The age at which the deficiency occurs (for example fetal lambs are highly susceptible to demyelination due to copper deficiency in late fetal life)
- Differences in genotype requirements
- Discontinuous demands for trace elements because of changes in environment
- The challenge of infections, diet, and production demands
- Individual variations in response to the deficiency, the use of alternative pathways by the body in the face of a deficiency
- Size of the functional reserves

The trace elements are involved as component parts of many tissues, and one or more enzyme activities and their deficiency leads to a wide variety of pathological consequences and metabolic defects. These are summarized in Table 30.1.

The soil-plant-animal interactions in relation to the incidence of trace element deficiencies in livestock are being examined. The soil and its parent materials

are the primary sources of trace elements on which soil-plant-animal relationships are built. The natural ranges in concentration of most trace elements in soils are wide and range from deficient soils to those which are potentially toxic. The availability of trace elements to plants is controlled by their total concentration in the soil and their chemical form. Certain species of plants take up more trace elements than do others. The ingestion of soil can have a profound effect on trace element nutrition and metabolism. Geochemical surveys can now assist in the identification of areas in which livestock are exposed to excessive ingestion or deficiencies of trace elements.

The dose–response trial will continue to play a significant role in the delineation of trace element deficiencies because it is often difficult to determine the role of individual trace elements. A deficiency of one trace element may result in clinical disease, which may be indistinguishable from a deficiency of more than one trace element. Many of the trace element deficiencies may produce non-specific as well as specific effects.

A dose–response trial can be defined as the application of a test and a control substance to a group, or replicates, of individuals and the measurement of the response to the treatment. The requirements for a reliable dose–response trial include a careful appraisal of the basis for conducting the trial, a suitable form of the test substance for treatment, the careful selection of animals for the test, a reliable biochemical method for monitoring the response to the trace element, a measurable production response, an adequate system for measurement of the variable that may influence the response, and a means of measuring the economic impact.

The ad hoc field observations made by veterinarians who make a diagnosis of a trace element deficiency, followed by treatment or dietary changes, are subjective and usually lack controls but are nevertheless of value in indicating the magnitude and variability of response that might be expected in future experimental studies. Dose-response trials help to establish a link between a trace element and certain clinical signs; they may identify factors which modify the response to a trace element and, of paramount importance, give an indication of the economic importance of adequate supplementation of the element in the diet.

There are major problems in the diagnosis and anticipation of trace element deficiencies in grazing livestock. Because of the interplay between the constituents of the diet and the homeostatic mechanisms of the body, it is often impossible to predict from dietary composition alone whether a particular nutritional regimen will result in clinical disease. The assessment of the absorbable, rather than the total, concentration of elements in the diet is now considered to be more important in understanding the nutritional basis for the deficiencies.

**LABORATORY DIAGNOSIS OF MINERAL DEFICIENCIES**

The diagnosis of mineral deficiencies, particularly trace element deficiencies, will depend heavily on the interpretation of the biochemical criteria of the trace element status. This is because deficiencies of any one or more of several trace elements can result in non-specific clinical abnormalities, such as loss of weight, growth retardation, anorexia, and inferior reproductive performance.

The interpretation of biochemical criteria of trace element status are governed by three important principles: relationship with intake, time, and function.

1. **Relationship between the tissue concentrations of a direct marker and the dietary intake of the element** will generally be sigmoid in shape (a dose–response curve). The important point on the curve is the intake at which the requirement of the animal is passed, which is the intake of the nutrient needed to maintain normal physiological concentrations of the element and/or avoid impairment of essential functions. For several markers of trace element status, the position on the x-axis at which requirement is passed coincides with the end of the lower plateau of the response in marker concentration. Under these conditions, the marker is an excellent index of sufficiency and body reserves, but an insensitive index of a deficiency. If requirement is passed at the beginning of the upper plateau, the marker is a poor index of sufficiency, but a good index of deficiency. This principle allows direct markers to be divided into storage and non-storage types corresponding to the former and latter positions on the x-axis.

2. **Non-storage criteria can be divided into indicators of acute and chronic deficiency** and two types of relationships can be distinguished: a rapid, early decline in marker concentration followed by a plateau, and a slow, linear rate of decline. Markers with a slow, linear response will be good indices of a chronic deficiency, but unreliable indices of acute deficiency, because they cannot respond quickly enough. Conversely, the marker with a rapid, early decline will be a good index of acute deficiency, but an unreliable indicator for chronic deficiency if the low plateau is reached before functions are impaired. Those biochemical criteria that are based on metalloenzyme or metalloprotein concentrations in erythrocytes are of the slow type because the marker is incorporated into the erythrocyte before its release into the bloodstream, and thereafter its half-life is determined by that of the erythrocyte that is 150 days or more. Metalloenzymes or metalloproteins in the plasma with short half-lives provide markers of the rapid type.

3. A deficiency can be divided into four phases: depletion, deficiency (marginal), dysfunction, and clinical disease.

**Depletion** is a relative term describing the failure of the diet to maintain the trace element status of the body, and it may continue for weeks or months without observable clinical effects when substantial body reserves exist. When the net requirement for an essential element exceeds the net flow of absorbed element across the intestine then depletion occurs. The body processes may respond by improving intestinal absorption or decreasing endogenous losses. During the depletion phase, there is a loss of trace element from any storage sites, such as the liver, during which time the plasma concentrations of the trace element may remain constant. The liver is a common store for copper, iron, and vitamins A and B₁₂.

If the dietary deficiency persists, eventually there is a transition from a state of depletion to one of deficiency, which is marked by biochemical indications that the homeostatic mechanisms are no longer maintaining a constant level of trace elements necessary for normal physiological function. After variable periods of time, the concentrations or activities of trace element-containing enzymes will begin to decline leading to the phase of dysfunction. There may be a further lag period, the subclinical phase, before the changes in cellular function are manifested as clinical disease. The biochemical criteria can be divided, according to the phase during which they change, into indicators of marginal deficiency and dysfunction. The rate of onset of clinical disease will depend on the intensity of the dietary deficiency, the duration of the deficit and the size of the initial reserve. If reserves are non-existent, as with zinc metabolism, the effects may be acute and the separate phases become superimposed. The application of these principles to the interpre-
tation of biochemical criteria of trace element status are presented later in this chapter where applicable, under each mineral nutrient.

The definitive etiological diagnosis of a trace element deficiency will depend on the response in growth and health obtained following parenteral treatment or supplementation of the diet. The concurrent measurement of biochemical markers will aid in the interpretation and validation of those markers for future diagnosis. The strategies for anticipating and preventing trace element deficiencies include regular analysis of the feed and soil, which are not highly reliable; and monitoring samples from herds and flocks to prevent animals from entering the zone of marginal trace element deficiencies which precedes the onset of functional deficiency. The decision to intervene can be safely based on the conventional criteria of marginal trace element status.

REVIEW LITERATURE

COBALT DEFICIENCY
Cobalt deficiency is a disease of ruminants ingesting a diet deficient in cobalt, which is required for the synthesis of vitamin B\textsubscript{12}. The disease is characterized clinically by inappetence and loss of body weight. Some effects on reproductive performance in sheep have been reported. Cobalt was first shown to be an essential nutrient for sheep and cattle as an outcome of Australian investigations in the 1930s of two naturally occurring diseases, 'coast disease' of sheep, and 'wasting disease' or enzootic marasmus, of cattle.

Necropsy findings
- Emaciation
- Hemorrhages of spleen

Diagnostic confirmation
Vitamin B\textsubscript{12} and cobalt of liver.

Differential diagnosis list
- Common causes of ill-thrift in ruminants:
  - Copper deficiency
  - General nutritional deficiency (protein and energy)
  - Johne's disease
  - Intestinal helminthiasis.

Treatment
Oral dosing with cobalt or parenteral injections of vitamin B\textsubscript{12}.
Control
Dietary supplementation with cobalt. Cobalt-heavy pellets.

ETIOLOGY
The disease is caused by a deficiency of cobalt in the diet which results in a deficiency of vitamin B\textsubscript{12}.

EPIDEMIOLOGY
Occurrence
The literature on the diagnosis, treatment, control of cobalt deficiency in ruminants in New Zealand has been reviewed. The literature on the occurrence of cobalt deficiency, and the use of diagnostic tests in sheep, and their limitations and reference ranges for various age groups has also been reviewed.

Cobalt deficiency occurs in Australia, New Zealand, the UK, North America, the Netherlands, and probably occurs in many other parts of the world. Where the deficiency is extreme, large tracts of land are unsuitable for the raising of ruminants, and in certain areas suboptimal growth and production may be limiting factors in the husbandry of sheep and cattle.

Historically, in severely cobalt deficient areas in New Zealand, ill-thrift was so marked that calves and lambs died. In those that survived, growth rates were markedly depressed and often zero over summer months compared with cobalt supplemented lambs. In New Zealand, cobalt deficiency is now mainly confined to lambs, because severely deficient areas, where the deficiency occurred in adult sheep and cattle, and in lambs, have had cobalt fertilizer applied for many decades.

Cobalt responsive ill-thrift in lambs still occurs where cobalt fertilizer applications or vitamin B\textsubscript{12} injections to lambs are haphazard. Live weight gains to supplementary vitamin B\textsubscript{12} injections of up to 180 g/d have been reported.

The concentration of cobalt in the soil can vary widely as, for example, in Irish cattle farms where the soil cobalt content varied between 0.2 and 18 mg/kg dry matter (DM), the forage had marginal to normal cobalt content, and low or very low blood vitamin B\textsubscript{12} status was found in 55% of herds sampled. However, the significance of the cobalt deficiency clinically is uncertain. Cattle and sheep are similarly affected and the signs are similar in both species. Cattle are slightly less susceptible than sheep, and lambs and calves are more seriously affected than adults. Cobalt-vitamin B\textsubscript{12} deficiency occurs in grazing lambs in the Netherlands and chronic hepatitis or ovine white liver disease are manifestations of the deficiency.

Although the disease occurs most commonly in ruminants at pasture in severely deficient areas, sporadic cases occur in marginal areas, especially after long periods of stable feeding. Bulls, rams, and calves are the groups most commonly affected, although dairy cows kept under the same conditions may develop a high incidence of ketosis.

A disease of moose called 'moose sickness' occurs in Eastern North America is related to a cobalt- and vitamin B\textsubscript{12} deficiency. Affected moose are geographically localized mainly to the regions of the Tobeatic and Cape Breton Highlands of Nova Scotia in Canada. There are low concentrations of cobalt and vitamin B\textsubscript{12} in liver and increased concentrations of methylocobalamin in the plasma. There are striking similarities between the North American moose sickness and the mysterious' moose disease in Sweden, which is caused by molybdenosis.

Frank deficiency is unlikely to occur in pigs, or in other omnivores or carnivores, because vitamin B\textsubscript{12} is present in meat and other animal tissues, but there are some reports of improved weight gains following supplementation of the ration with cobalt. Horses appear to be unaffected.

Risk factors
Dietary and environmental factors
Pastures containing less than 0.07 and 0.04 mg/kg DM result in clinical disease in sheep and cattle, respectively. The daily requirement for sheep at pasture is 0.08 mg/kg DM of cobalt; for growing lambs the need is somewhat greater and at pasture levels of less than 0.10 mg/kg DM inefficient rates of gain are likely. For growing cattle, an intake of 0.04 mg/kg DM in the feed is just below requirement levels. Variations in the cobalt content of pasture occur with seasonal variations in pasture growth and with drainage conditions. The increased incidence of the disease, which has been observed in the spring, may be related to domination of the pasture by rapidly growing grasses, which have a lower cobalt content than legumes. There is also a great deal of variation between years in the severity of the...
losses encountered due to variations in the cobalt status of the animals. Forage grown on well-drained soils has a greater cobalt content than that grown on poorly drained soils of the same cobalt status. Plant growth is not visibly affected by a low cobalt content of the soil, but the addition of excessive quantities may retard growth.

Cobalt is also protective against the liver damage in sheep exposed to annual ryegrass.12

**Primary cobalt deficiency occurs only on soils which are deficient in cobalt.** Such soils do not appear to have any geological similarity, varying from wind-blown shell sands to soils derived from pumice and granite. Japanese soils composed largely of volcanic ash are seriously deficient. A survey in New Brunswick, Canada, revealed the average value for grass samples was 0.028 mg/kg DM, and for legume samples, 0.088 mg/kg DM, which justifies supplementation of ruminant diets with cobalt. The soils in New Brunswick are naturally acidic and with the heavy annual rainfall of 120 cm the cobalt content of the soil is decreased by leaching.

After the introduction of domestic livestock into New Zealand, it was realized that in some areas livestock did not thrive, or were affected with particular diseases not occurring in other areas. Large parts of New Zealand were subsequently discovered to be trace-element deficient (cobalt, selenium, and copper) and these deficiencies have been a significant part of the agricultural scene ever since.13 Livestock grazing pastures grown on such soils may be deficient in one or more of these trace elements.

In New Zealand, soil types are categorized as severe, moderate or marginal. In total, of the land considered suitable for farming, about 1 million hectares in the North Island and 918,000 hectares in the South Island have been defined as cobalt deficient.6

Outbreaks of cobalt deficiency have occurred in cattle grazing on pastures on the granite-derived northern tablelands of New South Wales in Australia, and in sheep grazing pasture on soils derived from weathered rhyolite and ignimbrite, the former being inherently low in cobalt. Cobalt deficiency is now occurring in areas where it has never before been diagnosed, and in seasons of lush spring and summer pasture growth, cobalt deficiency should be suspected as a cause of unthriftiness. Lambs grazing cobalt-deficient pastures of the Northern Netherlands are 6.7 times more likely to die if unsupplemented with cobalt than supplemented lambs.13 In the Netherlands, on farms with a history of ill-thrift caused by cobalt/vitamin B12 deficiency, the acetic acid-extractable soil cobalt content of the pastures was above the reference value for cobalt deficiency (50.30 mg Co/kg dried soil).4 These concentrations are below the minimum requirement for sheep (0.07 mg/kg DM). The high soil pH (6.5) and the good drainage conditions on the farm were probably primary factors responsible for the low soil cobalt availability.

Although soils containing less than 0.25 mg/kg cobalt are likely to produce pastures containing insufficient cobalt, the relationship between levels of cobalt in soil and pasture is not always constant. The factors governing the relationship have not been determined, although heavy liming is known to reduce the availability of cobalt in the soil. Manganese appears to have a similar action, but the agricultural significance of the relationship is unknown.

**Ovine white liver disease**

A specific hepatic dysfunction of sheep has been described in New Zealand, Australia, the UK,14 Norway,15 and in grazing lambs in the Netherlands.4 It has been called ‘white liver disease’ because of the grayish color of the liver. Clinically, it is manifested by photosensitization when the disease is acute, and anemia and emaciation when the disease is chronic. It seems likely that the disease is a toxic hepatopathy against which adequate levels of dietary cobalt are protective.16

**Hepatic lipidosis in goats**

Hepatic lipidosis has occurred in Omani goats in many parts of Oman for many years but the cause was unknown.17,18 It is now known that low levels of serum vitamin B12 or low levels cobalt in the liver are associated with the liver lesion, and it can be experimentally reproduced using low levels of cobalt intake.19 Abattoir surveys of goat livers found that hepatic lipidosis was one of the most frequent causes of their condemnation.18 Because the goat is the predominant domesticated animal type raised for meat in the Sultanate of Oman, the condemnation of goat livers at slaughter represents a significant economic loss.18

**Experimental reproduction of cobalt deficiency in sheep**

Cobalt deficiency can be reproduced in sheep diet containing less than 70 µg/kg cobalt. Feeding a diet containing 4.5 µg/kg to lambs produced a severe vitamin B12 deficiency, characterized by subnormal plasma and liver concentrations of vitamin B12 and reduced growth rate, serous ocular discharge, alopecia, and emaciation, similar to naturally occurring outbreaks of cobalt deficiency in sheep.30 Fatty degeneration of the liver was associated with reduced concentrations of vitamin B12 (14.5 pmol/g) at necropsy. Liver lesions included accumulation of lipid droplets and lipofuscin particles in hepatocyte, dissociation and necrosis of hepatocyte, and sparse infiltration by neutrophils, macrophages, and lymphocytes. Ultrastructural hepatocytic alterations included swelling, condensation and proliferation of mitochondria, hypertrophy of smooth endoplasmic reticulum, vesiculation and loss of arrays of rough endoplasmic reticulum, and accumulation of lipid droplets and lipofuscin granules in cytoplasm of hepatocytes. Co-factors are not a prerequisite to development of hepatic damage in cobalt-deficient sheep. Reduced activities of the vitamin B12-dependent enzymes, methylmalonyl CoA mutase and methionine synthesis, and lipid peroxidation are likely pathogenetic importance in the development of the lesions.

**PATHOGENESIS**

Cobalt is unique as an essential trace element in ruminant nutrition because it is stored in the body in limited amounts only and not in all tissues. In the adult ruminant, its only known function is in the rumen and it must, therefore, be present continuously in the feed.

The effect of cobalt in the rumen is to participate in the production of vitamin B12 (cyanocobalamin), and compared with other species the requirement for vitamin B12 is very much higher in ruminants. In sheep, the requirement is of the order of 11 µg/d, and probably 500 µg/d are produced in the rumen, most being lost in the process. Animals in the advanced stages of cobalt deficiency are cured by the oral administration of cobalt or by the parenteral administration of vitamin B12. On cobalt-deficient diets, the appearance of signs is accompanied by a fall of as much as 90% in the vitamin B12 content of the feces, and on oral dosing with cobalt the signs disappear and vitamin B12 levels in the feces return to normal. Parenteral administration of cobalt is without appreciable clinical effect, although some cobalt does enter the alimentary tract in the bile and leads to the formation of a small amount of cobalamin.

The **essential defect in cobalt deficiency in ruminants is an inability to metabolize propionic acid**. A key biochemical pathway for propionic acid from rumen fermentation involves adenosyl cobalamin, one of several cobalt-containing coenzymes of the vitamin B12 complex that is required for the conversion of methylmalonyl coenzyme A to succinyl coenzyme A, both intermediates in the utilization pathway of propionate. Lack of vitamin B12 results in accumulation of methylmalonic acid which can be measured in the serum.
The pathogenesis of ovine white liver disease is unclear. It is unknown if the disease is a simple cobalt deficiency, or a hepatotoxic disease in cobalt/vitamin B12-deficient lambs. Marginal to deficient cobalt-deficient grass is essential for the development of the disease. Cobalt fertilization of deficit pastures results in an increase in vitamin B12 in lambs. Hepatic dysfunction occurs in affected sheep. Affected lambs generally have higher serum levels of copper than in cobalt/vitamin B12-supplemented lambs grazing the same pastures. Dosing affected lambs with copper oxide needles resulted in toxic levels of liver copper. It is suggested that the disease is a manifestation of B12 deficiency made worse by factors triggering early hepatic fatty change, resulting in more severe liver damage and loss of intracellular homeostasis, rendering the hepatocytes more vulnerable to other elements such as copper. The amount of fructan in the pasture may be an important factor in the pathogenesis of the lesion. One hypothesis suggests that the high level of fructan may initiate hepatic lipodystrophy, leading to hepatic insufficiency, growth reduction and ovine white liver disease. Vitamin B12 is therapeutic.

The pathological changes in lambs grazing cobalt-deficient pastures are related to blood concentrations of vitamin B12, methylmalonic acid, and homocysteine, and lesions are confined mainly to the liver and brain. Acute and chronic hepatic steatosis are characteristic and the liver lesions are associated with polymicrocavitation of the brain.

Hepatic encephalopathy associated with cobalt deficiency and white liver disease has been described in lambs. Symmetrical vacuolation and status spongiosus of the neuropil in the brain were characteristic and hyperammonemia secondary to the hepatic lesion is considered to be the cause of the brain lesions.

Caprine hepatic lipidosis has been induced experimentally using low intakes of low levels of dietary cobalt. Goats provided with a diet which contains the minimum daily requirement of cobalt as specified for sheep not only developed a syndrome characterized by reduced weight gains, dry, scruffy hair coat and a decline in erythrocyte indices but also lesions consistent with hepatic lipidosis. Goats fed diets containing levels of cobalt less than 0.1 mg/kg DM could experience even greater clinical and pathological consequences.

In 'Moose sickness' there are low concentrations of cobalt and vitamin B12 in liver and increased concentrations of methylmalonic acid in plasma.

**CLINICAL FINDINGS**

No specific signs are characteristic of cobalt deficiency. A gradual decrease in appetite is the only obvious clinical sign. It is accompanied by loss of body weight, emaciation, and weakness, and these are often observed in the presence of abundant green feed. Pica is likely to occur, especially in cattle. There is marked pallor of the mucous membranes and affected animals are easily fatigued. Growth, lactation, and wool production are severely retarded, and the wool may be tender or broken. In sheep, severe lacrimation with profuse outpouring of fluid sufficient to mat the wool of the face is one of the most important signs in advanced cases. Signs usually become apparent when animals have been on affected areas for about 6 months and death occurs in 3–12 months after the first appearance of illness, although severe wasting may be precipitated by the stress of parturition or abortion.

Cobalt deficiency in pregnant ewes can result in decreased lambing percentage, increased percentage of stillbirths, and increased neonatal mortality. Lambs deficient from ewes are slower to start suckling, have reduced concentrations of serum colostal immunoglobulins, and have lower serum vitamin B12 and higher methylmalonic acid concentrations than lambs from cobalt-adequate dams.

'Moose sickness' in Nova Scotia is characterized by a loss of fear of man, weakness, and a staggering gait, apparent blindness, drooping of the ears, and emaciation and infestation by ticks. A decreased intake of food, increasing lethargy and collapse, accompanied by loss of use of one or more limbs, precedes death.

**CLINICAL PATHOLOGY**

Biochemical criteria to determine cobalt and vitamin B12 status

Changes in the concurrent serum concentrations of methylmalonic acid and vitamin B12 of ewes and their lambs on cobalt-deficient pastures, and their response to cobalt supplementation can be evaluated and monitored. Those same changes can be evaluated during supplementation of lambs while suckling and after weaning on farms in the South Island of New Zealand considered to be cobalt-deficient. These measurements are commonly done along with recording live weight gains, and analysis of pasture for cobalt content at the sampling times for blood MMA and vitamin B12.

Growth responses to cobalt or vitamin B12 supplementation is anticipated when cobalt levels in herbage fall below 0.08–0.1 mg/K DM.

**Serum and hepatic cobalt and vitamin B12 concentrations**

Serum cobalt. Cobalt concentrations in the serum of normal sheep are of the order of 1–3 μg/dL (0.17–0.51 μmol/L), and in deficient animals these are reduced to 0.03–0.41 μmol/L.

Serum vitamin B12. Clinical signs of cobalt deficiency in sheep are associated with serum vitamin B12 levels of less than 0.20 mg/mL, and serum vitamin B12 levels are used as a laboratory test of cobalt status in animals. Levels of 0.2–0.25 μg/L are indicative of cobalt deficiency. These rise rapidly to 0.5–1.0 μg/L on treatment. The value of serum vitamin B12 assay as a diagnostic tool is in some doubt, but correctly interpreted they appear to be worthwhile. Serum vitamin B12 values greater than 0.2 μg/L are indicative of a normal vitamin B12 status in cattle. Deprivation of feed from sheep for 24 h results in a marked increase in serum vitamin B12. The serum vitamin B12 levels of sheep at pasture are unreliable indicators of liver vitamin B12.

Concurrent serum MMA and vitamin B12 concentrations. Concurrent changes in serum MMA and vitamin B12 concentrations in cobalt-supplemented ewes and their lambs on cobalt-deficient farms were monitored. Serum concentrations of vitamin B12 fell below 250 pmol/L during early lactation, and as low as 100 pmol/L. MMA concentration was maintained below 2 μmol/L in serum from supplemented ewes but increased to mean concentrations ranging from 7 to 14 μmol/L at the nadir of serum vitamin B12 concentration during
peak lactation. A significant live weight response to supplementation occurred in ewes, and the vitamin B$_{12}$ concentration in the ewe's milk and in the livers of their lambs more than doubled. Serum MMA in the ewe's milk and in the livers of their performance of the lamb for response to supplementation occurred in centimeters are necessarily indicative of concentrations nor elevated concentration provides a more precise bullet appears to protect the growth supplementation. Neither very low serum vitamin MMS have been compared as indices responsiveness are conservatively high concentrations in excess of $>13$ $\mu$mol/L indicate unresponsiveness. In $<7$ $\mu$mol/L represent subclinical deficiency. Cobalt-adequate lambs have plasma MMA levels of less than $<5$ $\mu$mol/L, urinary MMA less than $<2$ $\mu$mol/L and urinary MMA/creatinine values of less than $<0.022$ $\mu$mol MMA/mmol of urinary creatinine. In a cobalt-deficient animal the methylmalonic content of urine is abnormally high and this has some merit as a test for the presence of the deficiency. Cobalt levels in the liver. In normal sheep, iron levels in the liver and spleen, and low cobalt levels in the liver. In normal sheep, cobalt levels in the liver are usually above 0.20 mg/kg DM, but in affected sheep are typically less than 0.05 mg/kg DM. Liver cobalt levels in cattle fed excessive amounts of cobalt and thought to be affected by cobalt poisoning can be as high as 69 mg/kg DM.

Necropsy findings

At necropsy, emaciation is extreme. The livers of sheep affected with white liver disease are pale and fatty. In most cases of cobalt deficiency, the spleen is dark due to the accumulation of hemosiderin. The microscopic changes of ovine white liver disease include hepatocellular dissociation and intracytoplasmic accumulations of lipid and ceroid-lipofuscin within hepatocytes. The ultrastructural changes of experimentally-induced ovine white liver disease have also been documented.

Biological assays reveal very high iron levels in the liver and spleen, and low cobalt levels in the liver. In normal sheep, cobalt levels in the liver are usually above 0.20 mg/kg DM, but in affected sheep are typically less than 0.05 mg/kg DM. Liver cobalt levels in cattle fed excessive amounts of cobalt and thought to be affected by cobalt poisoning can be as high as 69 mg/kg DM.

Normal levels of vitamin $B_{12}$ in the liver are of the order of 0.3 mg/kg, falling to 0.1 mg/kg in deficient lambs. In cattle, clinical signs occur with liver vitamin $B_{12}$ levels of less than 0.10 mg/kg, and levels of 0.3 mg/kg of liver are necessary for optimum growth. Normal levels of the vitamin of cattle in New Zealand are 0.70–1.98 mg/kg of liver. After oral dosing with cobalt, the level of the element in the liver rises, but returns to the pretreatment level in 10–30 days. Since serum $B_{12}$ levels reflect cobalt status, it is often useful to submit sera from surviving herdmates when attempting to confirm the diagnosis.

Samples for confirmation of diagnosis
- Toxicology - 50 g liver (ASSAY Co), 2 mL serum (ASSAY $B_{12}$)
- Histology - formalin-fixed liver (LM)
## Differential Diagnosis

Cobalt deficiency must be differentiated from other causes of 'ill-thrift' or 'enzootic marasmus'. Ill-thrift in young animals, in which this situation is most often encountered, nutritional deficiencies of copper, selenium, and vitamin D are possible causes of ill-thrift. Lack of total digestible nutrients is the most common cause of thin animals, but owners are usually aware of the shortage and do not present their animals for diagnosis. However, it does happen, especially with urban people who become farmers and are unaware of the actual needs of animals. So it is best to check the feed supply and also to check whether or not the animals have any teeth. These circumstances are seen so commonly in today's era of hobby farms that a new disease category 'hobby farm malnutrition' is warranted.

### Internal Parasitism

Careful necropsy or fecal examination will determine the degree of helminth infestation, but cobalt-deficient animals are more susceptible to parasitism and the presence of a heavy parasite load should not rule out the diagnosis of primary cobalt deficiency. It is also common for parasitic disease and cobalt deficiency to occur together in the one animal. It is then necessary to make two diagnoses and conduct two control programs. In sheep, special care is needed to differentiate the disease from Johne’s disease. The differential diagnosis of anemia has been discussed elsewhere.

### Dietary Supplementation Response

The most conclusive method of determining if animal production is being affected by the deficiency of a trace mineral is to measure the response of a production parameter, such as weight gain, milk production, wool production, or reproductive performance following supplementation of animals with the element under consideration. However, if the degree of response can be related to a tissue level of the element, or its metabolites, then tissue analyses can replace the need for field trials, which require considerable expertise and resources and can take several months to monitor the results and obtain a quantitative outcome.

### Growth Response Curve to Supplementation

A new approach to defining mineral deficiencies is based on constructing response curves for any specified level of serum vitamin B12 that can be used to determine live weight response to supplementation and the probability of obtaining a response. The technique closely relates the tissue mineral or biochemical indicator with the degree of production response to treatment. The advantages of this method over the traditional method have been described. The results from published and unpublished cobalt/vitamin B12 weight response trials in young sheep grazing pasture in New Zealand have been reviewed. No significant weight gain responses occurred to vitamin B12 or cobalt treatment in trials with serum vitamin B12 levels above 500 pmol/L. For serum vitamin B12 levels greater than 500 nmol/kg, the fitted response curve approached 0 g/day at 500 pmol/L for serum vitamin B12 and 375 nmol/kg for liver vitamin B12. The minimum vitamin B12 at which an economic response to treatment (10 μg/day BW gain) is not likely is 336 pmol/L for serum and 282 nmol/kg for liver. Variable responses to cobalt or vitamin B12 include age, breed, sex, energy intake, concurrent disease, and length of pasture. Higher soil contamination on short pastures may result in increased cobalt intake and reduced response to vitamin B12 or cobalt. Serum vitamin B12 levels may also increase following prolonged yarding, and within 24-48 h after changes in dietary cobalt.

## TREATMENT

### Cobalt and Vitamin B12

Affected animals respond satisfactorily to oral dosing with cobalt or the IM injection of vitamin B12. Oral dosing with vitamin B12 is effective, but much larger doses are required. Oral dosing with cobalt sulfate is usually at the rate of about 1 mg cobalt/d in sheep and can be given in accumulated doses at the end of each week. Intervals of 2 weeks between dosing are inadequate for the best possible response. On the other hand, the monthly dosing of lambs with oral doses of 300 mg cobalt is sufficient greatly to reduce deaths and permit some growth at suboptimal levels. The response to dosing is very quick, significant elevation of serum vitamin B12 levels being evident within 24 h. When large doses of cobalt are administered to some sheep, other undosed sheep on the same pasture may find sufficient additional cobalt on the pasture from the feces of their flockmates to meet their needs. No exact data are available on dose rates for cattle but ten times the prophylactic rate should be effective. Vitamin B12 should be given in 100-300 μg doses for lambs and sheep at weekly intervals. Vitamin B12 therapy is not likely to be used generally because of the high cost and the comparable effect of oral cobalt administration. However, vitamin B12 (hydroxocobalamin) may be a suitable therapeutic agent. One injection of 1 mg provides protection to lambs for 14 weeks, and for weaners, protection for up to 40 weeks. Treatment of lambs with ovine white liver disease with hydroxocobalamin results in an immediate beneficial response and treatment is repeated 10 days later.

### Cobalt Toxicity

Overdosing with cobalt compounds is unlikely, but toxic signs of loss of weight, rough hair coat, listlessness, anorexia, and muscular incoordination appear in calves at doses rates of about 40-45 mg of elemental cobalt per 50 kg BW/d. Sheep appear to be much more resistant to the toxic effects of cobalt than are cattle. Pigs have tolerated up to 200 mg cobalt/kg of diet. At intakes of 400 and 600 mg/kg there is growth depression, anorexia, stiff legs, incoordination and muscle tremors. Supplementation of the diet with methionine, or with additional iron, manganese, and zinc alleviates the toxic effects.

## CONTROL

### Supplement Diet with Cobalt

The recommended level of cobalt in the diet for sheep and cattle has for many years been about 100 μg/kg DM. Based on the levels of homocysteine and methylmalonic acid together with the vitamin B12 and hepatic folate status as predictors of the magnitude of cobalt-vitamin B12 status in assessing the cobalt requirements in cattle, the recommended levels of dietary cobalt to achieve maximum vitamin B12 levels are 250 μg/kg DM. If such levels are not available, supplementation of the diet with cobalt is necessary. Calves reared on cobalt-deficient pastures require cobalt or vitamin B12 supplementation prior to weaning.

### Top Dressing of Pastures with Cobalt

Cobalt deficiency in grazing animals can be prevented most easily by the top-dressing of affected pasture with cobalt salts. The amount of top-dressing required will vary with the degree of deficiency. Recommendations include 400-600 g/ha cobalt sulfate annually or 1.2-1.5 kg/ha every 3-4 years. The response to pasture treatment is slow, requiring some weeks to complete. Affected animals should be treated orally or by injection of vitamin B12 to obtain a quick, interim response.

In New Zealand, the requirement for cobalt of ruminants grazing on the pumice soils of the Central Plateau was established in the 1930s and top-dressing to increase the cobalt intake was widely practiced for many years. An on-farm survey conducted in 1978-1979 indicated that cobalt inputs could be halved because adequate reserves of soil cobalt had accumulated. However, the economic downturn in agriculture resulted in less use of cobalt, and follow-up surveys indicated a general overall decline in soil and pasture cobalt levels, which was pronounced in areas with a poor history of top-dressing. There is now a need to increase the soil level of cobalt to prevent cobalt deficiency in grazing ruminants. A regular cobalt input is required to build up reserves. This input requirement is about 350 g cobalt sulfate/ha for 7-10 years on
The use of 'heavy pellets' containing 90% pasture, and animal cobalt status. To achieve a level of cobalt of 0.08 mg/kg DM in pasture (the critical level for sheep) a soil cobalt level of 1.7 and 2.2 mg/kg DM is required for the yellow-brown pumice soils and yellow-brown loams, respectively. Supplementation of the diet with 0.1 mg cobalt/d for sheep and 0.3–1.0 mg/d for cattle is required, and can be accomplished by inclusion of the cobalt in salt or a mineral mixture. Cobalt can also be supplied to cattle in their drinking water supply.

**Cobalt-heavy pellet**
The use of 'heavy pellets' containing 90% cobalt oxide is an alternative means of overcoming the difficulty of maintaining an adequate cobalt intake in a deficient area. The pellet is in the form of a bolus (5 g for sheep, 20 g for cattle) which, when given by mouth, lodges in the reticulum and gives off cobalt continuously in very small but adequate amounts. Reports on their use in sheep and cattle indicate that they are effective. Administration of the pellets to lambs and calves less than 2 months old is likely to be ineffective because of failure to retain them in the undeveloped reticulum. The problem of cobalt deficiency in suckling animals can be overcome in part if the dams are treated because of the increased vitamin B12 content of their milk, but the daily intake of the lambs will still be much below the minimal requirement. In about 5% of animals, the pellets do not lodge in the reticulum and approximately 20% are rejected during the year after administration. If no response occurs, re-treatment is advisable. A further possible cause of failure is where pellets become coated with calcareous material, particularly if the drinking water is highly mineralized or if pasture top-dressing is heavy. The effects of pellet coating can be overcome by simultaneous dosing with an abrasive metal pellet. The cost is relatively high and, where top-dressing of pastures is practiced, addition of cobalt to the fertilizer is the cheaper form of administration. Pellets are preferred in extensive range grazing where top-dressing is impractical and animals are seen only at infrequent intervals.

**Controlled release glass boluses of cobalt**
Boluses of controlled release glass containing cobalt are available for oral administration to cattle and sheep. The boluses are retained in the forestomachs for up to several months and slowly release cobalt. **Combine cobalt with administration of anthelmintics**
Anthelmintics are convenient and efficient vehicles for supplementing the diet with selenium and cobalt on a regular basis, because both the selenium and cobalt status of lambs decline as they become dependent on forage, with its adherent nematode larvae, for their nutrients. As a result, the periods of highest incidence of cobalt and selenium deficiency and hemolymphosis coincide. In one trial, there were lasting responses to selenium but transient, though significant, responses to the cobalt in the form of increases in plasma vitamin B12. In some trials, the administration of a monthly bolus of 250 mg cobalt was more effective than the cobalt in the anthelmintic. The optimum level of cobalt supplementation of an anthelmintic ranges from 20 to 100 mg cobalt per treatment. When the anthelmintic is given at 3-weekly intervals, there may be a cumulative effect. A comparison of giving 500 μg cyanocobalamin subcutaneously to one group of lambs, with 2.5 mg cobalt orally in an anthelmintic to another group, revealed that even the lowest dose of cobalt in anthelmintics will be of some nutritional benefit.

**Vitamin B12 injections**
The relationship in lambs between daily weight gains and vitamin B12 status in the serum and liver vitamin B12 concentrations is well defined. Lambs with serum vitamin B12 concentrations >335 pmol/L and liver vitamin B12 concentrations >280 nmol/kg fresh tissue are cobalt deficient and will show a marked increase in growth rates when supplemented with cobalt or vitamin B12.

The subcutaneous injection of a soluble vitamin B12 in lambs was effective in increasing and maintaining the vitamin B12 status for about 24 days. In cobalt deficient areas lambs should be given a 2 mg dose of vitamin B12 at least bi-monthly to reduce the risk of vitamin B12 deficiency.

A microencapsulated vitamin B12 in lactide/glycolide copolymers is able to increase and maintain vitamin B12 status of lambs for at least 210 days. The treatment of ewes grazing cobalt deficient pastures 4–5 weeks prior to mating should ensure an increase in the storage of vitamin B12 in the fetal liver and an increase in the vitamin B12 content of colostrum and milk. The growth rates of cobalt deficient lambs, 4–6 weeks of age, were markedly improved by injections of 3.0, 4.5, or 6.0 mg of microencapsulated vitamin B12 and live weights were maintained for at least 260 days. An injection of 3 mg microencapsulated vitamin B12 given to lambs at tailing will prevent cobalt deficiency and increase and maintain live weight gains in a flock for up to 8 months.

The vitamin B12 status of ewes can be increased during gestation and lactation by three injections of a long-acting preparation of vitamin B12 microencapsulated in an organic acid polymer given subcutaneously at 120 days prepartum (30 days after the ram had bred the ewes), 40 days prepartum, and 40 days post partum. Compared with controls, serum and liver vitamin B12 concentrations of the treated ewes were increased by 70% during gestation. Fetal liver vitamin B12 concentrations were increased 270%. Over the lactation, ewe serum and milk vitamin B12 concentrations were increased at least 200% and 44%, respectively. The liver vitamin B12 stores of the newborn lambs from vitamin B12 treated ewes were depleted within 58 days. Ewes with a high vitamin B12 status will ensure an adequate supply of vitamin B12 to their lambs for at least the first 30 days of life.

A long-acting injectable microencapsulated vitamin B12 at a dose rate of 0.12–0.24 mg/kg BW will increase and maintain the vitamin B12 in dairy calves for at least 110 days.

COPPER DEFICIENCY

Synopsis

Etiology Primary copper deficiency due to inadequate levels in diet. Secondary copper deficiency due to conditioning factors such as excess molybdenum and sulfur in the diet.

Epidemiology Primarily in young pastured ruminants (cattle, sheep, goats, and farmed deer) in spring and summer. Primary deficiency occurs in sandy soil and heavily weathered areas; secondary in peat or muck soil areas. Feed and water supplies may contain molybdenum, sulfate and iron salts, which interfere with copper metabolism. May be congenital in newborn lambs (swayback) if ewes deficient or delayed in nursing lambs (enzootic ataxia). Some breeds of sheep highly susceptible.

Signs Herd problem. Young growing ruminants on pasture. Unthriftiness, changes in hair color, chronic diarrhea in molybdenosis (secondary deficiency), chronic lameness, neonatal ataxia, anemia later stages of deficiency and falling disease in adult cattle.

Clinical pathology Low serum and hepatic copper. Ceruloplasmin. Anemia.

Necropsy findings Anemia, emaciation, hemosiderosis, osteodystrophy, demyelination in enzootic ataxia, myocardiopathy.

Diagnostic confirmation Low serum and hepatic copper and response to treatment.

Differential diagnosis list Copper deficiency must be differentiated from herd problems associated with the following clinical findings.

- Unthriftiness due to intestinal parasitism
- Malnutrition due to energy-protein deficiency
- Lameness caused by osteodystrophy due to calcium, phosphorus, and vitamin D imbalance
- Anemia due to pediculosis
- Neonatal ataxia in lambs (congenital swayback and enzootic ataxia) from border disease; cerebellar hypoplasia (daft lamb disease); hypothyroidism; meningitis
- Sudden death due to other causes

Treatment Copper sulfate orally; copper glycinate parenterally.

Control Provide source of copper by oral dosing or dietary supplementation in feed or on pasture. Parenteral administration of copper at strategic times. Copper oxide feeds orally for prolonged effectiveness. Controlled-release boluses. Genetic selection. Removal of sulfates from water supply.

ETIOLOGY

Copper deficiency may be primary, when the intake in the diet is inadequate, or secondary (conditioned) when the dietary intake is sufficient but the utilization of the copper by tissues is impeded.

Primary copper deficiency

The amount of copper in the diet may be inadequate when the forage is grown on deficient soils or on soils in which the copper is unavailable.

Secondary copper deficiency

In secondary copper deficiency, the amount of copper in the diet is adequate, but conditioning dietary factors interfere with the utilization of the copper. Such secondary copper deficiencies are summarized in Table 30.2. The administration of copper is preventive and curative. The conditioning factor is known only in some instances, but a dietary excess of molybdenum is one of the most common. A high molybdenum intake can induce copper deficiency even when the copper content of the pasture is quite high and a higher copper intake can overcome the effect of the molybdenum. Conversely, supplementation of the diet with molybdenum can be used to counteract the copper intake when its content in the diet is dangerously high. There are species differences in response to high copper and molybdenum intake; sheep are much more susceptible to copper poisoning, cattle to excess molybdenum.

Zinc, iron, lead, and calcium carbonate are also conditioning factors and in New Zealand, the administration of selenium to sheep on copper-deficient pastures increases copper absorption and improves the growth rate of lambs. The use of zinc sulfate for the control of facial eczema may cause a depression of plasma copper levels, which can be alleviated by the injection of copper glycinate.

Dietary inorganic sulfate in combination with molybdenum has a profound effect on the uptake of copper by ruminants. Sheep consuming a complete diet, low in sulfur and molybdenum and with a modest 12–20 mg copper/kg dry matter (DM), may die from copper toxicity, while others grazing pasture of similar copper content but high in molybdenum and sulfur can give birth to lambs affected with the copper deficiency disease swayback.

An increase of sulfate concentration in a sheep diet from 0.1% to 0.4% can potentiate a molybdenum content as low as 2 mg/kg (0.02 mmol/kg) to reduce copper absorption to below normal levels. Additional sulfate in the diet also has a depressing effect on the absorption of selenium so that areas of a country with marginal copper and selenium levels in the soil may produce deficiency syndromes in animals if sulfate is added; this is likely to happen when heavy dressings of superphosphate are applied. Such combined deficiencies are becoming more common. The possibility of interaction between copper and selenium must also be considered because of the reported failure of animals to respond to treatment unless both elements are provided.

EPIDEMIOLOGY

Occurrence

Copper deficiency is endemic in ruminants worldwide and causes diseases of economic importance that may be severe enough to render large areas of otherwise fertile land unsuitable for grazing by ruminants of all ages, but primarily young, growing ruminants. Based on serum copper surveys of cattle herds in Britain, copper deficiency constitutes a serious problem requiring vigilance. It is estimated that characteristic clinical signs of copper deficiency develop annually in about 0.9% of the cattle population in the UK. In some surveys, the lowest levels of serum copper were in heifers being reared as heifer replacements. Although heavy mortalities occur in affected areas, the major loss is due to...
failure of animals to thrive. Enzootic ataxia may affect up to 90% of a lamb flock in badly affected areas and most of these lambs die of inanition. In falling disease, up to 40% of cattle in affected herds may die.

Copper deficiency is the most common trace element deficiency in farmed deer in New Zealand. The deficiency in deer is widespread and is a problem in many herds. It can be diagnosed from clinical signs such as enzootic ataxia and osteochondrosis.

**Geographical distribution**

Primary copper deficiency

The diseases caused by a primary deficiency of copper in ruminants are enzootic ataxia of sheep in Australia, New Zealand, and the USA, licksickness, or likskucht of cattle in Holland and falling disease of cattle in Australia.

Copper deficiency occurs naturally in grazing livestock in many parts of the world. It has long been recognized as an endemic disease in the Salado's river basin in Buenos Aires Province, Argentina, affecting over 50% of the cattle population. Some 81% of this wide area of 56 000 km² is devoted to breeding over 6.5 million head of beef cattle. The copper content in the grass is inadequate for most of the year and is most critical in autumn.

A concurrent deficiency of both copper and cobalt occurs in Australia (coast disease) and Florida in the USA (salt sickness) and is characterized by the appearance of clinical signs of both deficiencies in all species of ruminants. The disease is controlled by supplementation of the diet with copper and cobalt.

In the USA, copper deficiency is not restricted to a single geographic region. In a survey of 2007 beef cows and heifers from 256 herds, 1.7% were deficient and 38% were marginally deficient. In herds, 36% were marginally deficient and 0.8%, deficient. Approximately 50% of the producers reported use of copper supplements, but a significant portion of cattle from those herds were classified as marginally deficient or deficient.

A survey in Saskatchewan, Canada, found that 67% of slaughter cattle had liver levels lower than 10 mg copper/kg on a wet weight (WW). A survey of the copper status of the fetuses and livers from adult animals found that 20% of steers, 54% of pregnant cows, 52% of heifers, and 77% of non-pregnant cows had liver levels <25 mg/kg DM. The concentrations of copper in the liver of the fetuses were directly proportional to the liver copper concentrations in the dams. Liver copper levels of fetuses from dams with liver copper levels <25 mg/kg DM were higher than those in fetuses from dams with liver copper levels >25 mg/kg DM. During gestation, the level of copper progressively increased in the fetal liver and decreased in the maternal liver. The concentration of copper in fetal livers increased with increasing fetal age and at term, the newborn calf has high levels of liver copper to meet postnatal requirements because cows' milk is a poor source of copper. The magnitude of copper deficiency in some areas is extensive and emphasizes the importance of adequate copper nutrition in pregnant cattle in order to maintain adequate fetal levels of copper.

Copper deficiency has been diagnosed in Canada in a herd of captive musk-oxen, which had originated in the Northwest Territories.

Copper deficiency may also cause anemia in sucking pigs and reduced growth rate and cardiac disease in growing pigs. Adult horses are unaffected, but abnormalities of the limbs and joints of foals reared in copper-deficient areas do occur. Osteochondrosis is associated with a copper deficiency in young, farmed red deer and wapiti X red deer hybrids in New Zealand.

Secondary copper deficiency

The diseases caused by secondary copper deficiency, mostly due to high dietary intakes of molybdenum and sulfate, are listed in Table 30.2. They include syndromes characterized by diarrhea or by unthriftiness. *Yellow calf*, a disease of nursing calves occurs on Hawaii's rangeland where copper content of forages ranges from 2.6 to 11.8 mg/kg and the molybdenum from <1 to 39 mg/kg.

**Swayback** of lambs in the UK has been classified as a secondary copper deficiency, but no conditioning factor has been determined. While swayback is a naturally occurring disease caused by a primary deficiency of copper, identical lesions occur experimentally by feeding molybdenum and sulfate to the ewes. There is some evidence that heavy lime dressing of a pasture may predispose to swayback. A wasting disease similar to peat scours and preventable by the administration of copper and unthriftiness ('pine') of calves, occur in the UK, but in both instances the copper and molybdenum intakes are normal. Molybdenum appears to be the conditioning agent in enzootic ataxia in the USA. A dietary excess of molybdenum is known to be the conditioning factor in the diarrheic diseases, peat scours in New Zealand, California, and Canada and 'tear' in Britain.

High concentrations of molybdenum in forage (21–44 mg/kg DM) have been identified in several reclaimed mining areas in British Columbia but cattle have grazed these areas for 12-week periods yearly for 3 years without developing secondary copper deficiency. One-half of the animals received a copper supplement and there were no differences in weight gain, liver molybdenum, serum copper, and molybdenum and milk copper and molybdenum between the two groups. The results indicated that the upper tolerable dietary concentrations of 5–10 mg molybdenum described by the National Research Council and the minimum safe copper to molybdenum ratio of 2:1 are not universal.

**Moose sickness** is a disease of moose (*Alces alces* L.) in Sweden. The disease has also been known as 'Alvsborg disease' and 'wasting disease'. About 4–5% of the moose population is affected annually. The appearance of the disease coincided with intensified liming of wetlands, lakes, and forests during the 1980s, undertaken to counteract the deleterious effects of acid rain. The increase in pH caused by the liming affected the availability of nutrients in the soil, reducing copper availability and increasing molybdenum.

Copper deficiency may be a factor contributing to the population decline of moose in North-western Minnesota. In moose found dead, the copper concentrations based on criteria set for cattle, were deficient in 39.5% of livers, marginally deficient in 29.5% and adequate in 31%.

Table 30.2: Secondary copper deficiency cases
The lower concentrations of copper in moose from bog and forest areas compared with the agricultural and prairie areas of North-western Minnesota coincide with a lower calf-to-cow ratio in the north-west forest area compared with the northwestern prairies.

**Seasonal incidence**
Both primary and secondary copper deficiency occur most commonly in spring and summer coinciding with the lowest levels of copper in the pasture.

Large monthly variations occur in the serum levels of copper in both beef and dairy cattle and are commonly correlated with the rainfall; the higher the rainfall the lower the copper level.

The incidence of secondary copper deficiency may be highest at other times, depending upon the concentration of the conditioning factor in the forage. For example, the molybdenum content may be highest in the autumn when rains stimulate a heavy growth of legumes.

**Risk factors**
Several factors influence the plasma and tissue concentrations of copper, particularly in ruminants, including:

- **Age of animal**
- **Demands of pregnancy and lactation**
- **Stage of growth**
- **Copper sources available to the animals**
- **Mineral composition of feed**
- **Season of the year**
- **Soil characteristics and its mineral composition**
- **Breed of animal**
- **Concentration of minerals, such as sulfur and molybdenum, which can interfere with the availability of copper.**

**Animal factors**
Age susceptibility
Young animals are more susceptible to primary copper deficiency than adults. Calves on dams fed deficient diets may show signs at 2-3 months of age. As a rule, the signs are severe in calves and yearlings, less severe in 2-year-olds and of minor degree in adults. Enzootic ataxia is primarily a disease of sucking lambs whose dams receive insufficient dietary copper. Ewes with a normal copper status take some time to lose their hepatic reserves of copper after transfer to copper-deficient pastures and do not produce affected lambs for the first 6 months. The occurrence of the disease in sucklings and its failure to appear after weaning, point to the importance of fetal stores of copper and the inadequacy of milk as a source of copper. Milk is always a poor source of copper and when it is the sole source of nourishment the intake of copper will be low. Milk from normal ewes contains 20-60 µg/dL (3.1-9.4 µmol/L) copper, but under conditions of severe copper deficiency this may be reduced to 1-2 µg/dL (0.16-0.31 µmol/L).

**Breed and species susceptibility**
There are marked genetic differences in copper metabolism between breeds of sheep. The Welsh Mountain ewe can absorb copper 50% more efficiently than the Scottish blackface, and the Texel cross blackface 145% more efficiently than pure blackface lambs. The susceptibility to, or protection from, the effects of copper deficiency and also copper poisoning, is influenced from birth by genetic effects. These affect copper status of the lamb at birth, through the maternal environment controlled by the dam's genes and through the effect of the lamb's own genes. Later in life, the animal's own genes become the predominant influence determining its copper status on any given nutritional regimen. These genetic differences have physiological consequences reflected in differences in the incidence of swayback, both between and within breeds and in effects on growth and possibly on reproduction. The differences observed are due to genetic differences in the efficiency of absorption of dietary copper.

The genetic effects determining the copper status of the lamb are already present in utero and the effects are not controlled by the lamb's own genotype but by that of its dam. The maternal effect is still present at weaning at 9 weeks of age, but disappears after weaning when the genetic differences are due to the sheep's own genotype.

The existence of genes determining plasma copper has been shown by the successful continued selection for high and low concentrations in closed lines of a single breed type. Ram selection is made on the basis of plasma copper concentrations at 18 and 24 weeks of age. The proportion of the normal variation in plasma copper that is heritable is 0.3. The high-line female sheep retain more copper in the liver than the low-line females, caused by a positive correlation between the concentration of copper in plasma and the efficiency of absorption.

The genetic variation in the copper metabolism of sheep has important physiological consequences. Breeds show wide variation in their susceptibility to swayback; the incidence of swayback may vary from 0 to 40% between breeds within one flock and the incidence according to breed type is closely related to the differences in the concentration of copper in the liver than in blood. When these high and low female lines are placed on improved and limed pasture, which can induce a severe copper deficiency, soon after birth there are indications of swayback, general dullness, lack of vigor and mortality in the lambs. By 6 weeks of age, the mortality rate is higher in the lambs from the low copper line than in those from the high copper line. In addition, at 6 weeks of age, lambs from the low line are 2 kg lighter than those in the high line.

There are significant differences in the copper requirements and tolerance between goats and sheep. The dietary copper requirements of goats are uncertain but may be higher than in sheep. Dietary levels of copper which could cause copper toxicity in sheep do not cause toxicity in goats. Some limited data on growth performance indicates a stimulatory effect of 100-300 ppm copper in the diet of Nubian goats. Extra copper accumulated in liver and to a lesser extent in other tissues and was excreted through the biliary system and into the feces.

Certain breeds of cattle, e.g. the Simmental and Charolais, may have higher copper requirements than other breeds, e.g. Angus and these differences may be related to differences in copper absorption in the gastrointestinal tract. Angus heifers have a lower minimal copper requirement than Simmental. Based on liver copper, the control diets containing 4.4 mg or 6.4 mg of copper/kg DM did not meet the copper requirement of either breed during gestation and lactation or growth. Addition of 7 mg of copper/kg DM to the control diets met the copper requirements of both breeds.

**Fetal liver copper**
During gestation, the copper concentration increases progressively in the ovine and bovine fetal liver and decreases in the maternal liver. The developing bovine fetus obtains its copper by placental transfer and at birth, the liver concentration of copper is high and declines postnatally to adult levels within the first few months. Placental transfer is less efficient in sheep and lambs are commonly born with low liver reserves, making the neonatal lambs susceptible to copper deficiency. In copper-deficient cattle, the accumulation of liver copper in the fetus continues independent of the dam's liver copper until the fetus is about 180 days, then a gradual decline in fetal liver copper occurs. The liver copper concentration in fetuses from dams on a copper-adequate diet continues to increase and not decline at 180 days of gestation. All of this indicates an increase in copper requirements by the dam during pregnancy; during the last month of pregnancy, the daily requirement for copper in cattle increases to approximately 70% above the maintenance requirements, which means that the dietary allowance of 10 mg/kg DM needs to be increased up to 25 mg/kg.
DM during pregnancy. The concentrations of copper, iron, manganese, and zinc are consistently lower than normal in the livers of aborted fetuses, indicating a non-specific change in trace element status which is probably an effect of abortion and not a cause.

Colostrum is rich in copper, allowing the newborn with its preferential ability to absorb copper to increase hepatic stores. Later, the copper content of milk declines rapidly so that it is usually insufficient to meet the requirements of the sucking neonate for copper. The young milk-fed animal is able to absorb about 80% of its copper intake, but the efficiency of absorption declines with age as the rumen becomes functional, when only 2–10% of available copper is absorbed.

**Dietary factors**

**Pasture composition**

The absorption (or availability) of copper is influenced by the type of diet, the presence of other substances in the diet such as molybdenum, sulfur, and iron, the interaction between the type of diet and the chemical composition of the diet and the genetic constitution of the animals. Copper is well-absorbed from diets low in fiber, such as cereals and Brassicas, but poorly absorbed from fresh forage. Conservation of grass as hay or silage generally improves its availability. This explains why copper deficiency is a problem of the grazing animal and seen only rarely in housed ruminants receiving diets that are commonly adequate in copper.

**Molybdenum and sulfur**

Only small increases in the molybdenum and sulfur concentration of grass will cause major reductions in the availability of copper. This is especially notable in ruminants grazing improved pastures in which the molybdenum and sulfur concentrations were increased. The copper content of feedstuffs should be expressed in terms of available copper concentration, using appropriate equations, which permits a more accurate prediction of clinical disease and can be used for more effective control strategies.

The effect of changes in molybdenum and sulfur concentrations in grass on the availability of copper is changed by conservation. At a given concentration of sulfur, the antagonistic effect of molybdenum is proportionately less in hay than in fresh grass. At a low concentration of molybdenum, the effect of sulfur is more marked in silage than in fresh grass. The use of formaldehyde as a silage additive may weaken the copper sulfur antagonism and yield material of high availability. Thus, fields of herbage high in molybdenum should be used for conservation when possible and sulfuric acid should not be used as an additive for silage unless accompanied by a copper salt because it significantly raises the sulfur concentration of the silage.

**Copper in diet**

For general purposes, pasture containing <3 mg/kg DM of copper will result in signs of deficiency in grazing ruminants. Levels of 3–5 mg/kg DM can be considered as dangerous and levels >5 mg/kg DM (preferably 7–12) are safe unless complicating factors cause secondary copper deficiency. The complexity of minimum copper requirements, affected as they are by numerous conditioning factors, necessitates examination under each particular set of circumstances. For example, plant molybdenum levels are related directly to the pH reaction of the soil. Grasses grown on strongly acidic molybdenum-rich soils are characterized by low molybdenum values (<3 mg/kg DM), whereas those associated with alkaline molybdenum-poor soils may contain up to 17 mg/kg DM. Thus, it seems likely that conditioned copper deficiency can be related to regionally enhanced levels of plant available rather than soil molybdenum. Heavily limed pastures are often associated with a less than normal copper intake and a low copper status of sheep grazing them. Secondary copper deficiency is also recorded in pigs whose drinking water contains very large amounts of sulfate.

**Dietary iron**

A dietary intake of iron can interfere with copper metabolism. Dietary levels of iron in the range of 500–1500 mg/kg DM, within the range of their fluctuation in silage and forage and higher levels, are a risk of inducing copper deficiency in ruminants, especially when the copper intake is marginal. Ruminants obtain iron from ingested soil and mineral supplements and, in areas where hypocuprisis is likely to occur, the risk can be minimized by avoiding the use of mineral supplements of high iron content, minimizing the use of bare winter pasture and avoiding the excessive contamination of silage with soil during harvesting.

Molybdenum-induced secondary copper deficiency in cattle occurred when motor oil containing molybdenum bisulfide was spilled on a pasture located on the side of a railway bed near the farm.

**Stored feeds**

Livestock that are housed have a slightly different dietary intake to those on pasture. Concentrates and proprietary feeds usually contain adequate copper. Pasture is less likely to contain sufficient copper, especially in early spring when the grass growth is lush and silage and haylage may be deficient. Hay is more mature and usually contains more of all minerals, so that animals housed for the winter are protected against copper deficiency for a few weeks after they come out onto pasture in the spring. Young, growing animals will be first affected. These comments should not be interpreted to mean that housed or feedlot animals cannot be affected by hypocuprosis; they can if the locally produced feed is copper-deficient, or more likely has a high concentration of molybdenum. Both are likely to be prevented, or less severe, if there is some supplementary feeding.

**Soil characteristics**

**Copper deficiency**

In general, there are two types of soil on which copper-deficient plants are produced. Sandy soils, poor in organic matter and heavily weathered, such as on the coastal plains of Australia and in marine and river silts, are likely to be deficient in copper as well as other trace elements, especially cobalt.

The second important group of soils is 'peat' or muck soils reclaimed from swamps and are soils more commonly associated with copper deficiency in the USA, New Zealand, and Europe. Such soils may have an absolute deficiency of copper, but more commonly, the deficiency is relative in that the copper is not available and the plants growing on the soils do not contain adequate amounts of the element.

The cause of the lack of availability of the copper is uncertain, but is probably the formation of insoluble organic copper complexes. An additional factor is the production of secondary copper deficiency on these soils due to their high content of molybdenum. A summary of the relevant levels of copper in soils and plants is given in Table 30.3.

**Molybdenum excess**

Pastures containing <3 mg/kg DM of molybdenum are considered to be safe, but disease may occur at 3–10 mg/kg DM if the copper intake is low. Pastures containing >10 mg/kg DM of molybdenum are dangerous unless the diet is supplemented with copper. Excess molybdenum may occur in soils up to levels of 10 and even 100 mg/kg. Perhaps more dangerous is the risk that overzealous application of molybdenum to pasture to increase bacterial nitrogen fixation may have similar effects, which are likely to be long-lasting.

In the UK, appreciable land is underlain by marine black shales rich in molybdenum, resulting in a high content of molybdenum in the soil and pastures and in a secondary copper deficiency that, potentially, limits livestock performance. Secondary (conditioned) copper deficiency is now recognized in cattle in many parts of Canada. Large areas of west-central Manitoba are underlain by molyb-

**PATHOGENESIS**

**Effects on tissues**

The consequences of hypocupremia include a failure of copper metalloenzymes, many of which form part of antioxidant defense systems such as copper/zinc superoxide dismutase (Cu/Zn SOD) and ceruloplasmin. Copper, as well as other essential trace elements, is an atypical antioxidant because it functions indirectly. Copper is a catalytic cofactor for Cu/Zn SOD and ceruloplasmin. Cu/Zn SOD catalyzes the dismutation of the superoxide anion, producing molecular oxygen and hydrogen peroxide, with the latter product usually metabolized by glutathione peroxidase and catalase. The ferrooxidase activity of ceruloplasmin mediates the oxidation of ferrous ions to the ferric state, thereby preventing ferrous iron-dependent formation of hydroxyl radicals via the Fenton reaction. Thus, in enabling Cu/Zn SOD and ceruloplasmin to function as described, copper can be classified as part of the antioxidant defense system of cells.

Copper deficiency can affect the antioxidant defense system resulting in oxidative damage to cellular components.

**Anemia**

The known importance of copper in the formation of hemoglobin accounts for the anemia in copper deficiency. The presence of hemosiderin deposits in tissues of copper-deficient animals suggests that copper is necessary for the reutilization of iron liberated from the normal breakdown of hemoglobin. There is no evidence of excessive hemolysis in copper-deficiency states. Anemia may occur in the later stages of primary copper deficiency, but is not remarkable in the secondary form unless there is a marginal copper deficiency, as occurs in sheep scours in New Zealand. The unusual relationship in New Zealand between copper deficiency and postpartum hemoglobinuria is unexplained. Heinz body anemia in lambs with deficiencies of copper or selenium and moved from improved pasture to rape (Brassica napus) has been reported.

**Bone**

The osteoporosis that occurs in some natural cases of copper deficiency is caused by the depression of osteoblastic activity. In experimentally induced primary copper deficiency, the skeleton is osteoporotic and there is a significant increase in osteoblastic activity. There is a marked overgrowth of epiphyseal cartilage, especially at costochondral junctions and in metatarsal bones. This is accompanied by beading of the ribs and enlargement of the long bones. There is also an impairment of collagen formation. When the copper deficiency is secondary to dietary excesses of molybdenum and sulfate, the skeletal lesions are quite different and characterized by widening of the growth plate and metaphysis and active osteoblastic activity.

Copper deficiency in foals causes severe degenerative disease of cartilage, characterized by breaking of articular and growth plate cartilage through the zone of hypertrophic cells, resulting in osteochondrosis of the articular-epiphyseal complex (A–E complex). The incidence and severity of osteochondrosis in foals can be decreased by supplementation of the diets of mares during the last 3–6 months of gestation.
months of pregnancy and the first 3 months of lactation. Foals from non-supplemented mares have separation of the thickened cartilage from the subchondral bone. Clinical, radiographic, and biochemical differences occur between copper-deficient and copper-supplemented foals and there may be a relationship between low copper intakes in rapidly growing horses, inferior collagen quality, biomechanically weak cartilage, and osteochondritis.

Copper is essential for metalloenzyme lysyl oxidase, which produces aldehydic groups on hydroxylsine residues as a prerequisite for eventual cross-link formation in collagen and elastin. Similar lesions in foals have been attributed to zinc toxicity from exposure of affected animals to pasture polluted by smelters. Experimentally, the addition of varying amounts of zinc to the diet of foals containing adequate copper will result in zinc-induced copper deficiency, but there are no effects with zinc intakes up to 580 ppm and it is suggested that 2000 ppm or higher are necessary to affect copper absorption in horses. Similar lesions of osteochondrosis have occurred in young farmed red deer and wapiti red deer hybrids in New Zealand.

Connective tissue
Copper is a component of the enzyme lysyl oxidase, secreted by the cells involved in the synthesis of the elastin component of connective tissues and has important functions in maintaining the integrity of tissues such as capillary beds, ligaments, and tendons.

Heart
The myocardial degeneration of falling disease may be a terminal manifestation of anemic anoxia, or be due to interference with tissue oxidation. In this disease, it is thought that the stress of calving and lactation contribute to the development of heart block and ventricular fibrillation when there has already been considerable decrease in cardiac reserve. Experimentally induced copper deficiency in piglets causes a marked reduction in growth and hematocrit and cardiac pathology and electrical disturbances.

Blood vessels
Experimentally produced copper deficiency has also caused sudden death due to rupture of the heart and great vessels in a high proportion of pigs fed a copper-deficient diet. The basic defect is degeneration of the internal elastic laminae. There is no record of a similar, naturally occurring disease. A similar relationship appears to have been established between serum copper levels and fatal rupture of the uterine artery at parturition in aged mares.

Pancreas
Lesions of the pancreas may be present in normal cattle with a low blood copper status. The lesions consist of an increase in dry matter content and a reduction in the concentrations of protein and copper in wet tissue. The cytochrome oxidase activity and protein:RNA ratio are also reduced. There are defects in acinar basement membranes, splitting, and disorganization of acini, cellular atrophy and dissociation and stromal proliferation.

Nervous tissue
Copper deficiency hampers the formation of myelin and causes demyelination in lambs, probably by a specific relationship between copper and myelin sheaths. Defective myelination can commence as early as the midpoint of the fetus’s uterine life. The focus of lesions in the white matter shifts from the cerebrum in lambs affected at birth (congenital swayback) to the spinal cord in delayed cases, which may reflect respective peaks of myelin development at those sites at 90 days’ gestation and 20 days after birth. The postnatal development of delayed swayback has been confirmed through its control by copper supplementation after birth. In experimental animals, it has been shown that copper deficiency does interfere with the synthesis of phospholipids. While anoxia is a cause of demyelination, an anemic anoxia is likely to occur in highly deficient ewes and anemic ewes produce a higher proportion of lambs with enzootic ataxia, there is often no anemia in ewes producing lambs with the more common subacute form of the disease. Severely deficient ewes have lambs affected at birth and in which myelin formation is likely to have been prevented. The lambs of ewes less severely deficient have normal myelination at birth and develop demyelination in postnatal life.

Reproductive performance
There is no evidence that copper deficiency causes reproductive failure in dairy cows. Copper glycinate given to dairy cattle does not affect the average interval in days between calving and first observed heat, services per conception, or first service conception rate compared with untreated cows in the same population. Experimentally, the addition of molybdenum to the diet of heifers delayed the onset of puberty, decreased the conception rate and caused anovulation and anestrus in cattle without accompanying changes in copper status or in live weight gain. Thus, the presence of molybdenum rather than low copper status may affect reproductive performance of cattle. Geochemical data indicate that approximately 10% of the cultivated area of England and Wales has soils that may result in forage molybdenum concentrations similar to those used in the above experimental diet. It appears inadvisable to ascribe poor reproductive performance to subclinical hypocuprosis on the evidence of blood copper analysis alone. Other factors, such as management and energy and protein intake, should be examined.

Immune system
Copper is an essential trace mineral with an important role in the immune response but the precise mechanism is not well understood. In experimental secondary copper deficiency in cattle induced by molybdenum at 30 ppm and sulfate at 225 ppm, the intracellular copper content of peripheral blood lymphocytes, neutrophils, and monocyte-derived macrophages was reduced between 40% and 70%. In copper deficient animals, the serum ceruloplasmin activity decreased to 50% of control values. Both the copper-dependent superoxide dismutase and the cytochrome c oxidase activities are significantly reduced in leukocytes. Thus, copper deficiency alters the activity of several enzymes, which mediate antioxidant defenses and ATP formation. These effects may impair cell immune function, affecting the bactericidal capacity and making the animals more susceptible to infection.

Copper deficiency results in decreased humoral and cell-mediated immunity, as well as decreased non-specific immunity regulated by phagocytic cells, such as macrophages and neutrophils. The decreased resistance to infection in sheep is amenable to treatment with copper and genetic selection. In lambs genetically selected for low and high concentrations of plasma copper, the mortality from birth to 4 weeks of age in the high line was half that in the low line. Most of the losses were due to a variety of microbial infections. Experimental viral and bacterial infections of cattle can cause a rapid, though transient, increase in serum ceruloplasmin and plasma copper in copper-replete animals, suggesting a major protective role for copper in infectious diseases. These changes in copper metabolism evolve from an interleukin-1 mediated increase in hepatic synthesis and release of ceruloplasmin, an acute phase protein. Copper concentrations in organs involved in immune regulations such as liver, spleen, thymus, and lung are substantially reduced by copper deficiency, suggesting that copper-deficient animals are at greater risk for infection than copper-adequate animals. However, experimental low copper diets with or without supplemental molybdenum does not alter the specific immunity of stressed cattle.

The severity of copper depletion needed for immune dysfunction is less than
required to induce clinical signs of copper deficiency and endogenous copper may contribute to the regulation of both non-immune and immune inflammatory responses. Low molecular weight complexes may have an anti-inflammatory effect in animal models of inflammation and it is postulated that the elevation of plasma copper-containing components during inflammatory disease represents a physiological response.

In experimental coliform mastitis in dairy cattle, copper in the diet at 20 ppm reduced the clinical response but not duration of the mastitis compared with animals receiving 6.5 ppm beginning 60 days prepartum through 42 days of lactation. Liver copper in the supplemented group was 162 and 33 ppm at calving and 256 and 45 ppm at 42 days post partum, respectively.

Copper deficiency in heifers in Northern India was associated with significant reduction in the candidacidal activity of neutrophils compared with copper supplemented animals.

Sequence of clinical signs development
In experimental copper deficiency in calves, beginning at 6 weeks of age, subclinical and clinical abnormalities appear after the following intervals: hypocupremia at 15 weeks, growth retardation from 15 to 18 weeks, rough hair coat at 17 weeks, diarrhea at 20 weeks and leg abnormalities at 23 weeks. These signs correlate well with the onset of hypocupremia and are indicative of a severe deficiency. Even with these signs of deficiency, the histological abnormalities may be only minor in degree.

In experimental primary copper deficiency in calves, beginning at 12 weeks of age, clinical signs of the deficiency may not become apparent for about 6 months. Musculoskeletal abnormalities include a stilted gait, a 'knock-kneed' appearance of the forelimbs, overextension of the flexors, splaying of the hooves and swellings around the metacarpophalangeal and carpopatellar joints. Changes in hair pigmentation occur after about 5 months and diarrhea between 5 and 7 months. The diarrhea ceased 12 h after oral administration of a small amount (10 mg) of copper.

Copper utilization
Sulfate and molybdate can interfere with mobilization of copper from the liver, inhibition of copper intake by the tissues, inhibition of copper transport both into and out of the liver and inhibition of the synthesis of copper-storage complexes and ceruloplasmin.

The clinical signs of hypocuprosis (such as steely wool) can occur in sheep on diets containing high levels of molybdenum and sulfate, even though blood copper levels are high. This suggests that under these circumstances copper is not utilizable in tissues and the blood copper rises in response to the physiological needs of the tissues for the element. In pigs, a copper–molybdenum complex can exist in animals and that in this form the copper is unavailable. This would interfere with hepatic metabolism of copper and the formation of copper-protein complexes such as ceruloplasmin.

Hepatic storage
The copper status of the liver depends on whether the animals are receiving adequate dietary copper. With adequate dietary levels, the liver copper levels are less in the presence of molybdate and sulfate. If the animals are receiving a copper-deficient diet such that copper is being removed from the liver, then the molybdate plus sulfate animals retain more copper in their liver than copper-deficient animals not receiving sulfate plus molybdate. This supports the hypothesis that molybdate and sulfate together impair the movement of copper into or out of the liver, possibly by affecting copper transport. Sulfate alone exerts an effect. An increase in intake reduces hepatic storage of both copper and molybdenum.

Phases of copper deficiency
The development of a deficiency can be divided into four phases:

1. Depletion
2. Deficiency (marginal)
3. Dysfunction
4. Disease.

During the depletion phase, there is loss of copper from any storage site, such as liver, but the plasma concentrations of copper may remain constant. With continued dietary deficiency, the concentrations of copper in the blood decline during the phase of marginal deficiency. However, it may be some time before the concentrations or activities of copper-containing enzymes in the tissues begin to decline and it is not until this happens that the phase of dysfunction is reached. There may be a further lag before the changes in cellular function are manifested as clinical signs of disease.
Summary
The overall effect of these interactions is as follows. Molybdate reacts with sulfides to produce thiomolybdates in the rumen. The subsequent formation of copper-thiomolybdate complexes isolates the copper from being bioavailable.1 The thiomolybdates reduce the effectiveness of enzymes containing copper and there are some significant interactions between copper, zinc, and iron.

CLINICAL FINDINGS
The general effects of copper deficiency are the same in sheep and cattle, but in addition to these general syndromes, there are specific syndromes more or less restricted to species and to areas. What follows is a general description of the disease caused by copper deficiency, in turn followed by the specific syndromes of enzootic ataxia, swayback, falling disease, peat scours, teart, and unthriftiness (pine).

Cattle
Subclinical hypocuprosis
No clinical signs occur, blood copper levels are marginal or below 57 mg/dL (90 mmol/L) and there is a variable response in productivity after supplementation with copper. Some surveys in copper-deficient areas found that about 50% of beef herds and 10% of dairy herds within the same area have low blood levels of blood copper associated with low copper intake from natural forages. The deficiency is likely to be suspected only if production is monitored and found to be suboptimal.

A perplexing feature of subclinical hypocuprosis is the wide variation in improved growth rate obtained when cattle of the same low copper status are fed supplementary copper under field conditions.

General syndrome
Primary copper deficiency
Primary copper deficiency causes unthriftiness, loss of milk production, and anemia in adult cattle. The coat color is affected, red and black cattle changing to a bleached, rusty red and the coat itself becomes rough and staring. In severely deficient states, which are now uncommon, calves grow poorly and there is an increased tendency for bones to fracture, particularly the limb bones and the scapula. Ataxia may occur after exercise, with a sudden loss of control of the hindlimbs and the animal falling or assuming a sitting posture. Normal control returns after rest. Itching and hair-licking are also recorded as manifestations of copper deficiency in cattle. Although diarrhea may occur, persistent diarrhea is not characteristic of primary copper deficiency and its occurrence should arouse suspicion of molybdenosis or helminthiasis. In some affected areas, calves develop stiffness and enlargement of the joints and contraction of the flexor tendons causing the affected animals to stand on their toes. These signs may be present at birth or occur before weaning. Paralysis and incoordination are not evident.

An increased occurrence of postparturient hemoglobinuria is also recorded, but only in New Zealand and may be unrelated to copper deficiency.

Secondary copper deficiency
This syndrome includes the signs of primary copper deficiency, except that anemia occurs less commonly, probably due to the relatively better copper status in the secondary state, anemia being largely a terminal sign in primary copper deficiency. For example, anemia occurs in peat scours of cattle in New Zealand, but in this instance, the copper intake is marginal. In addition to the other signs, however, there is a general tendency for diarrhea to occur, particularly in cattle. Because diarrhea is not a major sign in naturally occurring primary copper deficiency it is possible that it is due to the conditioning factor, which reduces the availability of copper. For example, the severity of the diarrhea is roughly proportional to the level of intake of molybdenum.

Falling disease
The characteristic behavior in falling disease is for cows in apparently good health to throw up their heads, bellow, and fall. Death is instantaneous in most cases, but some fall and struggle feebly on their sides for a few minutes with intermittent bellowing and running movement attempts to rise. Rare cases show signs for up to 24 h or more. These animals periodically lower their heads and pivot on the front legs. Sudden death usually occurs during one of these episodes.

Peat scours (‘teart’)
Persistent diarrhea with the passage of watery, yellow-green to black feces with an inoffensive odor occurs soon after the cattle go on to affected pasture, in some cases within 8–10 days. The feces are released without effort, often without lifting the tail. Severe debilitation is common, although the appetite remains good. The hair coat is rough and depigmentation is manifested by reddening or gray flecking, especially around the eyes, in black cattle. The degree of abnormality varies a great deal from season to season and year to year and spontaneous recovery is common. Affected animals usually recover in a few days following treatment with copper.

Unthriftiness (pine) of calves
The earliest signs are stiffness of gait and unthriftiness. The epiphyses of the distal ends of the metacarpus and metatarsus may be enlarged and resemble the epiphyses of rapidly growing calves deficient in calcium and phosphorus or vitamin D. The epiphyses are painful on palpation and some calves are severely lame. The pasterns are upright and the animals may appear to have contracted flexor tendons. The unthriftiness and emaciation are progressive and death may occur in 4–5 months. Grayness of the hair, especially around the eyes in black cattle, is apparent. Diarrhea may occur in a few cases.

Sheep
General syndrome
Primary copper deficiency
Abnormalities of the wool are the first observed signs and may be the only sign in areas of marginal copper deficiency. Fine wool becomes limp, glossy and loses its crimp, developing a straight, steely appearance. Black wool shows depigmentation to gray or white, often in bands coinciding with the seasonal occurrence of copper deficiency. The straight, steely defect may occur in similar bands and the staple may break easily. There appear to be some differences between breeds in susceptibility to copper deficiency. Merino sheep appearing to have a higher copper requirement than mutton sheep. The fleece abnormalities of Merino sheep in Australia have not been observed in Romney Marsh sheep in copper-deficient areas in New Zealand, but this may be due in part to the difficulty of detecting abnormality in wool that is normally rather straight and steely. Anemia, scurvy, unthriftiness and infertility may occur in conditions of extreme deficiency, but in sheep, the characteristic findings are in the lamb, the disease enzootic ataxia being the major manifestation. Retardation of growth, diarrhea, delay to marketing, and increased mortality are common clinical findings in lambs genetically selected for low plasma copper and placed on improved and limed upland pastures. Osteoporosis, with increased tendency of the long bones to fracture, has also been recorded under conditions of copper deficiency insufficient to cause enzootic ataxia.

Swayback and enzootic ataxia in lambs and goat kids
These diseases have much in common, but there are differences in epidemiology and some subtle clinical ones.

Swayback is the only authentic manifestation of a primary nutritional deficiency of copper in the UK. The incidence can vary greatly among breeds of sheep, reflecting the genetic differences in copper metabolism both between and within breeds of sheep. The disease occurs in several forms.

A congenital form, cerebrospinal swayback, occurs only when the copper
deficiency is extreme. Affected lambs are born dead or weak and unable to stand and suck. Incoordination and erratic movements are more evident than in enzootic ataxia and the paralysis is spastic in type. Blindness also occurs occasionally. There is softening and cavitation of the cerebral white matter and this probably commences about day 120 of gestation.

Progressive (delayed) spinal swayback begins to develop some weeks after birth with lesions and clinical signs appearing at 3–6 weeks of age.

Postnatal acute fatal swayback may be a third form of the disease and appears to occur only in Wales. It resembles the more usual delayed form, but develops suddenly. There is a sudden onset of recumbency with death occurring 1–2 days later due to acute swelling of the cerebrum.

Enzootic ataxia affects only unweaned lambs. In severe outbreaks, the lambs may be affected at birth, but most cases occur in the 1–2-month age group. The severity of the paresis decreases with increasing age at onset. Lambs affected at birth or within the first month usually die within 3–4 days. The disease in older lambs may last for 3–4 weeks and survival is more likely, although surviving lambs always show some ataxia and atrophy of the hindquarters. The first sign to appear in enzootic ataxia is incoordination of the hindlimbs, appearing when the lambs are driven. Respiratory and cardiac rates are also greatly accelerated by exertion. As the disease progresses, the incoordination becomes more severe and may be apparent after walking only a few yards. There is excessive flexion of joints, knuckling over of the fetlocks, wobbling of the hindquarters and finally falling. The hindlegs are affected first and the lamb may be able to drag itself about in a sitting posture. When the forelegs eventually become involved recumbency persists and the lamb dies of inanition. There is no true paralysis, the lamb being able to kick vigorously even in the recumbent stage. The appetite remains unaffected.

Goats
Enzootic ataxia due to copper deficiency has been reported in young goat kids. The disease is similar in most respects to the disease in lambs. Kids may be affected at birth, or the clinical signs may be delayed until the animals are several weeks of age. Cerebellar hypoplasia is a frequent finding in goats.

Other species
Deer
Enzootic ataxia in red deer is remarkably different from the disease in lambs in that it develops in young adults well past weaning age, and in adults. The clinical signs include ataxia, swaying of the hindquarters, a dog-sitting posture and, eventually, inability to use the hindlimbs. Spinal cord demyelination and midbrain neuronal degeneration are characteristic. Osteochondrosis of young, farmed deer with copper deficiency is characterized by lameness, one or more swollen joints and an abnormal 'bunny-hopping' gait or 'cow-hocked' stance. Copper deficiency in red deer in Australia during a period of drought caused loss of weight in lactating hind mammary glands (the hair had a lustre resembling that of so-called steely wool of copper-deficient sheep). Both adult and yearling stags had normal hair coats but those of the yearling hind mammary glands were patchy, with large areas of harsh, light colored, steely hair. The high sulfur content of the diet and possible accidental iron ingestion from being fed on the ground may have resulted in secondary copper deficiency.

Pigs
Naturally occurring enzootic ataxia has occurred in growing pigs 4–6 months of age. Posterior paresis progresses to complete paralysis in 1–3 weeks. Dosing with copper salts had no effect on the clinical conditions, but hepatic copper levels were 3–14 mg/kg (0.05–0.22 mmol/kg). Copper deficiency in piglets 5–8 weeks of age has been reported and was characterized clinically by ataxia, posterior paresis, nystagmus, inability to stand, paddling movements of the limbs and death in 3–5 days. Demyelination of the spinal cord and degenerative lesions of the elastic fibers of the walls of the aorta and pulmonary arteries are present.

The inclusion of copper sulfate, at levels of 125–250 mg/kg of copper, in the diets of pigs 11–90 kg live weight and fed ad libitum, results in slight improvements in growth rate and feed efficiency, but has no significant effect on carcass characteristics. The supplemental copper causes a marked increase in liver copper concentration which poses a potential hazard and it is recommended that copper supplementation be limited to starter and grower diets fed to pigs weighing less than 50 kg live weight.

Horses
Adult horses are unaffected by copper deficiency, but there are unconfirmed reports of abnormalities of limbs of foals. Foals in copper-deficient areas may be unthrifty and slow-growing, with stiffness of the limbs and enlargement of the joints. Contraction of the flexor tendons causes the animal to stand on its toes. There is no ataxia or indication of involvement of the central nervous system. Signs may be present at birth or develop before weaning. Recovery occurs slowly after weaning and foals are unthrifty for up to 2 years.

Geophagia or soil eating in horses in Australia has been associated with larger concentrations of iron and copper in soil samples compared to paired control samples, suggesting that these elements provide the stimulus for geophagia. Clinical pathology
The laboratory evaluation of the copper status of farm animals is complex because the biochemical values are often difficult to interpret and to correlate with the clinical state of the animal. Interpretation of the copper status of an individual animal is more difficult than that of a herd.

The guidelines for the laboratory diagnosis of primary and secondary copper deficiency in cattle and sheep are summarized in Table 30.4.

Herd diagnosis. The diagnosis of copper deficiency in a herd of animals is based on a combination of collection and interpretation of the history, clinical examination of the affected animals, laboratory tests on serum and liver samples, and examination of the environment including analysis of the feed and water supplies and perhaps soil analysis.

It is necessary to be especially careful when collecting specimens for copper analysis to avoid contamination by needles, copper-distilled water, vial caps, cans for liver specimens and other possible sources of copper. An additional problem is the possible effect of intercurrent disease on plasma levels of copper.

Treatment response trial. A comparison of health and production variables in a group of animals treated with copper and a similar group not treated with copper, is also desirable. Variables include calf growth rates, calf mortality and reproductive performance.

Copper status of herd. In order to assess the copper status of a herd, a standard practice is to take blood samples at random from at least 10% of clinically affected animals and from 10% of normal animals. However, this may be inappropriate when there may be a wide variation in the serum copper concentration within a herd. In some cases, a 10% sample may be too large and in other cases too small. The minimal sample size for random samples from a finite population of a normal continuously distributed variable has been calculated as follows:

\[ n = \frac{t_1 \cdot CV_E \cdot \sqrt{N}}{\frac{E_2 \cdot CV_2}{2}} \]

Where \( n \) = minimal sample size; \( N \) = herd size; \( t_1 \) = Student’s \( t \) value; \( CV \) = coefficient of variation; and \( E \) = allowable error.

Initial testing can be used to estimate variability of serum copper concentration within a herd and a minimal sample size may be calculated. Each class of animal according to age groups, diet and production status should also be sampled. Follow-up samples should be taken from the same animals following therapy or the institution of control measures.

Laboratory diagnosis
Historically, the laboratory diagnosis of copper deficiency in cattle and sheep centered on the determination of serum or plasma copper and liver copper. However, serum copper levels alone are not reliable as indicators of copper status and liver samples collected either by liver biopsy or at slaughter should be used to accurately assess copper status in cattle. Clinically normal animals may have marginal or deficient serum levels of copper, or unthrifty animals may have marginal or deficient serum levels of copper. Furthermore, when either the normal animals with the marginal levels of copper or the unthrifty animals with the marginal or deficient levels are treated with copper there may or may not be an improvement in weight gain as might be expected in the former, or improvement in clinical condition in the latter.

Phases
The development of a deficiency can be divided into four phases (Fig. 30.1):

1. Depletion
2. Deficiency (marginal)
3. Dysfunction
4. Disease.

During the depletion phase, there is loss of copper from any storage site, such as liver, but the plasma concentrations of copper may remain constant. With continued dietary deficiency, the concentrations of copper in the blood will decline during the phase of marginal deficiency. However, it may be some time before the concentrations or activities of copper-containing enzymes in the tissues begin to decline and it is not until this happens that the phase of dysfunction is reached. There may be a further lag before the changes in cellular function are manifested as clinical signs of disease.

Interpretation of laboratory results
The three principles governing the interpretation of biochemical criteria of trace element status include:
- The relationships between the concentration of the marker and the intake of the element
- The time the animal is on an adequate diet
- Disturbances of tissue function.

From these principles, the concentrations of liver copper are insensitive indices of deficiency, but good indicators of excess. Plasma copper <57 \( \mu g/dL \) (9 \( \mu mol/L \)) is a good index of marginal deficiency, but values may have to fall to below 19 \( \mu g/dL \) (3 \( \mu mol/L \)) before there is a risk of dysfunction and loss of production in sheep and cattle. However, these are only guidelines. The range of values and the cut-off levels above which animals are normal, or below which they are deficient, have not been well-established. There is considerable biological variation dependent on the species, the breed of animal, the length of time over which the depletion has occurred and the presence of intercurrent disease.

Serum copper concentration in cattle is fairly specific for detection of low liver copper but only marginally sensitive when serum copper concentration of 0.45 \( \mu g/g \) DM is used as a test endpoint. The value of serum copper concentration as a diagnostic indicator depends on the prevalence of copper deficiency in the particular area.

The interpretation of serum copper can change depending on what liver copper concentration is considered low. With a liver copper <20 \( \mu g/g \) DM as indicative of copper deficiency, serum copper concentrations >9 \( mmol/L \) will be a good indicator of copper deficient status but concentrations >9 \( mmol/L \) will be a poor indicator of copper sufficient status. If 10 \( \mu g/g \) DM is used as liver copper cut-off, then serum concentrations >9 \( mmol/L \) are reliable as indicative of copper sufficient status but not on concentrations >9 \( mmol/L \) as indicative of copper deficiency.

Concentrations of copper in liver and blood may be of diagnostic value but should be interpreted with caution since clinical signs of copper deficiency may appear before there are significant changes in the levels of copper in the blood and liver. Conversely, the plasma levels of copper may be very low in animals that are otherwise normal and performing well. There is a tendency to overestimate the presence of copper deficiency because veterinarians use a diagnostic threshold for copper deficiency that is too high.

Among veterinary laboratories, there is a
wide variation in the normal range currently used for equine serum copper values. Very low levels of both blood and liver copper in a group of animals need not be associated with clinical abnormalities. In a study in the Netherlands, in a group of dairy heifers, the copper status was determined at regular intervals over an 18-month period. One group was supplemented with copper sulfate and the other was not. The copper and molybdenum levels in the grass were within normal limits as accepted in the Netherlands; copper 7–15 mg/kg DM and molybdenum <5 mg/kg DM. The levels of copper in both the blood and liver were much below the reference ranges used in the Netherlands (6–15 μmol/L in blood and >30 μmol/kg DM in liver). No clinical signs of copper deficiency occurred and there were no differences in growth rate and reproductive performance.

**Plasma and liver copper levels**

**Cattle and sheep**

In cattle and sheep, plasma copper levels between 19 μg/dL and 57 μg/dL (3.0 and 9.3 μmol/L) represent marginal deficiency and levels below 19 μg/dL (3 μmol/L) represent functional deficiency or hypocuprosis. The internationally recognized threshold to assess copper deficiency is 9.4 μmol/L. In both species a value for plasma or serum of 11.0 μmol/L can be associated with a liver concentration from 789 to 3786 μmol/kg DM (50–240 mg/kg). By contrast, a value of 9.3 μmol/L will usually be associated with liver copper values of 315–789 μmol (20–50 mg/kg DM), which are regarded as marginally inadequate. Plasma copper levels of 49.9 μg/dL (7.85 μmol/L) or less are indicative of low liver copper levels. Plasma copper levels above 90.2 μg/dL (142 μmol/L) are usually associated with liver levels above 381 mg/kg (0.6 mmol/kg) DM. Of the two estimations, that on liver is the most informative as levels in blood may remain normal for long periods after liver copper levels commence to fall and early signs of copper deficiency appear. Levels of copper in adult liver above 200 mg/kg DM (3.14 mmol/kg) in sheep and above 100 mg/kg DM (1.57 mmol/kg) in cattle are considered to be normal. Levels of less than 80 mg/kg DM (1.5 mmol/kg) in sheep and less than 30 mg/kg DM (0.5 mmol/kg) in cattle are classed as low. Liver copper levels in fetuses and neonates are usually much higher than in adults and normal foals have had levels of 219 mg/kg (34 mmol/kg DM) compared with a normal of 31 mg/kg (0.49 mmol/kg DM) in adults.

**Liver copper**

Because the liver is a storage compartment for copper, the concentrations of liver copper indicate the state of depletion rather than deficiency. There is no particular threshold value for liver copper below which the performance and health of livestock are likely to be impaired. A broad range of values may, for example, coincide with the marginally deficient state, e.g. 5.1–20.3 mg (0.08–0.32 mmol) copper/kg liver DM. The concentration of hepatic copper in sheep is uniform and a single biopsy sample should be representative of the whole liver. The technique of liver biopsy for assessing the copper status of sheep has been evaluated. Frequency of biopsy does not affect copper concentration, the variability between successive samples is small and the biopsy procedure does not reduce body weight or rate of gain. Copper concentrations in the kidney cortex may be of more diagnostic value because concentrations are normally within a narrow range of 12.7–19.0 mg/kg DM (0.2–0.3 mmol/kg DM). Thus, concentrations below 12.7 mg/kg DM (0.2 mmol/kg DM) in the kidney may be a more reliable indicator of dysfunction than liver copper concentration.

The concentrations of copper in the livers of calves vary according to age and production class (dairy or beef) with no evidence of copper toxicosis or deficiency. In calves submitted for necropsy, the liver copper concentrations were as much as 60 mg/kg WW higher in dairy calves than beef calves. The concentration increased for the first 2 months of age, then declined until 9 months of age, after which it began to increase. Thus, the diagnosis of copper imbalance based on liver copper concentration in calves should take into account the diagnostic covariates of age and production class.

**Ceruloplasmin**

The difficulty of interpreting plasma levels of copper led to the estimation of plasma copper levels of copper-protein complexes, especially ceruloplasmin. Ceruloplasmin contains greater than 95% of the circulating copper in normal animals. There is a highly significant correlation between plasma copper levels and plasma ceruloplasmin activity, which is a less complicated and more rapid procedure than plasma copper. The regression analyses indicate a strongly positive correlation coefficient of ceruloplasmin with serum of cattle and sheep of 0.83 and 0.92, respectively. The correlation between serum ceruloplasmin activity and hepatic copper concentrations in cattle was only 0.35, indicating an unreliable relationship. Normal plasma ceruloplasmin levels in sheep are in the region of 45–100 mg/L. Normal levels of serum ceruloplasmin activity in cattle range from 120 to 200 mg/L. The mean copper and ceruloplasmin levels are higher in plasma than serum; the percentage of copper associated with ceruloplasmin is less in serum (55%) than in plasma (66%). Normal plasma ceruloplasmin levels in sheep range from 4.5 to 10 mg/dL. In experimental primary copper deficiency in calves, rapid decreases occur in plasma ceruloplasmin activity at least 80 days before overt clinical signs of deficiency.

**Erythrocyte dismutase**

The measurement of the activity of erythrocyte superoxide dismutase (ESOD), a copper-containing enzyme, is now being evaluated as a procedure for the diagnosis of copper deficiency. The activity of this enzyme decreases more slowly than plasma or liver copper in copper-deficient animals and may be more closely correlated with the presence of imminence of hypocuprosis. In marginal deficiency, the ESOD value ranges from 2 to 5 U/mg hemoglobin and in functional deficiency the value is below 2.

**Milk and hair copper**

The levels of copper in milk and hair are also lower in deficient than in normal cattle and estimation of the copper content of hair is now acceptable as a diagnostic aid. It has the advantage of providing an integrated progressive record of nutritional intake. The levels of copper in bovine hair are more markedly depressed when extra molybdenum is fed.

**Horses**

A threshold level of plasma copper of 16 μmol/L is used to distinguish between the normal and subnormal values. Liver copper from horses sampled at slaughter vary widely about a mean of 113.7 μmol/kg WW. The threshold of 52.5 μmol/kg WW of copper in liver is proposed to distinguish deficient from marginal liver copper status. Many healthy horses have serum values between 12 and 16 μmol/L. The mean hepatic copper concentrations of horses fed diets containing 6.9–15.2 mg copper/kg DM were 17.1–21.0 μg/g DM (0.27–0.33 μmol/g DM) tissue. The plasma copper concentrations ranged from 3.58 to 4.45 μg/dL (22.8–28.3 μmol/L). There was no simple mathematical relationship between plasma and hepatic copper concentrations. The range of serum copper concentrations in Thoroughbred horses at grass was 63–196 μg/dL (9.91–30.85 mmol/L) and in stabled Thoroughbreds the range was 47–111 μg/dL (7.40–17.47 mmol/L).

**Farmed red deer (Cervus elaphus)**

The suggested reference ranges for serum and liver copper concentrations to categorize the copper status of deer are: serum concentrations (μmol/L): <5, deficient; 5–9 marginal and; >8, adequate; and liver
copper concentrations (μmol/kg weight wet, Wt) >60, deficient; 60–100, marginal and >100, adequate.24 Enzootic ataxia and osteochondrosis occur when liver copper concentrations are <60 μmol/kg fresh tissue and serum copper concentrations are below 3–4 μmol/L.33 Growth responses to copper supplementation are equivocal when blood copper concentrations are <3–4 μmol/L, but are significant when mean blood copper concentrations are 0.9–4.0 μmol/L. No antler growth or body weight response to copper supplementation occurs when blood ceruloplasmin (ferroxidase) levels averaged 10–23 IU/L (equivalent to serum copper concentrations of 6–13 μmol/L) and liver concentrations averaged 98 μmol/kg fresh tissue. This suggests deficient, marginal and adequate ranges for serum copper concentrations should be <5, 5–8 and >8 μmol/L, respectively and those for liver copper concentrations should be <60, 60–100 and >100 μmol/kg, respectively.

Hematology
Anemia may occur in advanced cases of primary copper deficiency, hemoglobin levels being depressed to 50–80 g/L and erythrocytes to 2–4 × 10^12/L. A high proportion of cows in problem herds may have a Heinz-body anemia without evidence of hemoglobinuria and the severity of the anemia will be related to the hypocupremia.

NECROPSY FINDINGS
The characteristic gross findings in copper deficiency of ruminants are those of anemia and emaciation. Hair and wool abnormalities may be present as already described. Extensive deposits of hemosiderin can cause darkening of the liver, spleen and kidney in most cases of primary copper deficiency and in the secondary form if the copper status is sufficiently low. In lambs, there may be severe osteoporosis and long bone fractures. Osteoporosis is less evident in cattle, but can be confirmed radiographically and histologically. In naturally occurring secondary copper deficiency in cattle, associated with high dietary molybdenum and sulfate, there is widening of the growth plates due to abnormal mineralization of the primary spongiosa, resulting in a grossly rachitic appearance to the bones.

The most significant finding in enzootic ataxia is the degeneration of axons and myelin within the cerebellar and motor tracts in the spinal cord, a change only evident at the microscopic level. Chromatolysis of neurons in a variety of locations within the central nervous system is usually detectable. In a few extreme cases and in most cases of swayback, the myelin loss also involves the cerebrum, where there is destruction and cavitation of the white matter. There is marked internal hydro-

encephalus in such cases and the convolutions of the cerebrum are almost obliterated. Acute cerebral edema with marked brain swelling and cerebellar hemiaision, reminiscent of polioencephalomalacia, may also accompany the more typical myelopathy and multifocal cerebral leukomalacia in lambs with hypocupremia.

In falling disease, the heart is flabby and pale. There is generalized venous congestion and the blood may appear watery. The liver and spleen are enlarged and dark. Histological examination reveals atrophy of the cardiac muscle fibers and considerable cardiac fibrosis. Deposits of hemosiderin are present in the liver, spleen and kidney.

Necropsy findings associated with copper deficiency in non-ruminant species are not well-documented. Degenerative changes with subsequent rupture of the aorta have been experimentally induced in pigs, but this has not been described as a naturally occurring disease. A myelopathy with white matter changes similar to those of enzootic ataxia has also been reported in 4–5-month-old copper-deficient pigs. Musculoskeletal changes similar to those described for calves have also been reported in foals with hypocupremia.

Necropsy examinations should include assay of copper in visceral organs. The levels of copper in the liver are usually low (see Table 30.4) and in secondary copper deficiency, there may be a high level of copper in the kidney and high levels of molybdenum in the liver, kidney and spleen. Copper levels in body tissues and fluids in primary and secondary copper deficiency are listed in Table 30.4.

Samples for confirmation of diagnosis
Toxicology – 50 g liver, kidney (ASSAY (Cu) (Mo))
Histology – formalin-fixed samples of:
- long bone (including growth plate), skin, liver, spleen. Enzootic ataxia/swayback: half of midsagittally-sectioned brain, lumbar and cervical spinal cord. Falling disease: heart (several sections), bone marrow, spleen (LM).

DIFFERENTIAL DIAGNOSIS
The clinical findings which are common in young, growing ruminants, include a herd problem of unthriftness and progressive loss of weight, changes in hair coat color or texture of wool, chronic lameness, neonatal ataxia in lambs and kids and terminal anemia. In adult cattle on pasture with excess molybdenum, chronic diarrhea is characteristic. A combination of serum and liver copper and serum molybdenum, are major diagnostic aids in distinguishing between copper deficiency and the other diseases.

Several diagnostic tests that are herd or flock problems in cattle and sheep may resemble both primary and secondary copper deficiency. The emphasis is on many animals being affected at about the same time, with a chronic debilitating disease complex, under the same dietary and seasonal circumstances.

A scheme for the differential diagnosis of mineral and vitamin responsive disorders in beef cattle herds with subnormal mineral status should include three major directions: malnutrition (lack of feed); chronic infectious disease; and, lack of specific micronutrients.

Cattle
Unthriftness and progressive weight loss may be due to protein-energy malnutrition and examination of the diet will reveal the cause.

Changes in hair coat color in young growing cattle is caused only by copper deficiency.

Chronic lameness in young growing cattle may be caused by a calcium, phosphorus and vitamin D imbalance, which is determined by examination of the diet and radiography of the long bones. The radiographic changes in cattle with secondary copper deficiency consist of widened irregular epiphyseal plates with increased bone density in the metaphysis and metaphyseal lipping. These findings are similar to those described for rickets and secondary nutritional hyperparathyroidism in cattle.

Chronic diarrhea in young cattle may be due to intestinal parasitism and fecal examination and response to therapy are diagnostic. Diarrhea in a group of adult cattle on pasture known to be high in molybdenum is probably due to secondary copper deficiency and response to therapy is diagnostic.

Winter dysentery of cattle, salmonellosis, coccidiosis, and mucosal disease are acute diseases characterized by diarrhea but are accompanied by other signs and clinicopathological findings which facilitate their identification. Many poisons, particularly arsenic, lead, and salt, cause diarrhea in ruminants but there are usually additional diagnostic signs and evidence of access to the poison. Assay of feed and tissues helps to confirm a diagnosis of poisoning.

A diagnosis of peat scour is usually made if there is an immediate response to oral dosing with a copper salt.

Falling disease occurs only in adult cattle and must be differentiated from other causes of sudden death. Poisoning by the gidgee tree (Acacia Georganae) produces a similar syndrome in cattle.

Sheep and goats
Unthriftness and abnormal wool or hair as a flock or herd problem are characteristic of copper deficiency in sheep and goats, which must be differentiated from protein-energy malnutrition, intestinal parasitism, cobalt deficiency, and external parasites.

Lameness in a group of lambs several weeks of age must be differentiated from nutritional osteodystrophy due to a
The treatment of copper deficiency is relatively simple, but if advanced lesions are already present in the nervous system or myocardium, complete recovery will not occur. Oral dosing with 4 g of copper sulfate for calves from 2 to 6 months of age and 8–10 g for mature cattle given weekly for 3–5 weeks is recommended for the treatment of primary or secondary copper deficiency. Parenteral injections of copper glycinate may also be used and the dosages are given under control.

The diet of affected animals should also be supplemented with copper. Copper sulfate may be added to the mineral-salt mix at a level of 3–5% of the total mixture. A commonly recommended mixture for cattle is 50% copper–phosphorus mineral supplement, 45% cobalt–iodized salt, and 3–5% copper sulfate. This mixture is offered free of choice or can be added to a complete diet at the rate of 1% of the total diet.

**CONTROL**

**Dietary requirements**

The minimum dietary requirement for copper for cattle is 10 mg copper/kg DM and 5 mg/kg DM for sheep.

The requirement necessary to prevent subclinical or clinical copper deficiency will depend on the presence of interfering substances such as molybdenum, sulfur, and iron in the diet and possibly the genotype of the animal. Copper sulfate is considered a better supplement than copper oxide or injectable copper for cattle consuming diets containing excess molybdenum or molybdenum plus sulfur. Although there is a marked difference between breeds of sheep in their susceptibility to hypocuprosis, this would not seem to have an immediate practical application. The estimated copper requirement in the diet of mature ponies is 3.5 mg/kg DM. The levels of copper in liver samples of 50% of culled ewes and 40% of market lambs were high to toxic indicating that monitoring the dietary levels of copper is essential.

The copper requirements may also vary according to breed. Angus heifers have a lower minimal copper requirement than Simmental heifers. Based on liver copper, diets containing copper at 4.4 or 6.4 mg/kg DM, did not meet the requirement of either breed during gestation and lactation or growth. Supplementation of copper at 7 mg/kg DM to the control diets provided the requirements of both breeds.

There are significant differences in the copper requirements and tolerance between goats and sheep. The dietary copper requirements of goats are uncertain but may be higher than in sheep. Dietary levels of copper which could cause copper toxicity in sheep, do not cause toxicity in goats. Some limited data on growth performance indicates a stimulatory effect of 100–300 ppm copper in the diet of Nubian goats. Extra copper accumulated in liver and to a lesser extent in other tissues and was excreted through the biliary system and into the feces.

Supplementation of diets with copper of feedlot cattle under some circumstances can affect performance. As little as 20 mg/kg DM of supplemental copper can reduce performance in finishing steers. The addition of 10 or 20 mg/kg DM of supplemental copper to a high-concentrate diet containing 4.9 mg/kg DM alters lipid and cholesterol metabolism in steers but does not alter ruminal fermentation. Decreasing cholesterol and altering fatty acid composition (saturated to unsaturated) in beef produced for human consumption has potential health benefits.

Copper can be supplied by several different methods as outlined below. The dose rates given are those recommended for the control of primary copper deficiency and these may have to be increased or treatment given more frequently in some instances of secondary copper deficiency. In these circumstances it is often necessary to determine the most satisfactory dosing strategy by a field trial.

**Copper toxicity**

The incidence of copper toxicity in dairy cattle in the UK has increased recently. Apparent subclinical hepatopathy, with no clinical disease, due to excess copper intake in lactating dairy cattle has been described. On average, each cow received 963 mg copper daily from the mineral supplement alone. Calculation of the total dietary copper found that high producing cows had an estimated intake of 1325 mg copper daily, while each low producing cow received 1250 mg daily. The estimated copper requirements of the cows were 290 and 217 mg/cow per day, respectively. Thus oversupplementation of dairy cows with copper may be a significant problem in dairy herds without overt clinical signs of toxicity.

**Copper sulfate**

**Oral dosing**

Oral dosing with copper sulfate (5 g to cattle, 1.0 g to sheep, weekly) is adequate as prophylaxis and will prevent the occurrence of swayback in lambs if the ewes are dosed throughout pregnancy. Lambs can be protected after birth by dosing with 35 mg of copper sulfate every 2 weeks. However, regular oral dosing with copper sulfate is laborious and time-consuming and is no longer widely practiced.

**Dietary supplementation**

**Mineral mixture in feed.** The copper sulfate may be mixed with other minerals into a mineral premix, which is then incorporated into the concentrate part of the ration. The final concentration of copper is usually adjusted to provide an overall intake of at least 10 ppm of copper in the DM of the final ration. If the forage components of the ration contain much less than 10 ppm, the concentrate part of the ration may need to contain much larger concentrations of copper. Where a secondary copper deficiency is due to molybdenum in the forage, up to 1200 mg copper (approximately 5 g of hydrated copper sulfate) is added to the concentrate daily. When sheep are grazing toxic lupin stubble, the signs of lupinosis may be exacerbated by the supplementation of only 10 mg copper/kg DM as copper sulfate and therefore the supply of copper in the absence of suitable amounts of molybdenum and sulfur should be kept to a minimum.

**Salt-lick ad libitum.** If animals are not receiving concentrates containing copper, an alternative is to provide free access to a mineral mixture or salt-lick containing 0.25–0.5% of copper sulfate for sheep and 2% for cattle, which will supply sufficient copper provided an adequate intake of the mixture is assured. The mineral mixture usually contains iodized salt, cobalt, calcium, phosphorus, and other trace minerals.

**Top-dressing pastures.** In some deficient areas, an effective method of administering copper is by the annual top-dressing of pasture with 10 kg/ha copper sulfate, although the amount required may vary widely with the soil type and the rainfall. Top-dressing may cause copper poisoning if livestock are turned onto pasture while the copper salt is still adherent to the leaves. Treated pasture should be left unstocked for 3 weeks or until the first heavy rain. It is also possible that chronic copper poisoning may result if the copper status of the soil increases sufficiently over a number of years.

**Top-dressing grazing pastures of farmed red deer was compared with oral administration of copper oxide wire particles to some deer.**
Copper sulfate at a rate of 12 kg/ha, but not 6 kg/ha, in mid-March was effective increasing the copper status of weaning hinds; while pastures top dressed the 12 kg/ha copper sulfate in mid-March and dosing hinds with 10 g copper oxide in late-July were effective in increasing the copper status of pregnant hinds and in the case of the yearling hinds, significantly improved the copper status of their progeny from birth to weaning.

**Drinking water supplementation.**
Addition of copper salts to drinking water is usually impractical because the solution corrodes metal piping and maintenance of the correct concentration of copper in large bodies of water is difficult. However, if the need is great, some way around these difficulties can usually be found and a system has been devised for automatic supplementation for short periods via the drinking water and has been effective in controlling copper deficiency in cattle. Copper pellets which provide 2-3 mg copper/L of water have been recommended for cattle. Calves can tolerate copper in milk replacers at a concentration of 50 ppm but there is no advantage in providing more than 10 ppm.

**Molasses based mineral supplements.** Copper can be provided in molasses-based supplements. However, the high sulfur concentrations in the molasses may affect the availability, through the formation ruminal thiomylobdates and result in lower liver copper concentrations. A dietary copper concentration greater than 10 ppm may be necessary to ensure absorption in beef cattle fed molasses-based supplements.

**Removal of sulfates**
The removal of sulfates from drinking water by water purification, using a process of reverse osmosis, may have a positive effect on the copper status of beef cows. Cows drinking desulfated water had an increased availability of copper compared with those drinking water containing a large concentration of sulfates.

**Parenteral injections of copper**
To overcome the difficulty of frequent individual dosing or top-dressing of pasture, periodic parenteral injection of copper compounds that release copper gradually has given good results. They can be given at strategic times depending on the circumstances. They also have the advantage of avoiding fixation of copper by molybdenum in the alimentary tract. Injectable preparations of copper are now the method of choice for the prevention of swayback in lambs. The following have been evaluated under field conditions:

- Copper calcium ethylenediamine tetra-acetate (copper calcium edetate)
- Copper methionate
- Copper heptonate
- Copper glycinate
- Copper oxyquinoline sulfonate
- Copper phenylalanine complex.

The criteria used to judge these injections are minimal damage at the site of injections, satisfactory liver storage (90-100%) of the administered dose and a safe margin between therapeutic and toxic doses. The dose of copper in any of the compounds for cattle is 400 mg and for sheep 150 mg.

**Copper heptonate** at the rate of 25 mg of copper in 2 mL of preparation given by IM injection to ewes in mid-pregnancy was successful in preventing swayback in lambs. The IM injection of 1 or 2 mg Cu/kg BW as copper heptonate does not result in any signs of toxicity such as weakness, lethargy, or icterus. The copper is lost from the injection site within 7 days and most is transferred to the liver with little or no deposition in the skeletal muscle. The higher dose raised mean liver copper values to within the range of 13-52 mmol/kg DM, which is associated with copper toxicity.

In sheep on pasture of high molybdenum content, a single IM injection of copper heptonate providing 37.5 mg copper to adults or 25 mg copper to weaners increases the liver copper reserves for at least 9 and 3 months, respectively and is considered an acceptable alternative to copper oxide wire particles for preventing copper deficiency in sheep in southern Australia.

**Copper calcium edetate** has the advantage of giving maximum copper storage very quickly – 1 week after injection – and blood levels are elevated within a few hours. Because of the rapidity of the absorption, toxic effects can be encountered unless proper dose levels are observed. As well as deaths from serious overdosing, some deaths occur in groups of sheep for unexplained reasons. It is suggested that stress be minimized and simultaneous other therapy be avoided.

A marked local reaction occurs at the site of injection so that SC injection is preferable in animals to be used for meat, although to avoid an unsightly blemish, breeding animals should receive an IM injection. The injections are a small risk for precipitating blackleg in cattle on farms where this disease occurs. For sheep, a single injection of 45 mg of copper as copper glycinate in mid-pregnancy is sufficient to prevent swayback in the lambs.

The SC injection of copper calcium edetate or copper oxyquinoline sulfonate into sheep results in a rapid increase in the concentration of copper in whole blood, serum, and urine within the first 24 h. Following the injection of copper methionate, the concentration of copper in blood and serum rises steadily over a period of 10 days and there is no detectable increase in urinary copper. After the injection of any of the three compounds, there is a steady increase in serum ceruloplasmin activity over a period of 10-20 days, followed by a slow fall to preinjection activity by 40 days. The lower toxicity of copper injected as methionine compared with that as copper calcium edetate or copper oxyquinoline sulfonate is due to the slower absorption and transport of the copper to the liver and kidney. Death has occurred in sheep following the parenteral administration of diethylamine oxyquinoline sulfonate at recommended doses. Affected sheep manifest signs of hepatic encephalopathy and at necropsy, there was acute, severe, generalized, centrilobular hepatocellular necrosis. The use of copper disodium edetate at recommended doses in calves has also resulted in deaths associated with liver necrosis and clinical signs of hepatic encephalopathy.

**Injectable copper glycinate** is an excellent source of supplementary copper for increasing the concentration of copper in the serum of copper-deficient cattle and maintaining grazing cattle in an adequate copper status. One dose of copper glycinate will maintain adequate copper levels for about 60-90 days. The recommended dose in beef herds is 120 mg of copper for adult cattle and 60 mg of copper for calves. A supplemental source of copper is required for the calf during the pasture season because milk is a poor source of copper, particularly from copper-deficient cows and calves do not have the opportunity to increase or maintain body stores of copper while grazing. When the dam is severely hypocupremic in the spring, the calf is also severely hypocupremic or copper-deficient. Insufficient copper is secreted into the milk of copper-treated cows. Therefore, where the dam has not received an adequate copper intake during pregnancy, direct treatment of the calf will be required in early life. The copper reserves of newborn calves are increased in fetal liver at the expense of copper stores in the dam's liver, which are dependent on the availability of dietary or supplemental copper to the dam. Calves usually have sufficient liver copper at birth and do not need an injection of 50 mg until they are 6 weeks old. Because of the higher requirements for copper during the last trimester of pregnancy (demands of the fetal liver), a program of copper supplementation should involve the use of copper supplements, throughout the year as required.

One dose of copper glycinate is sufficient when cattle are grazing forage that contains no more than 3 mg/kg DM of
molybdenum and 3 g/kg DM of sulfur. With higher levels of molybdenum and sulfur, repeated injections of copper glycinate are recommended. The injectable copper may be supplemented by the use of copper sulfate in a mineral supplement at a level of 1%. The inclusion of copper sulfate in the mineral supplement may be adequate for cows, but the calves may not consume an adequate amount of mineral and injectable copper. The level of supplementation required to prevent a drop in serum copper over the pasture season will depend upon the concentration of dietary molybdenum and sulfur and their effect upon the coefficient of absorption of copper.

Injectable copper complex compounds have been evaluated as supplementary copper for grazing beef cattle under Canadian conditions. Copper edetate at 100 mg of copper, copper glycinate at 120 mg, and copper methionate at 120 mg were used and were equally effective in improving copper status of copper-deficient cattle and maintaining them in an adequate copper status for 90 days. The copper methionate was least acceptable because of the incidence and severity of reactions at the site of injection.

The use of injectable copper edetate in horses has been investigated as a method of increasing liver copper in foals at birth to reduce the incidence and severity of developmental bone and joint disease in newborn foals. The administration of 100 mg and 250 mg copper edetate IM to mares during the 9th and 10th months of gestation had no effect on the liver concentration of their foals at birth.43

Copper phenylalanine in a single injection to dairy cows in Uruguay maintained serum copper levels at an adequate level for at least 100 days.44

Controlled-release glass

Death due to poisoning is one of the dangers of parenteral administration because it is difficult to control the rate at which the supplement releases the copper, especially if the controlling mechanism is chemical binding. Methods used to control the release include the development of soluble controlled-release glass for oral administration to sheep and cattle. The copper is slowly released, absorbed, and stored in the liver. Initial field evaluations indicate that the boluses may not contain sufficient copper to maintain normal levels of copper for a sufficient length of time compared to the use of copper oxide needles.

Boluses of a soluble copper-containing controlled-release glass have been developed and evaluated. The boluses are based on a phosphate-type glass into which appropriate quantities of trace elements are incorporated. The boluses lodge in the rumen and release copper at a slow rate. They can provide additional supplies of copper to ruminants at an almost uniform rate for many months. One commercial product contains selenium and cobalt and in one experiment increased ceruloplasmin activity for at least 1 year. In one field study, the administration of two commercial soluble glass boluses containing copper and selenium, the selenium levels were increased from marginal to adequate, but adequate copper levels were not maintained.

A soluble glass bolus containing copper, cobalt, and selenium given to extensively grazed sheep in the North East of Scotland, under two different situations: lowland finishing lambs and upland sheep in their non-productive year between being a lamb and being a productive ewe (gimmer) was able to prevent or correct deficient and/or marginal cobalt and selenium status of sheep throughout the trial period. The bolus has little measured effect on the already adequate blood indicators of copper status, although the liver copper concentrations of the bolused sheep were higher.45

Copper oxide needles

Copper oxide needles or wire particles (fragments of oxidized copper wire up to 8 mm in length and 0.5 mm in diameter) are used for oral dosing and one of the most effective and safest methods for the control of copper deficiency in ruminants. Its major advantages are prolonged effectiveness and low cost. A single treatment can be effective for an entire summer or winter season. The needles are retained in the forestomachs and abomasum for up to 100 days or more and the copper is slowly released, absorbed and stored in the liver.

Sheep

A dose of 0.1 g/kg live weight (5 g) in sheep is safe and does not induce copper toxicity in the susceptible North Ronaldsay breed. The response in liver copper concentrations is dose-dependent. In sheep given doses ranging from 2.5 to 20 g per animal, the liver copper concentrations will peak 10 weeks after administration and will thereafter decline in a linear fashion over the next 40 weeks.

The administration of a single dose of 2 g copper oxide needles orally to lambs between 3 and 5 weeks of age is an effective method for the prevention of induced hypocupremia manifested as ill-thrift in lambs grazing pastures improved by liming and reseeding. The treatment maintained the lambs in normocupremia, provided adequate liver copper reserves, prevented clinical signs of hypocupremia and produced a live weight gain advantage. The administration of the needles to ewes in the first half of pregnancy is also effective for the prevention of swayback in their lambs. The administration of cupric oxide needles to ewes at parturition is effective in preventing hypocupremia for up to 17 weeks in animals on pasture previously shown to cause a molybdenum-sulfur-induced copper deficiency. The treatment of the ewes at parturition also resulted in higher concentrations of copper in the milk in the initial weeks of lactation.

However, this increase in milk copper will not be effective in preventing hypocupremia and hypocupremia in the lambs, which can be treated with cupric oxide needles at 6 weeks of age. Because some breeds of sheep may have a propensity to concentrate excess quantities of copper in the liver, it is important to adhere to the recommended dosage. Cupric oxide needles at a dose of 4 g per animal have also been used for the prevention of swayback in goats and to maintain liver copper levels for up to 5 months in farmed red deer grazing on a marginally copper-deficient pasture.

Copper oxide needles given to ewes in early pregnancy increases their liver copper status through gestation and early lactation and the copper status of their lambs from birth to 36 days old.46 Serum copper concentration was not affected by treatment but a marked rise was observed in all lambs between birth and 10 weeks of age.

Cattle

A single dose of 20 g of copper oxide needles to hypocupremic suckler cows was sufficient to maintain adequate copper status for at least 5 months. The use of 20 g of copper oxide needles to young cattle weighing 190 kg effectively prevented growth retardation and severe hypocupremia, which occurred in an undosed control over a 70-day trial period. The currently recommended doses for beef cattle are 5 g for calves, 10 g for yearlings and 20 g for heavier or adult cattle, which will give protection for at least 6 months. A single oral dose of 20 g of copper oxide needles at the beginning of the grazing season is effective in increasing or maintaining stores of copper in the liver of grazing cows and calves consuming low-copper, high-molybdenum forage, and high-sulfate water supplies. The use of 50 g of needles in adult cows (55 kg BW) sustained higher levels of plasma concentrations than the SC injection of copper glycinate and 100, 200, or 300 g of needles given orally did not cause clinical effects.

Farmed red deer

The administration of 20 g boluses of copper-oxide wire particles to rising 2-year-old red deer stags did not significantly alter velvet antler weight, daily velvet antler growth rate, days from casting to removal, grade or value, or stag live weight gain.47 Copper supplementation...
increased mean serum ceruloplasmin (ferroxidase) concentrations by approximately 10 IU/L. Mean liver copper concentrations in control deer was 99 μmol/kg and ranged from 194 to 386 μmol/kg in the treated groups.

Field trials on New Zealand deer farms using 5g of copper oxide wire particles given to deer 4–7 months old found no effect on live weight gain despite evidence of hypocupremia in 38% of non-supplemented animals, which gained weight at similar rates to those which had adequate plasma copper levels. This suggests that the extent of the hypocupremia was either not sufficiently severe, or not maintained for a long enough period to cause copper deficiency resulting in live weight gain. This indicates that deer farmers need to reassess the need for copper supplementation in young deer.

Copper oxide powder

Copper oxide powder administered in the form of experimental, sustained-release rumen boluses significantly increased blood and liver copper concentrations in growing sheep, in out-wintered suckler calves, and in growing cattle at grass in the summer periods over periods of at least 170 and 123 days, respectively.

Genetic selection

It is now possible to manipulate trace element metabolism by genetic selection in farm animals. Within a period of 5 years, selection of sheep based on plasma concentration of copper resulted in two divergent sets of progeny, one with a high level of copper status, the other with a lower level, which resulted in clinical manifestations of copper deficiency in the low level and protection in the high level.

General guidelines

Several rules of thumb are important and useful.

- A dietary intake of copper equivalent to 10 mg/kg DM will prevent the occurrence of primary copper deficiency in both sheep and cattle.
- Diets containing less than 5 mg/kg DM will cause hypocupremia.
- Diets with copper: molybdenum ratios of less than 5:1 are conducive to secondary hypocupremia.
- The newborn calf is protected against neonatal hypocupremia by donations from the dam, but newborn lambs assume the same copper status as the ewe.
- Cattle are more susceptible to copper deficiency than are sheep.

**REFERENCES**

**IODEINE DEFICIENCY**

**ETIOLOGY**

Primary dietary deficiency of iodine or secondary to conditioning factors such as calcium, Brassica plants, or bacterial pollution of water.

**EPIDEMIOLOGY**

In all species, most common in continental land masses. Neonatal animals. Diets of dams deficient in iodine or containing conditioning factors such as certain plants.

**Signs**

Goiter as palpable enlargement of thyroid gland. Neonatal mortality due to stillbirths, weak neonates may not be able to suck and die in few days, alopecia at birth, myxedema.

**Clinical pathology**

- Blood iodine levels.
- Necropsy findings: Thyroid enlargement, alopecia, myxedema.

**Diagnostic confirmation**

Goiter and iodine deficiency.

**Differential diagnosis list**

- Weak calf syndrome
- Abortion
- Congenital defects.
- Hypothyroidism

**Treatment**

Not usually undertaken.

**Control**

Insure dietary intake of iodine in pregnant animals.
were affected with iodine deficiency, which were both primary and secondary due to the presence of nitrates, thiocyanates, or glucosinolates in the diet. The importance of subclinical iodine deficiency as a cause of neonatal mortality could be much greater than clinical disease. For example, in southern Australia, ewes supplemented with iodine by the single injection of iodine in oil, have had less mortality in the lambs, have grown larger lambs, or performed the same as controls. In New Zealand, subclinical iodine deficiency has been recognized in a sheep flock in which fertility and lamb perinatal mortality occurred and corrected by supplementation of the ewes with iodine. The annual cost associated with iodine deficiency in one Manawata Romney flock was conservatively estimated at $6.00 per ewe. Iodine supplementation has been shown to reduce perinatal mortality and increased lambing percentage by 14–21% in pasture-fed ewes. Thus subclinical iodine deficiency can affect reproductive performance and perinatal lamb mortality rates. Young animals are more likely to bear goitrous offspring than older ones and this may account for the apparent breed susceptibility of Dorset Horn sheep, which mate at an earlier age than other breeds.

A survey of crossbred cows in the Punjab of India, found that 35.9% of cows were iodine deficient with considerable geographic variation from 0 to 86% within Punjab. The cardinal clinical signs of iodine deficiency were absent and basal plasma T3 (triiodothyronine) and T4 (plasma thyroxine) concentrations and their ratio did not differ between deficient and control cows. The response to injection of 1 mL of 78% ethiodized oil can prevent the deficiency for more than 70 days.

**Risk factors**

Dietary and environmental factors

A simple deficiency of iodine in the diet and drinking water may occur and is related to geographical circumstances. Areas where the soil iodine is not replenished by cyclical accessions of oceanic iodine include large continental land masses and coastal areas where prevailing winds are offshore. In such areas, iodine deficiency is most likely to occur where rainfall is heavy and soil iodine is continually depleted by leaching. Over a 3-year period, several calves were born with goiter in a dairy herd located 200 km from the sea on sandy soil. The calves were born from first-calf heifers which had not received any iodine supplementation.

Soil formations rich in calcium or lacking in humus are also likely to be relatively deficient in iodine. The ability of soil to retain iodine under conditions of heavy rainfall is directly related to their humus content, and limestone soils are, in general, low in organic matter. A high dietary intake of calcium also decreases intestinal absorption of iodine, and in some areas, heavy applications of lime to pasture are followed by the development of goiter in lambs. This factor may also be important in areas where drinking water is heavily mineralized.

There are several situations in which the relationship between iodine intake and the occurrence of goiter is not readily apparent. Goiter may occur on pasture containing adequate iodine; it is then usually ascribed to a secondary or conditioned iodine deficiency. A diet rich in plants of the *Brassica* spp. containing cabbages and brussels sprouts, may cause simple goiter and hypothyroidism in rabbits, which is preventable by administered iodine. Severe iodine deficiency can occur when ewes are fed Brassica crops for long periods. *Brassicas* such as swedes, turnips, and kale have low iodine content and contain goitrogens, and may result in weak newborn lambs with enlarged thyroid glands. Goiter occurred in 85% of lambs examined at necropsy, born from ewes on the Brassica crop and not supplemented with iodine. Diffuse hyperplastic goiter has occurred in calves in beef cows in Japan which were on pasture or being fed feed containing *Rorippa indica*, *Hiern*, genus Brassica, family Crucifera, ‘Inugarash’, which contains thiocyanate. The iodine content of the waters on affected farms was low at 0.361 μg/L and 0.811 μg/L and that of the pastures, 87 and 121 μg/kg, on two different farms. Hypothyroidism has also been produced in rats by feeding rapeseed meal. Feeding large quantities of kale to pregnant ewes causes a high incidence of goiter and hypothyroidism, also preventable by administering iodine in the newborn lambs. The goitrogenic substance in these plants is probably a glucosinolate capable of producing thiocyanate in the rumen. The thiocyanate content, or potential content, varies between varieties of kale, being much less in rape-kale, which also does not show the two-fold increase in thiocyanate content other varieties show in autumn. Small young leaves contain up to five times as much thiocyanate as large, fully formed leaves. Some of these plants are excellent sources of feed, and in some areas, it is probably economical to continue feeding them, provided suitable measures are taken to prevent goiter in the newborn. Although kale also causes mild goiter in weaned lambs this does not appear to reduce their rate of gain.

A diet high in linseed meal (20% of ration) given to pregnant ewes may result in a high incidence of goitrous lambs, which is preventable with iodine or thyroxine. Under experimental conditions, groundnuts are goitrogenic for rats, the goitrogenic substance being a glycoside-arachidoside. The goitrogenic effect is inhibited by supplementation of the diet with small amounts of iodine. Soybean byproducts are also considered to be goitrogenic. Gross bacterial contamination of drinking water by sewage is a cause of goiter in humans in countries where hygiene is poor. There is a record of a severe outbreak of goitrous calves from cattle running on pasture heavily dressed with crude sewage. Prophylactic dosing of the cows with potassium iodide prevented further cases. Feeding sewage sludge is also linked to the occurrence of goiter.

**Goiter in lambs** may occur when permanent pasture is plowed and resown. This may be due to the sudden loss of decomposition and leaching of iodine-binding humus in soils of marginal iodine content. In subsequent years the disease may not appear. There may be some relation between this occurrence of goiter and the known variation in the iodine content of particular plant species, especially if new pasture species are sown when the pasture is plowed. The maximum iodine content of some plants is controlled by a strongly inherited factor and is independent of soil type or season. Thus, in the same pasture, perennial rye grass may contain 146 μg iodine per 100 g dry matter (DM) and Yorkshire for grass only 7 μg/100 g DM. Because goiter has occurred in lambs when the ewes are on a diet containing less than 30 μg iodine per 100 g DM, the importance of particular plant species becomes apparent. A high incidence of goiter associated with heavy mortality has been observed in the newborn lambs of ewes grazing on pasture dominated by white clover and by suterannean clover and perennial rye grass.

**Congenital goiter has been observed in foals** born to mares on low iodine intake, but also to mares fed an excessive amount of iodine during pregnancy.

**PATHOGENESIS**

Iodine deficiency results in a decreased production of thyroxine and stimulation of the secretion of thyrotropic hormone by the pituitary gland. This commonly results in hyperplasia of thyroid tissue and a considerable enlargement of the gland. Most cases of goiter of the newborn are of this type. The primary deficiency of thyroxine is responsible for the severe weakness and hair abnormality of the affected animals. Although the defect is described as hairlessness, it is truly hypoplasia of the hairs, with many very slender hairs present and a concurrent absence and
Defective ossification has also been reported, the manifestation is collapse of the central and third tarsal bones leading to lameness and deformity of the hock. Enlargement of the thyroid also occurs commonly in adult horses in affected areas, Thoroughbreds and light horses being more susceptible than draft animals.

In cattle, the incidence of thyroid enlargement in adults is much lower than in horses and the cardinal manifestations are gross enlargement of the thyroid gland and weakness in newborn calves. If they are assisted to suck for a few days, recovery is usual, but if they are born on the range during inclement weather, many will die. In some instances, the thyroid gland is sufficiently large to cause obstruction to respiration. Affected calves have a thick neck and appear to be suffocating.6 Lethargy, weakness, and difficulty in consuming colostrum are common. Partial alopecia is a rare accompaniment.

In pigs, the characteristic findings are birth of hairless, stillborn or weak piglets often with myxedema of the skin of the neck. The hairlessness is most marked on the limbs. Most affected piglets die within a few hours of birth. Thyroid enlargement may be present but is never sufficiently great to cause visible swelling in the live pig. Survivors are lethargic, do not grow well, have a waddling gait and leg weakness due to weakness of ligaments and joints.

Adult sheep in iodine-deficient areas may show a high incidence of thyroid enlargement but are clinically normal in other respects. Newborn lambs manifest weakness, extensive alopecia, and palpebral, if not visible, enlargement of the thyroid glands. The gestation length of ewes may be increased and increased perinatal mortality, especially in inclement weather.1 Marginal iodine deficiency can result in non-specific production losses from embryonic mortality or high perinatal lamb death and are difficult to diagnose.3

Goats present a similar clinical picture, except that all abnormalities are more severe than in lambs. Goat kids are goitrous and alopecic. The degree of alopecia varies from complete absence of hair, through very fine hair, to hair that is almost normal. Animals surviving the initial danger period after birth may recover, except for partial persistence of the goiter. The glands may pulsate with the normal arterial pulse and may extend down a greater part of the neck and cause some local edema. Auscultation and palpation of the jugular furrow may reveal the presence of a murmur and thrill, the ‘thyroid thrill’, due to the increased arterial blood supply of the glands.

Experimental hypothyroidism produced in horses by surgical excision of the gland results in a syndrome of poor growth, cold sensitivity, long, dull hair coat, docility, lethargy, edema of hindlimbs, and a coarse, thick appearance of the face. The rectal temperature is depressed and blood cholesterol levels are high. Administration of thyroprotein reverses the syndrome. Congenital hypothyroidism has been induced in guinea pigs using a low-iodine diet to compare the developmental abnormalities which occur in horses with congenital hypothyroidism.10 Many of the abnormalities in guinea pig pups from the experimentally treated dams were similar to those described in foals.

Goiter has occurred in newborn foals whose mares were supplemented with excess iodine during the last 24 h of pregnancy.11

**CLINICAL PATHOLOGY**

Several criteria have been used for the laboratory diagnosis of iodine deficiency in sheep.17 They include thyroid weight, lamb thyroid to body weight ratio, comparison of serum T4 (serum thyroxine) concentrations in lamb and dam (T4 concentrations are lower in the lamb than in the dam when iodine deficiency is present, serum T4 concentrations in the ewe and pasture iodine concentrations.18 In New Zealand, pasture iodine, and serum thyroxine (T4) and tri-iodothyronine (T3) concentrations of ewes were unreliable in predicting the occurrence of increased litter size and reduced perinatal mortality in response to iodine supplementation.12 Newborn lambs from ewes unsupplemented with iodine, had mean thyroid weight (g) to body weight (kg) ratio of 0.40 g/kg or greater.12 Other tests are concentrations of iodine in plasma, milk, and urine all of which measure current iodine status.

Estimations of iodine levels in the blood and milk are reliable indicators of the thyroxine status of the animal. Organic or protein-bound iodine is estimated in serum or plasma and used as an index of circulating thyroid hormone, provided access to exogenous iodine in the diet, or as treatment, is adequately controlled. There may be between-breed differences in blood iodine levels but levels of 2.4-14 μg of protein-bound iodine per 100 mL of plasma appear to be in the normal range. In ewes, an iodine concentration in milk of below 8 μg/L indicates a state of iodine deficiency. Bulk tank milk iodine content should be greater than 300 μg/L.

Levels of thyroxine in the blood have not been used much to measure thyroid gland sufficiency in animals. Work in ewes has shown that normal lambs at birth have twice the serum thyroxine levels of their dams, but goitrous lambs have levels...
less than those of their dams. However, low mean thyroxine levels (50 nmol/L is normal) are not a definitive indication of iodine deficiency because of the variety of factors affecting thyroxine levels. These levels fall rapidly after birth and approximate the dam’s levels at 5–6 weeks of age.

Changes in serum thyroid hormone levels in newborn calves have been used as a diagnostic index in endemic goiter but their high variation has been unreliable. The T4/T3 ratio of calves with goiter was lower than in healthy calves and adult cows, and may be a useful diagnostic aid. In determining the iodine status of an area, iodine levels in soil and pasture should be obtained but the relationship between these levels, and between them and the status of the grazing animal, may be complicated by conditioning factors.

**NECROPSY FINDINGS**

Macrosopic thyroid enlargement, alopecia and myxedema may be evident. The weights of thyroid glands have diagnostic value. In full-term normal calves the average fresh weight is 6.5 g, in lambs 2 g is average. Newborn lambs from ewes unsupplemented with iodine, had mean thyroid weight (g) to body weight (kg) ratio of 0.40 g/kg or greater. In calves with severe thyroid hypertrophy, the gland may be heavier than 20 g.

The iodine content of the thyroid will also give some indication of the iodine status of the animal. At birth, a level of 0.03% of iodine on a wet weight basis (0.1% on dry weight) can be considered to be the critical level in cattle and sheep. On histological examination, hyperplasia of the glandular epithelium may be seen. Follicles depleted of colloid, infolded and lined by columnar epithelium are indicative of hypothyroidism in lambs born from ewes unsupplemented with iodine.

The hair follicles will be found to be hypoplastic. Delayed osseous maturation, manifested by absence of centers of ossification, is also apparent in goitrous newborn lambs.

**Samples for confirmation of diagnosis**

- **Toxicology** – 1 thyroid gland (ASSAY (Iodine))
- **Histology** – skin, thyroid (LM).

**DIFFERENTIAL DIAGNOSIS**

Iodine deficiency is easily diagnosed if goiter is present but the occurrence of stillbirths without obvious goiter may be confusing. Abortion due to infectious agents in cattle and sheep must be considered in these circumstances. In stillbirths due to iodine deficiency, gestation is usually prolonged beyond the normal period, although this may be difficult to determine in animals bred at pasture. Inherited defects of thyroid hormone synthesis are listed under the heading of inherited diseases. Hyperplastic goiter without gland enlargement has been observed in newborn foals in which rupture of the common digital extensor tendons, forelimb contracture, and mandibular prognathism also occur. The cause of the combination of defects is unknown.

**TREATMENT**

Treatment of neonates with obvious clinical evidence of iodine deficiency is usually not undertaken because of the high case fatality rate. When outbreaks of iodine deficiency occur in neonates, the emphasis is usually on providing additional iodine to the pregnant dams. The recommendations for control can be adapted to the treatment of affected animals.

**CONTROL**

The recommended dietary intake of iodine for cattle is 0.8–1.0 mg/kg DM of feed for lactating and pregnant cows, and 0.1–0.3 mg/kg DM of feed for non-pregnant cows and calves.

Pastures in New Zealand which contain 0.24 mg iodine/kg DM provide an adequate intake for dairy cows. The injection of iodine (iodized oil) IM three times at a dose of 2370 mg iodine/dose at the start of lactation and at 100-day intervals increased iodine concentrations in milk to 58 μg/L for at least 98 days after each treatment. Two iodine injections at 100-day intervals increased milk iodine concentrations to 160 μg/L and 211 μg/L at least 55 days after each treatment but had no effect on serum thyroid hormone concentrations. Iodine supplementation had no effect on milk, milkfat, or milk protein yield. Increasing iodine concentration in milk by IM injection of iodine could provide a method for increasing iodine intakes of humans, especially children.

Iodine can be provided in salt or a mineral mixture. The loss of iodine from salt blocks may be appreciable and an iodine preparation that is stable but contains sufficient available iodine is required. Potassium iodide satisfies these requirements and should be provided as 200 mg of potassium iodate per kg of salt. Potassium iodide alone is unsuitable, but when mixed with calcium stearate (8% of the stearate in potassium iodide) it is suitable for addition to salt – 200 mg/kg of salt.

Individual dosing of pregnant ewes, on two occasions during the 4th and 5th months of pregnancy, with 280 mg potassium iodide or 370 mg potassium iodate has been found to be effective in the prevention of goiter in lambs when the ewes are on a heavy diet of kale. For individual animals, weekly application of tincture of iodine (4 mL cattle, 2 mL pig and sheep) to the inside of the flank is also an effective preventive. The iodine can also be administered as an injection in poppy seed oil (containing 40% bound iodine): 1 mL given IM 7–9 weeks before lambing is sufficient to prevent severe goiter and neonatal mortality in the lambs. Control of goiter can be achieved for up to 2 years. The gestation period is also reduced to normal. A similar injection 3–5 weeks before lambing is less efficient.

The administration of long-acting injectable iodine (iodized oil) at a dose of 390 mg iodine to ewes, 5 weeks pre-mating, prevented goiter in newborn lambs from ewes fed swedes or swedes/tumips/kale as winter supplement. A device to release iodine slowly into the forestomachs, while still retaining its position there, has given good results in preventing congenital goiter in lambs when fed to ewes during late pregnancy.

**IRON DEFICIENCY**

**Synopsis**

**Etiology** Dietary deficiency of iron.

**Epidemiology** Young animals on milk diet, most commonly nursing piglets which have not received supplemental iron. Housed nursing lambs. Occurs in veal calves fed milk with limited quantities of iron. Continued blood loss due to hemorrhage (lice, blood sucking helminths). Subclinical iron deficiency occurs in calves and foals of doubtful significance. May be more susceptible to infectious diseases.

**Signs** Pale white skin of well grown nursing piglets, dyspnea, pallor of mucousae, sudden death may occur. Stillbirths if sows iron deficient. Secondary infectious diseases.
Clinical pathology Subnormal levels of hemoglobin of serum iron, microcytic hypochromic anemia.
Necropsy findings Pallor, thin watery blood, anasarca, dilated heart, enlarged liver.
Diagnosis confirmation Low serum hemoglobin and serum iron with microcytic hypochromic anemia. Response to iron therapy.
Differential diagnosis Other causes of anemia. See Chapter 9.
Treatment Parenteral and oral iron salts.
Control Insure adequate iron intake. Parenteral iron dextran to nursing piglets and lambs.

ETIOLOGY
Iron deficiency is usually primary and most likely to occur in newborn animals whose sole source of iron is the milk of the dam, milk being a poor source of iron. Deposits of iron in the liver of the newborn are insufficient to maintain normal hemopoiesis for more than 2–3 weeks, and are particularly low in piglets.

EPIDEMIOLOGY
Iron-deficiency states are not common in farm animals except in the very young confined to a milk diet.

Iron deficiency anemia occurs in nursing piglets for three reasons:
1. They do not have access to soil, which is a main source of iron for young farm animals
2. They grow rapidly and their absolute requirements for iron are high
3. Milk is a poor source of iron.

The administration of iron dextran to the piglets at a few days of age is preventive and is a routine health management strategy in modern pig production. If they do not receive supplemental iron dextran, clinical disease occurs usually when the piglets are 3–6 weeks old. The losses that occur include those due to mortality, which may be high in untreated pigs and to failure to thrive. Under modern pig production systems, piglets do not have access to sufficient dietary iron until they are weaned to a dry diet containing supplemental iron. Thus, the need for parenteral iron dextran at a few days of age. Even piglets raised outdoors with access to soil perform better when supplemented with iron.1 Iron injected piglets raised outdoors are heavier at weaning, there is less pre-weaning morbidity and mortality and they have higher blood hemoglobin concentrations compared to non-supplemented piglets.

Iron deficiency in pigs increases the severity of Trichuris suis and Ascaris suum infections.

Iron deficiency anemia occurs in nursing lambs that are housed and do not have access to soil, do not consume

much feed other than their dam’s milk for the first 7–10 days of life, and grow at 0.4 kg/d.2 The parenteral administration of iron dextran at 24 h of age prevents the anemia.3 Abomasal bloat occurs in these lambs with lower serum iron concentration and iron dextran injections is preventive, as well as having a significant effect on weight gain, red blood cell and iron parameters.4

Continued blood loss by hemorrhage in any animal may result in subclinical anemia and iron deficiency. Cattle heavily infested with sucking lice may develop serious and even fatal anemia. The chronic form is characterized by a non-regenerative anemia with subnormal levels of serum iron, and treatment with iron is necessary for an optimal response. Horses carrying heavy burdens of bloodsucking strongyloid worms often have subnormal hemoglobin levels and respond to treatment with iron. On occasions veal calves, and possibly young lambs and kids, may also suffer from an iron deficiency.

Good quality veal is traditionally pale in color and is produced by feeding calves an all-liquid milk replacer diet with a low concentration of available iron.5,6 The pallor of veal is due largely to low concentrations of myoglobin and other iron-containing compounds in muscle. Milk replacers containing only 10 mg iron/kg DM results in marked anemia and reduced growth performance.6 Feeding milk replacers with 50 mg iron/kg DM is considered, physiologically, the optimum amount of iron for veal calves but may be too high for acceptable carcass yield in some countries.8 A severe iron deficiency with reduced growth rate in veal calves may be associated with a higher incidence of infectious disease because of an impaired immune system.9 The objective in veal calf management is to walk the narrow line between the maximum production of white meat and a degree of anemia insufficient to interfere with maximum production.

Subclinical iron-deficiency anemia also occurs in newborn calves and kids but there is debate as to whether the condition has practical significance. In newborn calves affected with a normochromic, normocytic, and poikilocytic anemia the levels of serum iron are not significantly different from normal calves.8 It has been proposed that severe poikilocytosis in calves is associated with abnormalities of hemoglobin composition and protein 42 in the erythrocyte membrane, and iron deficiency is the cause of moderate poikilocytosis in calves.9

Clinicopathological anemia, without clinical signs, is most likely to occur when calves are born with low hemoglobin and hematocrit levels, a relatively common occurrence in twins. It is possible that suboptimal growth may occur during the period of physiological anemia in early postnatal life. There is some evidence for this in calves in which hemoglobin levels of 11 g/dL at birth fell to about 8 g/dL between the 30th and 70th days and only begin to rise when the calves start to eat roughage. The daily intake of iron from milk is 2–4 mg in calves, and their dietary requirement during the first 4 months of life is of the order of 50 mg, so that iron supplementation of the diet is advisable if the calves are fed entirely on milk. Even when hay and grain are fed to calves and lambs in addition to milk, there is a marked growth response to the administration of iron-dextran preparations at the rate of 5.5 mg/kg BW. The dietary iron requirement for fast-growing lambs is between 40 and 70 mg/kg BW, and growth rate is suboptimal on diets of less than 25 mg/kg BW.

Low serum iron concentration and low serum ferritin have been observed in hospitalized young foals.10 Hemoglobin concentrations and packed cell volume decrease in foals from values at birth, which are similar to those for adult horses, to mean values during the first weeks and months of life below those reported in adults. Serum iron concentration, total iron-binding capacity, and packed cell volume decreased during the foal’s first 24 h of life.11 Based on the studies of foals from birth to 1 year of age, the potential for iron deficiency developing under 5 weeks of age is possible because 65% of foals had minimum ferritin concentrations = 45 ng/mL, and 81% of foals had these minimum values recorded between 2 and 4 weeks.

Competition horses are frequently given iron supplementation to treat anemia and to improve performance despite the fact that neither application has any scientific basis.12 In contrast, iron overload and toxicity have occurred in competition horses.13 Some studies have shown high total plasma iron in British 3-day event team horses prior to transport (77 μmol/L compared with normal levels of 24 μmol/L. Immediately after traveling for 3 days on the road, the plasma levels had declined to 29 μmol/L.14 The iron-binding antioxidant activity, an indicator of transferrin saturation, had also declined, suggesting greater saturation of available transferrin in the plasma or a decreased capacity to sequester iron. The saturation of mechanisms to sequester iron, such as may occur with excessive supplementation, may predispose the horses to iron-catalyzed oxidant injury.14 The total iron intake exceeded the normal recommendation of between 550 and 600 mg/d. Anemia (or a low packed cell volume) is not synonymous with iron deficiency but is frequently associated with disease processes. Poor performance in an iron-
deficient animal is more likely due to a reduction in the activity of metabolically active iron-containing enzymes rather than a reduction in oxygen transport. In addition, iron deficiency is unlikely to occur in healthy horses.

- **Calcium carbonate** added to the diet of weaned and finishing pigs may cause a conditioned iron deficiency and a moderate anemia but this effect is not apparent in mature pigs. Manganese may exert a similar antagonistic effect.

**PATHOGENESIS**

More than half the iron in the animal body is found as a constituent of hemoglobin. A relatively small amount is found in myoglobin and in certain enzymes which play a part in oxygen utilization.

Piglets at birth have hemoglobin levels of about 90–110 g/L. A physiological fall to 40–50 g/dL occurs in all pigs, the lowest levels occurring at about the 8th–10th day of life. Levels of iron in the liver at birth are unusually low in this species and cannot be increased appreciably by supplementary feeding of the sow during pregnancy. The IM injection of iron-dextran preparations to sows during late pregnancy does elevate the hemoglobin levels of the piglets during the first few weeks of life but not sufficiently to prevent anemia in them. Piglets with access to iron show a gradual return to normal hemoglobin levels starting at about the 10th day of life, but in pigs denied this access the hemoglobin levels continue to fall.

One of the important factors in the high incidence of anemia in piglets is the rapidity with which they grow in early postnatal life. Piglets normally reach four to five times their birth weight at the end of 3 weeks, and 15 times their birth weight at the end of 8 weeks. The daily requirement of iron during the first few weeks of life is of the order of 15 mg. The average intake in the milk from the sow is about 1 mg/d and the concentration in sow's milk cannot be elevated by feeding additional iron during pregnancy or lactation. Apart from the specific effect on hemoglobin levels, iron-deficient piglets consume less creep feed, and after the first 3 weeks of life make considerably slower weight gains than supplemented piglets. Although specific pathogen-free pigs show a less marked response to the administration of iron than pigs reared in the normal manner, it is obvious that they need supplementary iron to prevent the development of anemia. Iron-deficient piglets appear to be more susceptible to diarrhea at about 2 weeks of age than are piglets that have received iron. A marked impairment of gastric secretion of acid and chloride and atrophic gastritis occurs in iron-deprived piglets. Villous atrophy of the small intestine and changes in the gastrointestinal flora also occur in iron-deficient piglets which may contribute to the increased susceptibility to diarrhea.

In iron deficient piglets, lymphocyte activity is impaired resulting in a decrease in circulating B-lymphocyte numbers and decreased immunocompetence.15 Severe iron deficiency in veal calves is characterized by impaired growth and reduced feed intake and utilization. The growth rate is reduced only when hemoglobin concentrations fall below 70 g/L.16 The reduced growth rate may be due to reduction in the half-life of growth hormone.

**CLINICAL FINDINGS**

The highest incidence of iron deficiency anemia in piglets occurs at about 3 weeks of age, but it can occur up to 10 weeks of age.

Affected pigs may be well grown and in good condition, but the growth rate of anemic pigs is significantly lower than that of normal pigs and feed intake is reduced. A mild diarrhea may occur but the feces are usually normal in color. Dyspnea, lethargy and a marked increase in amplitude of the apex beat of the heart can be felt after exercise. The skin and mucosae are pale and may appear yellow in white pigs. Edema of the head and forequarters, giving the animal a fat, puffed-up appearance may be present. A lean, white hairy look is probably more common. Death usually occurs suddenly, or affected animals may survive in a thin, urthiny condition. A high incidence of infectious diseases, especially enteric infection with *Escherichia coli*, is associated with the anemia, and streptococcal pericarditis is a well-recognized complication. Under experimental conditions, similar signs occur in calves and there is, in addition, an apparent atrophy of the lingual papillae. A high incidence of stillbirths is recorded in the litters of sows suffering from iron-deficiency anemia.

**CLINICAL PATHOLOGY**

In normal piglets there is a postnatal fall of hemoglobin levels to about 8 g/L and sometimes to as low as 4–5 g/L during the first 10 days of life. In iron-deficient pigs there is a secondary fall to 20–40 g/L during the 3rd week. The hemoglobin level at which clinical signs appear in pigs is about 40 g/L.17 Erythrocyte counts also fall from a normal of 5–8 × 10^6/L down to 3–4 × 10^12/L and may be a better index of iron status than hemoglobin levels. Iron-deficiency anemia in piglets is a microcytic hypochromic anemia. In chronic blood loss anemia in cattle infested with sucking lice, there is a non-regenerative anemia and a decrease in serum iron levels. Serum levels of iron considered to be normal in sheep and cattle are 100–200 μg/dL (17.9–35.8 μmol/L). In newborn calves, the levels are 170 μg/dL (30.4 μmol/L) at birth and 67 μg/dL (12.0 μmol/L) at 50 days of age. Serum ferritin concentration is an index for monitoring pre-latent iron deficiency of calves.18 The borderline of iron-deficiency anemia of veal calves at 16–20 weeks of age has been defined as a hemoglobin concentration of 9 g/L and a saturation of total iron binding capacity of 10%.19

**NECROPSY FINDINGS**

The carcass is characterized by pallor, watery blood and moderate anasarca. The heart is always dilated, sometimes extremely so. The cardiac dimensions in severely anemic neonatal pigs indicate that dilatation and hypertrophy occur consistently. The liver in all cases is enlarged, and has a mottled tan-yellow appearance. Histological examination of the bone marrow reveals maturation asynchrony of the erythroid line and a lack of hemosiderin stores. Other microscopic changes described include periacinar hepatocellular changes typical of hypoxia and decreased numbers of parietal cells in the gastric mucosa.

**Samples for confirmation of diagnosis**

- **Toxicology** – 50 g liver (ASSAY (Fe)) (Note that serum ferritin iron surviving littermates is a better indicator of iron status)
- **Histology** – liver, heart, bone marrow, stomach (LM).

**DIFFERENTIAL DIAGNOSIS**

Confirmation of the diagnosis will depend upon hemoglobin determinations and curative and preventive trials with administered iron. The possibility that anemia in piglets may be caused by copper deficiency should not be overlooked especially if the response to administered iron is poor. Isoimmunization hemolytic anemia can be differentiated by the presence of jaundice and hemoglobinuria, and the disease occurs in much younger pigs. Erythrozoonosis occurs in pigs of all ages and the protozoan parasites can be detected in the erythrocytes.

**TREATMENT**

The recommendations for the prevention of the disease are set out below and can be followed when treating clinically affected animals. Horses with poor racing performance often have suboptimal blood levels of hemoglobin and a blood loss anemia due to parasitism, and respond well to treatment with iron. Treatment is usually parenteral and consists of organic iron preparations such as iron-dextran, iron-
sorbitol-citric acid complex, iron saccharate, or gluconate. These must be given exactly as prescribed by the manufacturer as some are quite irritant, causing large sloughs when injected IM. The dose rate is 0.5–1 g elemental iron in one injection per week. When given IV, or even IM, some horses show idiosyncratic reactions and literally drop dead. Vitamin B12 (cyanocobalamin) is often used in the same injection at a dose rate of 5000 μg/week in a single dose. Other additives, especially folic acid and choline, are also used but with little justification. Oral treatment with iron sulfate or gluconate at a dose rate of 2–4 g daily for 2 weeks is as effective and much cheaper, but lacks the style of the parenteral injection. It has the disadvantage of being unpalatable and is best dispensed in liquid form to be mixed with molasses and poured onto dry feed.

**CONTROL**

Preventive measures must be directed at the neonatal piglets because treatment of the sows before or after farrowing is generally ineffective, although some results are obtained if the iron preparations are fed at least 2 weeks before farrowing. Ferric choline citrate appears to have some special merit in this field. Allowing the nursing piglets access to pasture or dirt yards, or periodically placing sows in indoor pens, offer adequate protection. Where indoor housing on impervious floors is necessary, iron should be provided at the rate of 15 mg/d until weaning either by oral dosing with iron salts of a commercial grade or by the IM injection of organic iron preparations. These methods are satisfactory, but the results are not usually as good as when piglets are raised outdoors. However, indoor housing is practiced in many areas to avoid exposure to parasitic infestation and some bacterial diseases, especially erysipelas. If sows are put into pens care must be taken to insure that infestation and some bacterial diseases, especially erysipelas. If sows are put into pens care must be taken to insure that these diseases are not introduced.

**Dietary supplementation**

**Sows**

Feeding sows a diet supplemented with 2000 mg iron/kg DM of diet will satisfactorily prevent iron-deficiency anemia in the piglets. The piglets will ingest about 20 g of sows feces per day, which will contain sufficient iron and obviate the need for IM injection of iron-dextran. The piglets grow and thrive as well as those receiving the iron-dextran.

**Veal calves**

Milk replacers for veal calves may contain up to 40 mg/kg DM of iron for the first months, but commonly only 10–15 mg/kg DM for the finishing period. The best indicator of the onset of anemia in calves on vealer diets is loss of appetite, which is a more sensitive indicator than biochemical measurement.

**Heifer calf herd replacements**

The National Research Council recommends that milk replacers fed to herd replacements or dairy beef contain 100 mg/kg of DM, with an upper limit of 1000 mg/kg DM. The pre-ruminant calf can tolerate between 2000 and 5000 ppm DM iron in milk replacer.

**Oral dosing**

Daily dosing with 4 mL of 1.8% solution of ferrous sulfate is adequate. Iron pyrophosphate may also be used (300 mg/d for 7 days). To overcome the necessity for daily dosing, several other methods of administering iron have been recommended. A single oral treatment with iron-dextran or iron-galactan has been recommended, provided an excellent creep feed is available, but the method seems unnecessarily expensive. With this oral treatment it is essential that the iron be given within 12 h of birth because absorption has to occur through the perforate neonatal intestinal mucosa; later administration is not followed by absorption. Reduced iron (British Veterinary Codex) can be administered in large doses because it does not cause irritation of the alimentary mucosa.object: A single dose of 0.5–1 g once weekly is sufficient to prevent anemia. Alternatively, the painting of a solution of ferrous sulfate on the sow’s udder has been recommended (450 g ferrous sulfate, 75 g copper sulfate, 450 g sugar, 2 L water – applied daily) but has the disadvantage of being sticky and of accumulating litter. Pigs raised on steel gratings can derive enough iron from them to avoid the need for other supplementation. Excessive oral dosing with soluble iron salts may cause enteritis, diarrhea, and some deaths in pigs. High intakes of ferric hydroxide cause diarrhea, loss of weight, and low milk production in cattle. The presence of diarrhea in a herd prevents absorption of orally administered iron, and treatment by injection is recommended in this circumstance.

**Intramuscular injection of iron preparations**

Suitable preparations must be used and are usually injected IM in piglets on one occasion only, between the 3rd and 7th day of life. Iron-dextran, fumarate, and glutamate are most commonly used. A dose of 200 mg of a rapidly absorbed and readily utilisable form of iron within the first few days of life will result in greater body weights at 4 weeks of age than piglets given only 100 mg. Multiple injections give better hemoglobin levels but have not been shown to improve weight gain and, thus, a second injection at 2–3 weeks of age may not be economical. A total dose of 200 mg is usually recommended as being required to avoid clinically manifest iron-deficiency anemia, but in order to avoid any chance of a subclinical deficiency the feed should contain additional iron at the level of 240 mg/kg. A new preparation (Heptomer) contains 200 mg/mL of iron, permitting a full dose in one injection. Contrasting information is that one injection of 100 mg of iron is adequate for baby pigs. Acute poisoning and rapid death occurs in piglets given iron-dextran compounds parenterally if the piglets were born from sows which were deficient in vitamin E and selenium during gestation. This is discussed under iron-dextran poisoning. In normal piglets, the iron-dextran compounds are safe and are usually not toxic even on repeated injection. These preparations are ideal for treatment because of the rapid response they elicit and the absence of permanent discoloration of tissues after their use if given during the first month of life. A combination of sodium selenite and iron-dextran has been given to piglets at 3 days of age and is superior to treatment with iron alone when the piglets are deficient in selenium.

Iron supplementation should also be administered to suckling piglets raised outdoors. Iron deficiency anemia in housed lambs is preventable by the IM injection of 300 mg iron dextran at 24 h of age. At 12 and 24 days after treatment, the hematological values in the treated group were significantly different from the unsupplemented group, and at weaning, the treated lambs were 1.0 kg heavier than untreated lambs. An oral iron supplement given to these housed lambs improved red cell and iron parameters but did not improve performance.

Comparable doses of parenteral iron-dextran compounds have been used for the treatment of iron-deficiency or iron-loss anemias in other species, but accurate doses have not been established and the use of these preparations in cattle and horses is expensive. In addition, iron-dextran preparations given IM to horses may cause death within a few minutes after administration. The most inexpensive method of supplying iron is to use ferrous sulfate orally at a dose of 2–4 g daily for 2 weeks to adult cattle and horses with iron-deficiency anemia.

Iron injection of beef calves in the first week after birth will result in an increase in packed cell volume (PCV), hemoglobin (Hb), mean corpuscular volume (MCV), and mean corpuscular hemoglobin (MCH) which persists for 12 weeks. However, weight gains during the first 18 weeks of life were not affected.
In dairy cattle on a sodium-deficient diet there is polyuria, polydipsia, salt hunger, pica, including licking dirt and each other’s coats, drinking urine, loss of appetite and weight, and a fall in milk production. Urination is frequent and the urine has a lower than normal specific gravity and the urine concentrations of sodium and chloride are decreased and the potassium increased. The salivary concentration of sodium is markedly decreased, the potassium is increased, and the salivary sodium-potassium ratio is decreased. The concentration of serum sodium and chloride are also decreased, but the measurement of urinary or salivary sodium concentration is a more sensitive index of sodium intake than plasma sodium concentration. Of these, it is urinary sodium which is depressed first and is therefore the preferred indicator in cattle and horses. The polyuria associated with severe sodium depletion may be an antiuretic hormone insensitivity due to lack of an effective countercurrent mechanism and hyperaldosteronism.

Supplementation of salt to dairy cows on a pumice soil in New Zealand resulted in a 12.8% increase in milk yield with unaltered composition. The cows were grazing ryegrass/clover pastures averaging 0.12% sodium and chlorine and decreased water intake and reduced weight gains. Experimentally induced sodium deficiency in young pigs causes anorexia, reduced water intake and reduced weight gains. The provision of salt in the diet at a level of 0.5% is considered to be fully adequate for all farm animal species. Under practical conditions, salt mixes are usually contain added iodine and cobalt. In some situations the salt mixes are provided on an ad libitum basis rather than adding them to the diet. However, voluntary consumption is not entirely reliable. The daily amount consumed by animals having unrestricted access to salt can be highly variable and often wasteful. Two factors influencing voluntary salt intake include the physical form of the salt and the salt content of the water and feed supplies. Some cattle consume much more loose than block salt, though the lower intakes of block salt may be adequate. Also, animals dependent on high saline water for drinking consume significantly less salt than when drinking non-saline water. Voluntary salt consumption is generally high in cows on low-sodium pastures, which are low inherently or as a result of heavy potash fertilization. Lactating goats may require 0.7% salt in their diets and energy efficiency in feedlot cattle may be improved by feeding high levels (5% of diet) of salt in the diet of finishing steers.

Diseases associated with deficiencies of mineral nutrients

SODIUM CHLORIDE DEFICIENCY

A dietary deficiency of sodium is most likely to occur:

- During lactation, as a consequence of losses of the element in the milk, in rapidly growing young animals fed on low-sodium, cereal-based diets
- Under very hot environmental conditions where large losses of water and sodium occur in the sweat and where the grass forage and the seeds may be low in sodium
- In animals engaged in heavy or intense physical work and in animals grazing pastures on sandy soils heavily fertilized with potash, which depresses forage sodium levels.

Naturally occurring salt deficiency causing illness in grazing animals is uncommon except under certain circumstances. The most commonly cited occurrences are on alpine pastures and heavily fertilized pasture leys. Pasture should contain at least 0.15 g/100 g dry matter (DM) and clinical signs are evident after about 1 month on pasture containing 0.1 g/100 g DM. Under experimental conditions, lactating cows give less milk until the chloride deficiency is compensated. After a period of up to 12 months there is considerable deterioration in the animal’s health and anorexia, a haggard appearance, lusterless eyes, rough coat, and a rapid decline in body weight occur. High-producing animals are most severely affected and some may collapse and die. The oral administration of sodium chloride is both preventive and rapidly curative. Experimental sodium depletion in horses for up to 27 days has no deleterious effect on general health.

In dairy cattle on a sodium-deficient diet there is polyuria, polydipsia, salt hunger, pica, including licking dirt and each other’s coats, drinking urine, loss of appetite and weight, and a fall in milk production. Urination is frequent and the urine has a lower than normal specific gravity and the urine concentrations of sodium and chloride are decreased and the potassium increased. The salivary concentration of sodium is markedly decreased, the potassium is increased, and the salivary sodium-potassium ratio is decreased. The concentration of serum sodium and chloride are also decreased, but the measurement of urinary or salivary sodium concentration is a more sensitive index of sodium intake than plasma sodium concentration. Of these, it is urinary sodium which is depressed first and is therefore the preferred indicator in cattle and horses. The polyuria associated with severe sodium depletion may be an antiuretic hormone insensitivity due to lack of an effective countercurrent mechanism and hyperaldosteronism.

Supplementation of salt to dairy cows on a pumice soil in New Zealand resulted in a 12.8% increase in milk yield with unaltered composition. The cows were grazing ryegrass/clover pastures averaging 0.05% sodium whereas the recommended concentration for dairy cows is 0.12%. Measurement of the sodium content of the pasture is the most simple and reliable method of diagnosing salt deficiency compared to saliva sodium-potassium ratio. It is considered likely that sodium deficiency will become more prevalent on dairy farms in the future and that there cost-effective benefits to using salt where deficiencies occur.

Experimental restriction of chloride in the diet of dairy cows in early lactation results in a deprived appetite, lethargy, reduced feed intake, reduced milk production, scant feces, gradual emaciation and severe hypochloremia and secondary hypokalemic metabolic alkalosis. Lethargy, weakness, and unsteadiness occur after about 6 weeks on the chloride-deficient diet. Bradycardia is also common. The concentration of chloride in cerebrospinal fluid is usually maintained near normal, while the serum concentrations decline. The experimental induction of a severe, total body chloride deficit by the provision of a low-chloride diet and the daily removal of abomasal contents results in similar clinical findings to those described above and lesions of nephrocalcinosis.

The diagnosis of salt deficiency is dependent on the clinical findings, analysis of the feed and water supplies, serum levels of sodium and chloride and determination of the levels of sodium in the saliva, urine, and feces of deficient animals. The concentration of sodium in saliva is a sensitive indicator of sodium deficiency. In cattle receiving an adequate supply of sodium and chlorine, the sodium levels in saliva vary from 140 to 150 mmol/L, in deficient cattle the levels may be as low as 70-100 mmol/L. The levels of sodium in the urine are low, with a reciprocal rise in potassium. The serum sodium levels are less reliable, but licking begins when the level falls to 137 mmol/L and signs are intense at 135 mmol/L.

The biochemical methods have been evaluated to estimate the sodium intake of dairy cows. Groups of cows were given 10-20, 30-50, or 70-100 g salt per day, and two groups were given salt ad libitum either in bowls or in salt blocks. The concentrations of sodium and potassium were measured in serum and urine. Cows receiving 70-100 g salt daily, and those in the ad libitum group, had higher urinary sodium concentrations than the other groups. Those receiving 10-20 g day had a higher urinary ratio of potassium/sodium in their urine than all other groups, in which the ratio decreased as the level of supplementary salt increased.

Experimentally induced sodium deficiency in young pigs causes anorexia, reduced water intake and reduced weight gains. The provision of salt in the diet at a level of 0.5% is considered to be fully adequate for all farm animals. Under practical conditions, salt mixes usually contain added iodine and cobalt. In some situations the salt mixes are provided on an ad libitum basis rather than adding them to the diet. However, voluntary consumption is not entirely reliable. The daily amount consumed by animals having unrestricted access to salt can be highly variable and often wasteful. Two factors influencing voluntary salt intake include the physical form of the salt and the salt content of the water and feed supplies. Some cattle consume much more loose than block salt, though the lower intakes of block salt may be adequate. Also, animals dependent on high saline water for drinking consume significantly less salt than when drinking non-saline water. Voluntary salt consumption is generally high in cows on low-sodium pastures, which are low inherently or as a result of heavy potash fertilization. Lactating goats may require 0.7% salt in their diets and energy efficiency in feedlot cattle may be improved by feeding high levels (5% of diet) of salt in the diet of finishing steers.
MAGNESIUM DEFICIENCY

A nutritional deficiency of magnesium plays a role in causing lactation tetany in cows and hypomagnesemic tetany of calves, and these diseases are dealt with in Chapter 28 on metabolic diseases. In both diseases, there are complicating factors that may affect the absorption and metabolism of the element.

Hypomagnesemia may occur in up to 50% of adult horses hospitalized for severe gastrointestinal disease such as colic, acute diarrhea, and infectious respiratory disease. Young horses were able to regulate serum total magnesium concentrations more efficiently than adult horses which were more likely to be hospitalized longer, but the mortality rate was not higher.

Magnesium is an essential constituent of rations for recently weaned pigs. Experimentally induced deficiency causes weakness of the pasterns, particularly in the forelegs, causing backward bowing of the legs, sickled hocks, approximation of the knees and hocks, arching of the back, hyperirritability, muscle tremor, reluctance to stand, continual shifting of weight from limb to limb, and eventually tetany and death. A reduction in growth rate, feed consumption and conversion, and levels of magnesium in the serum also occur. The requirement of magnesium for pigs weaned at 3–9 weeks of age is 400–500 mg/kg of the total ration.

REFERENCES

ZINC DEFICIENCY (PARAKERATOSIS)

Etiology
Diabetic deficiency of zinc and factors which interfere with zinc utilization.

Epidemiology
Growing pigs, cattle and sheep. Excess of calcium favors disease in pigs.

Signs
Pigs: Loss of body weight gain.

Symmetrical, crusty skin lesions (parakeratosis) over dorsum and ears, tail; become thick and fissured. No pruritus.

Ruminants: Alopecia, over muzzle, ears, tail-head, hindlegs, flank, and neck. Stiff gait and swelling over coronets. Loss of wool and thickened skin in sheep. Influenza in rams. Poor growth in goats and skin lesions.

Clinical pathology
Serum zinc levels lower than normal.

Necropsy findings
Parakeratosis.

Diagnostic confirmation
Histology of skin lesions and serum zinc levels.

Differential diagnosis list
• Sarcoptic mange in cattle and pigs
• Exudative epidermitis in pigs.

Treatment
Add zinc to diet.

Control
Supplement zinc in diet.

ETIOLOGY

Pigs
A zinc deficiency in young, growing pigs can cause parakeratosis, but it is not due to a simple zinc deficiency. The availability of zinc in the diet is adversely affected by the presence of phytic acid, a constituent of plant protein sources such as soybean meal. Much of the zinc in plant protein is in the bound form and unavailable to the monogastric animal such as the pig. The use of meat meal or meat scraps in the diet will prevent the disease because of the high availability of the zinc. Another unique feature of the etiology of parakeratosis in swine is that an excess of dietary calcium (0.5–1.5%) can favor the development of the disease, and the addition of zinc to such diets at levels much higher (0.002% zinc carbonate or 100 mg/kg zinc) than those normally required by growing swine prevents the occurrence of the disease. The level of copper in the diet may also be of some significance, increasing copper levels decreasing the requirement for zinc.

A concurrent enteric infection with diarrhea exacerbates the damage done by a zinc deficiency in pigs.

Ruminants
A primary zinc deficiency due to low dietary zinc in ruminants is rare but does occur. Many factors influence the availability of zinc from soils, including the degree of compaction of the soil, and the nitrogen and phosphorus concentration. The risk of zinc deficiency increases when soil pH rises above 6.5 and as fertilization with nitrogen and phosphorus increases. Some legumes contain less zinc than grasses grown on the same soil, and zinc concentration decreases with aging of the plant. Several factors may deleteriously affect the availability of zinc to ruminants and cause a secondary zinc deficiency. These include the consumption of immature grass, which affects digestibility, the feeding of late-cut hay, which may be poorly digestible, and the presence of excessive dietary sulfur. The contamination of silage with soil at harvesting can also affect the digestibility of zinc.

EPIDEMIOLOGY

Pigs
Parakeratosis in pigs was first recorded in North America in rapidly growing pigs, particularly those fed on diets containing growth promoters. The disease occurs most commonly during the period of rapid growth, after weaning and between 7 and 10 weeks of age. From 20 to 80% of pigs in affected herds may have lesions, and the main economic loss is due to a decrease in growth rate. In general, the incidence is greater in pigs fed in dry lot on self-feeders of dry feed than in pigs with access to some pasture, which is preventive and curative.

A low level of dietary zinc intake during pregnancy and lactation of gilts can result in skin lesions, stressful parturition, and an increased incidence of intrapartum mortality of piglets and deleterious effects on neonatal growth.

It has been suggested that parakeratosis occurs because very rapidly growing pigs outstrip their biosynthesis of essential fatty acids, and when the diet is high in calcium the digestibility of fat in the diet is reduced at the same time. The net effect in rapidly growing pigs could be a relative deficiency of essential fatty acids.

Ruminants
There are naturally occurring cases in cattle, sheep, and goats. The disease is well-recognized in Europe, especially in calves. It is common in some families of cattle and an inherited increased dietary requirement for zinc is suspected. The inherited disease occurs in Friesian and Black Pied cattle and is known as lethal trait A46. Signs of deficiency appear at 4–8 weeks of age. The main defect is an almost complete inability to absorb zinc from the intestine; zinc administration is curative.

The disease in cattle has been produced experimentally on diets low in zinc, and naturally occurring cases have responded to supplementation of the diet.
with zinc. Calves remain healthy on experimental diets containing 40 mg/kg zinc, but parakeratosis has occurred in cattle grazing pastures with a zinc content of 20–80 mg/kg (normal 93 mg/kg) and a calcium content of 0.6%. There is also an apparently improved response in cattle to zinc administration if copper is given simultaneously. Parakeratosis has also been produced experimentally in goats and sheep.

Zinc nutrition may be involved in the immune responses of feedlot calves. When calves are stressed by transportation or challenged with the infectious bovine rhinotracheitis virus, they tend to have reduced fevers, higher dry matter intake and less body weight loss when fed organic zinc and manganese sources than the corresponding oxide forms.

Outbreaks of the disease have occurred in Sudanese Desert ewes and their lambs fed on a zinc-deficient diet of Rhodes grass containing less than 10 mg/kg of zinc. The disease has also been diagnosed in mature sheep and goats and the cause of the deficiency could not be determined. A marginal zinc deficiency, characterized by subnormal growth and fertility and low concentration of zinc in serum, but without other clinical signs, can occur in sheep grazing pastures containing less than 10 mg/kg zinc.

In Germany, skin lesions have occurred in alpacas and llamas with low zinc and copper status. In the affected herd, the average serum zinc and copper levels were 0.17 and 0.49 μg/mL for alpacas and 0.22 and 0.38 μg/mL for llama, respectively. The levels considered normal in llamas is 0.30 μg for zinc and 0.40–0.70 μg copper per mL.

**PATHOGENESIS**

The pathogenesis of zinc deficiency is not well-understood. Zinc is a component of the enzyme carbonic anhydrase, which is located in the red blood cells and parietal cells of the stomach, and is related to the transport of respiratory carbon dioxide and the secretion of hydrochloric acid by the gastric mucosa. Zinc is also associated with RNA function and related to insulin, glucagon, and other hormones. It also has a role in keratinization, calcification, wound healing, and somatic and sexual development. Because it has a critical role in nucleic acid and protein metabolism a deficiency may adversely affect the cell-mediated immune system.

A zinc deficiency results in a decreased feed intake in all species and is probably the reason for the depression of growth rate in growing animals and body weight in mature animals. Failure of keratinization resulting in parakeratosis, loss and failure of growth of wool and hair and lesions of the coronary bands probably reflect the importance of zinc in protein synthesis. There are lesions of the articular walls of the dermis. The bones of zinc-deficient ruminants reveal abnormal mineralization and retardation of bone concentration in bones. Retarded testicular development occurs in ram lambs, and complete cessation of spermatogenesis suggests impairment of protein synthesis.

**CLINICAL FINDINGS**

**Pigs**

A reduced rate and efficiency of body weight gain is characteristic. Circumscribed areas of erythema appear on the skin on the ventral abdomen and inside the thigh. These areas develop into papules 3–5 mm in diameter, which are soon covered with scales followed by thick crusts. These crusts are most visible in areas about the limbs and ears and are distributed symmetrically in all cases. The crusts develop fissures and cracks, become quite thick (5–7 mm) and easily detached from the skin. They are crumbly and not flaky or scaly. A greasiness is present except in the depths of fissures. Little scratching or rubbing occurs. Diarrhea of moderate degree is common. Secondary subcutaneous abscesses occur frequently, but in uncomplicated cases, the skin lesions disappear spontaneously in 10–45 days if the ration is corrected.

**Ruminants**

In the naturally occurring disease in cattle, in severe cases, parakeratosis and alopecia may affect about 40% of the skin area. The lesions are most marked on the muzzle, vulva, anus, tailhead, ears, backs of the hindlegs, knee folds, and neck. Most animals are below average body condition and are stunted in growth. After treatment with zinc, improvement is apparent in 1 week and complete in 3 weeks. Experimentally produced cases exhibit the following signs:

- Poor growth
- A stiff gait
- Swelling of the coronets, hocks, and knees
- Soft swelling containing fluid on the anterior aspect of the hind fetlocks
- Alopecia
- Wrinkling of the skin of the legs, scrotum and on the neck and head, especially around the nostrils
- Hemorrhages around the teeth
- Ulcers on the dental pad

The experimental disease in cattle is manifested by parakeratotic skin, mainly on the hindlimbs and udder, and similar lesions on teats, which tend to become eroded during milking. The fetlocks and pasterns are covered with scabby scales. There is exudation first with matting of hair, then drying and cracking. The skin becomes thickened and inelastic. Histologically, there is parakeratosis. Clinical signs develop about 2 weeks after calves and lambs go onto a deficient diet so that there is no evidence of storage of zinc in tissues in these animals. In goats, hair growth, testicular size, and spermatogenesis are reduced, and growth rate is less than normal. Return to a normal diet does not necessarily reverse these signs and the case fatality rate is high. There is a marked delay in wound healing.

**Sheep**

The natural disease in sheep is characterized by loss of wool and the development of thick, wrinkled skin. Wool-eating also occurs in sheep and may be one of the earliest signs noticed in lambs after being on a zinc-deficient diet for 4 weeks. Induced cases in lambs have exhibited reduced growth rate, salivation, swollen hocks, wrinkled skin and open skin lesions around the hoof and eyes. The experimental disease in goats is similar to that in lambs. One of the most striking effects of zinc deficiency in ram lambs is impaired testicular growth and complete cessation of spermatogenesis. Diets containing 2.44 mg/kg dry matter (DM) caused poor growth, impaired testicular growth, cessation of spermatogenesis, and other signs of zinc deficiency within 20–24 weeks. A diet containing 17.4 mg/kg DM of zinc is adequate for growth, but a content of 32.4 mg/kg DM is necessary for normal testicular development and spermatogenesis. On severely deficient experimental diets, other clinical signs in young rams are:

- Drooling copious amounts of saliva when ruminating
- Parakeratosis around eyes, on nose, feet, and scrotum
- Shedding of the hooves
- Dystrophy and shedding of wool, which showed severe staining
- Development of a pungent odor.

In naturally occurring cases in rams the animals stood with their backs arched and feet close together.

A marginal zinc deficiency in ewes may be characterized by only a reduction in feed intake and a slightly reduced body weight, and no other external signs of disease. This is important because, in grazing ruminants, the lack of external signs indicates that zinc deficiency could easily pass undetected.

**Infertility in ewes**

Infertility in ewes and a dietary deficiency of zinc have not been officially linked, but
a zinc-responsive infertility has been described in ewes. Again, attention is drawn to the need for response trials when soil and pasture levels of an element are marginal.

An experimental zinc deficiency in pregnant ewes results in a decrease in the birth weight of the lambs and a reduced concentration of zinc in the tissues of the lambs; these effects are due to the reduced feed intake characteristic of zinc deficiency. The zinc content of the diet did not significantly influence the ability of the ewes to become pregnant or maintain pregnancy. The combination of pregnancy and zinc deficiency in the ewe leads to highly efficient utilization of ingested zinc, and the developing fetus will accumulate about 35% of the total dietary intake of zinc from the ewe during the last trimester of pregnancy. The disease is correctable by the supplementary feeding of zinc.

Goats
Experimentally induced zinc deficiency in goats results in poor growth, low food intake, testicular hypoplasia, rough dull coat with loss of hair, and the accumulation of hard, dry, keratinized skin on the hindlimbs, scrotum, head, and neck. On the lower limbs the scabs fissure, crack, and produce some exudate. In naturally occurring cases in pygmy goats there was extensive alopecia, a kyphotic stance, extensive areas of parakeratosis, abnormal hoof growth, and flaky, painful coronary bands. A zinc-responsive alopecia and hyperkeratosis in Angora goats has been described. Affected animals had recurrent pruritus, hyperemia, exfoliation, fleece loss over the hindquarters, face and ears, and a decline in reproductive performance.

Immediately before parturition in cows, there is a precipitate fall in plasma zinc concentration, which returns to normal slowly after calving. The depression of zinc levels is greater in cows that experience dystocia. This has led to the hypothesis that dystocia in beef heifers may be caused in some circumstances by a nutritional deficiency of zinc and that preparturient supplementation of the diet with zinc may reduce the occurrence of difficult births. This phenomenon does not appear to occur in sheep. The level of serum zinc increased in cattle during the season of facial eczema when sporidesmin intoxication causes depletion of liver zinc.

Zinc in serum and hair
Serum zinc levels may have good diagnostic value. Normal levels are 80–120 μg/dL (12.2–18.2 μmol/L) in sheep and cattle. Calves and lambs on deficient diets may have levels as low as 18 μg/dL (3.0 μmol/L). Normal serum zinc levels in sheep are above 78 μg/dL (12 μmol/L), and values below 39 μg/dL (6 μmol/L) or less are considered as evidence of deficiency. There is a general relationship between the zinc content of the hair and the level of zinc in the diet, but the analysis of hair is not considered to be a sufficiently accurate indicator of an animal's zinc status. In experimental disease in piglets, there is a reduction in serum levels of zinc, calcium, and alkaline phosphatase, and it is suggested that the disease could be detected by measuring the serum alkaline phosphate and serum zinc levels. Levels of zinc in the blood are very labile and simple estimations of it alone are likely to be misleading. For example, other intercurrent diseases commonly depress serum calcium and copper levels. In addition, zinc levels in plasma fall precipitately at parturition in cows; they are also depressed by hypertherm stress. After 1 week on a highly deficient diet, serum zinc levels fall to about 50% of normal, or pretreatment levels.

**NECROPSY FINDINGS**

Necropsy examinations are not usually performed, but histological examination of skin biopsy sections reveals a marked increase in thickness of all the elements of the epidermis. Tissue levels of zinc differ between deficient and normal animals but the differences are statistical rather than diagnostic.

**DIFFERENTIAL DIAGNOSIS**

Sarcoptic mange may resemble parakeratosis, but is accompanied by much itching and rubbing. The parasites may be found in skin scrapings. Treatment with appropriate parasiticides relieves the condition. Exudative epidermitis is quite similar in appearance, but occurs chiefly in unweaned pigs. The lesions have a greasy character that is quite different from the dry, crumbly lesions of parakeratosis. The mortality rate is higher.

**TREATMENT**

In outbreaks of parakeratosis in swine, zinc should be added to diet immediately at the rate of 50 mg/kg DM (200 mg of zinc sulfate or carbonate per kg of feed). The calcium level of the diet should be maintained at between 0.65 and 0.75%. The injection of zinc at a rate of 2–4 mg/kg BW daily for 10 days is also effective. Zinc oxide suspended in olive oil and given IM at a dose of 200 mg of zinc for adult sheep and 50 mg of zinc for lambs will result in a clinical cure within 2 months. The oral administration of zinc at the rate of 250 mg zinc sulfate daily for 4 weeks resulted in a clinical cure of zinc deficiency, in goats in 12–14 weeks.

**CONTROL**

**Pigs**

The calcium content of diets for growing pigs should be restricted to 0.5–0.6%. However, rations containing as little as 0.5% calcium and with normal zinc content (30 mg/kg DM) may produce the disease. Supplementation with zinc (to 50 mg/kg DM) as sulfate or carbonate has been found to be highly effective as a preventive and there appears to be a wide margin of safety in its use, diets containing 1000 mg/kg DM added zinc having no apparent toxic effect. The standard recommendation is to add 200 g of zinc carbonate or sulfate to each tonne of feed. Weight gains in affected groups are appreciably increased by the addition of zinc to the diet. The addition of oils containing unsaturated fatty acids is also an effective preventive. Access to green pasture, reduction in food intake, and the deletion of growth stimulants from rations will lessen the incidence of the disease but are not usually practicable.

**Ruminants**

For cattle, the feeding of zinc sulfate (2–4 g daily) is recommended as an emergency measure followed by the application of a zinc-containing fertilizer. As an alternative to dietary supplementation for ruminants, an intra-ruminal pellet has been demonstrated in sheep. It was effective for 7 weeks only and would not be satisfactory for long-term use. The creation of subcutaneous depots of zinc by the injection of zinc oxide or zinc metal dust has been demonstrated. The zinc dust offered a greater delayed effect. A soluble galus bolus containing zinc, cobalt, and selenium was able to correct experimentally induced zinc deficiency in sheep. The bolus supplied the daily requirement of the sheep for zinc without detrimental effect on their copper status.

Zinc-methionine, an organic zinc supplement for dairy goats improved udder health and enhanced the absorption of nitrogen and increased nitrogen retention.

MANGANESE DEFICIENCY

A dietary deficiency of manganese (Mn) may cause infertility and skeletal deformities both congenitally and after birth.

ETIOLOGY

A primary deficiency occurs endemically in some areas because of a geological deficiency in the local rock formations. Apart from a primary dietary deficiency of manganese, the existence of factors depressing the availability of ingested manganese is suspected. An excess of calcium and/or phosphorus in the diet is known to increase the requirements of manganese in the diet of calves, and is considered to reduce the availability of dietary manganese to cattle generally.

Congenital chondrodystrophy in calves has been associated with a manganese deficiency, and an outbreak of congenital skeletal defects in Holstein calves due to manganese deficiency has been reported.

EPIDEMIOLOGY

Soils containing less than 3 mg/kg of manganese are unlikely to be able to support normal fertility in cattle. In areas where manganese-responsive infertility occurs, soils on farms with infertility problems have contained less than 3 mg/kg of manganese, whereas soils on neighboring farms with no infertility problems have had levels of more than 9 mg/kg. A secondary soil deficiency is thought to occur and one of the factors suspected of reducing the availability of manganese in the soil to plants is high alkalinity. Thus, heavy liming is associated with manganese-responsive infertility. There are three main soil types on which the disease occurs:

- Soils low in manganese have low output even when pH is less than 5.5
- Sandy soils where availability starts to fall
- Heavy soils where availability starts to fall at pH of 7.0

Many other factors are suggested as reducing the availability of soil manganese but the evidence is not conclusive. For example, heavy liming of soils to neutralize sulfur dioxide emissions from a neighboring smelter is thought to have reduced the manganese intake of grazing animals.

Herbage on low manganese soils, or on marginal soils where availability is decreased (possibly even soils with normal manganese content), is low in manganese. A number of figures are given for critical levels. It is suggested that pasture containing less than 80 mg/kg of manganese is incapable of supporting normal bovine fertility, and that herbage containing less than 50 mg/kg is often associated with infertility and anestrus. The Agricultural Research Council feels that, although definite figures are not available, levels of 40 mg/kg dry matter (DM) in the diet should be adequate. Other authors state that rations containing less than 20 mg/kg DM may cause anestrus and reduction in conception rates in cows and the production of poor quality semen by bulls. Most pasture contains 50–100 mg/kg DM. Skeletal deformities in calves occur when the deficiency is much greater than the above; for example, a diet containing more than 200 mg/kg DM is considered to be sufficient to prevent them.

Rations fed to pigs usually contain more than 20 mg/kg DM of manganese, and deficiency is unlikely unless there is interference with manganese metabolism by other substances.

There are important variations in the manganese content of seeds, an important matter in poultry nutrition. Maize and barley have the lowest content. Wheat or oats have three to five times as much, and bran and pollard are the richest natural sources with 10–20 times the content of maize or wheat. Cows' milk is exceptionally low in manganese.

PATHOGENESIS

Manganese plays an active role in bone matrix formation, and in the synthesis of chondroitin sulfate, responsible for maintaining the rigidity of connective tissue. In manganese deficiency, these are affected deleteriously and skeletal abnormalities result. Only 1% of manganese is absorbed from the diet and the liver removes most of it, leaving very low blood levels of the element.

CLINICAL FINDINGS

In cattle, the common syndromes are infertility, calves with congenital limb deformities, and calves which manifest poor growth, dry coat, and loss of coat color. The deformities include knuckling over at the fetlocks, enlarged joints and, possibly, twisting of the legs. The bones of affected lambs are shorter and weaker than normal and there are signs of joint pain, hopping gait, and reluctance to move.

A severe congenital chondrodystrophy in Charolais calves occurred on one farm. The limbs were shortened and the joints enlarged. The pregnant cows were fed on apple pulp and corn silage both of which were low in manganese.

An outbreak of congenital skeletal malformations in Holstein calves was characterized clinically by small birth weights (average 15 kg). Abnormalities included joint laxity, doming of the foreheads, superior brachynathia, and a dwarflike appearance due to the short long-bones. The features of the head were similar to those of the wildebeest. The majority of affected calves were dyspeptic at birth, and snorting and grunting respiratory sounds were common. Affected calves failed to thrive and most were culled due to poor performance.

A manganese-responsive infertility has been described in ewes and is well known in cattle. In cattle, it is manifested by slowness to exhibit estrus, and failure to conceive, often accompanied by subnormal size of one or both ovaries. Subestrus and weak estrus have also been observed.

Functional infertility was once thought to occur in cattle on diets with calcium to phosphorus ratios outside the range of 1:2 to 2:1. This was not upheld on investigation but may have been correct if high calcium to phosphorus intakes directly reduced manganese (or copper or iodine) availability in diets marginally deficient in one or other of these elements.

In pigs, experimental diets low in manganese cause reduction in skeletal growth, muscle weakness, obesity, irregular, diminished or absent estrus, agalactia and resorption of fetuses or the birth of stillborn pigs. Leg weakness, bowing of the front legs and shortening of bones also occur.

CLINICAL PATHOLOGY

The blood of normal cattle contains 18–19 μg/dL (3.3–3.5 μmol/L) of manganese (Mn), although considerably lower levels are sometimes quoted. The livers of normal cattle contain 12 mg/kg (0.21 mmol/kg) of manganese and down to 8 mg/kg (0.15 mmol/kg) in newborn calves, which also have a lower content in hair. The manganese content of hair varies with intake. The normal level is about 12 mg/kg (0.21 mmol/kg) and infertility is observed in association with levels of less than 8 mg/kg (0.15 mmol/kg). In normal cows, the manganese content of hair falls during pregnancy from normal levels of 12 mg/kg (0.21 mmol/kg) in the first month of pregnancy to
4.5 mg/kg (0.08 mmol/kg) at calving. All of these figures require much more critical evaluation than they have had, before they can be used as diagnostic tests.

Although tissue manganese levels in normal animals have been described as being between 2 and 4 mg/kg (0.04 and 0.07 mmol/kg), in most tissue there appears to be more variation between tissues than this. However, tissue levels of manganese do not appear to be depressed in deficient animals, except for ovaries in which levels of 0.6 mg/kg (0.01 mmol/kg) and 0.85 mg/kg (0.02 mmol/kg) are recorded in contrast to a normal level of 2 mg/kg (0.04 mmol/kg).

There is then no simple, single diagnostic test permitting detection of manganese deficiency in animals. Reproductive functions, male and female, are most sensitive to manganese deficiency and are affected before possible biochemical criteria, e.g. blood and bone alkaline phosphatase, and liver arginase levels, are significantly changed. The only certain way of detecting moderate deficiency states is by measuring response to supplementation. Clinical findings in response to treatment which may provide contributory evidence of manganese deficiency are set out below.

**NECROPSY FINDINGS**

In congenital chondrodystrophy in calves, the limbs are shortened and all the joints are enlarged. Histologically, there is poor cartilage maturation with excessive amounts of rarefied cartilage matrix. There are degenerative changes in the chondrocytes and severe reduction in the mucopolysaccharide content of all body hyaline cartilage.

**TREATMENT AND CONTROL**

The NRC estimated the maintenance requirement (0.002 of available Mn/kg BW) of dairy cows from dietary concentrations of Mn reported to cause Mn deficiency in cattle. Based on NRC of 200 equations, the maintenance requirement for Mn represents 82% of the total Mn requirement for a nonlactating, late gestation cow and 53% for a cow producing 40 kg/d of milk. Fecal loss of endogenous Mn is assumed to comprise the entire maintenance requirement. Assuming typical DM, a diet with approximately 14 mg Mn/kg DM will meet the requirement for a 700 kg non-lactating cow during the last month of lactation. Recent research has determined that Mn intake had to equal 580 mg/d to meet the metabolic fecal Mn requirement. The corresponding dietary concentration, assuming DM of 21 and 12 kg/d for lactating and dry cows, respectively, were 28 and 49 mg/kg DM. These concentrations are approximately 1.6 and 2.7 times higher than those needed to meet the Mn requirements for lactating and dry cows, respectively, as calculated using the 2001 NRC dairy nutrient requirements model.

For pigs, the recommended dietary intake is 24–57 mg manganese per 45 kg BW. Expressed as a proportion of food intake, the recommended dietary level is 40 mg/kg DM in feed. The manganese requirements for gestation and lactation are 20 ppm of the diet.

**REFERENCES**

**POTASSIUM DEFICIENCY**

Naturally occurring dietary deficiency of potassium is thought to be rare. However, calves fed on roughage grown on soils deficient in potassium, or in which the availability of potassium is reduced, may develop a clinical syndrome of poor growth, anemia, and diarrhea. Supplementation of the diet with potassium salts appears to be curative. A similar syndrome has been produced experimentally in pigs that manifested poor appetite, emaciation, rough coat, incoordination, and marked cardiac impairment as indicated by electrocardiographic examination. The optimum level of potassium in the diet of young, growing pigs is about 0.26%, and in ruminants 0.5% (i.e. 65 mg/kg BW).

Electrocardiographic changes have also been observed in cattle on potassium-deficient diets and these are probably related to the degeneration of Purkinje fibers of the myocardium which occurs on such diets. Similar changes have been recorded on diets deficient in magnesium or vitamin E.

An intake of potassium above requirement is more likely to occur than a deficiency and, although very large doses of potassium are toxic, ruminants are capable of metabolizing intakes likely to be encountered under natural conditions. It seems probable, however, that potassium interferes with the absorption of magnesium and heavy applications of potassium chloride may cause the development of the hypomagnesemia of lactation tetany.

**Hypokalemia in cattle**

May occur secondary to anorexia, diarrhea, upper gastrointestinal obstruction, right-side displacement and torsion of the abomasum, and impaction of the abomasum. In most cases, the hypokalemia is not severe enough to cause weakness and recumbency. Hypokalemia resulting in severe weakness and recumbency has occurred in dairy cattle treated with isoflupredone acetate for ketosis. Serum potassium levels were below 2.3 mEq/L. Cows ranged in age from 2 to 7 years, all had a history of moderate to severe ketosis and had calved within the previous 30 days. Most had been treated with insulin, glucose IV, and propylene glycol orally. Affected cows were recumbent, profoundly weak, appeared flaccid, and lay in sternal or lateral recumbency. They were unable to support the weight of their heads off the ground and they were commonly held in their flanks. Anorexia was common. Cardiac arrhythmias were detectable on auscultation, and atrial fibrillation was confirmed on electrocardiography. Treatment included IV and oral administration of potassium chloride and fluid therapy, but the response was ineffective. Most affected cattle died or were euthanized. At necropsy, muscle necrosis was present in the pelvic limbs, and histological examination of non-weight bearing muscle revealed multifocal myonecrosis with macrophage infiltration and myofiber vacuolation, which is characteristic of hypokalemic myopathy in man and dogs. It is important to note that myopathy was also present in muscles not subject to ischemia or recumbency.

Potassium excretion by the kidneys is via secretion by the distal tubular cells. Aldosterone or other steroids with mineralocorticoid activity enhance distal tubular secretion of potassium by increasing permeability of the tubular luminal membranes to potassium and increasing losses of potassium in the urine. Glucocorticoids are often used to treat ketosis; the most commonly used are dexamethasone and isoflupredone acetate. Dexamethasone has little mineralocorticoid activity compared with prednisone and prednisolone, which are related chemically to isoflupredone. It is recommended for the treatment of ketosis in dairy cattle at a single dose of 10–20 mg IM, and repeated if necessary, 12–24 h later. Field observations indicate that repeated doses of isoflupredone acetate decreases plasma concentrations of potassium by 70–80%, which suggests a strong mineralocorticoid activity. It is recommended that isoflupredone be used judiciously and animals be monitored for plasma potassium and any evidence of weakness and recumbency. Treatment with oral potassium chloride may be required, but may be ineffective.
SELENIUM AND/OR VITAMIN E DEFICIENCIES

Several diseases of farm animals are associated with a deficiency of either selenium or vitamin E alone or in combination, usually in association with predisposing factors such as dietary polyunsaturated fatty acids, unaccustomed exercise and rapid growth in young animals. These are summarized in Table 30.5. All of these diseases are described under one heading because both selenium and vitamin E are important in the etiology, treatment and control of the major diseases caused by their deficiencies.

They are also known as selenium-vitamin E-responsive diseases because, with some exceptions, they can be prevented by adequate supplementation of the diet with both nutrients.

The term ‘selenium-responsive disease’ has created some confusion relative to the selenium-deficiency diseases. In some regions of the world, particularly New Zealand and in parts of Australia and North America, diseases such as ill-thrift in sheep and cattle and poor reproductive performance respond beneficially to selenium administration. While these usually occur in selenium-deficient regions, they may not be due solely to selenium deficiency. Thus, there are some reasonably well-defined selenium-deficiency diseases and some ill-defined ‘selenium-responsive’ diseases.

ETIOLOGY

The selenium- and vitamin E-responsive or deficiency diseases of farm animals are caused by diets deficient in selenium and/or vitamin E, with or without the presence of conditioning factors such as an excessive quantity of polyunsaturated fatty acids in the diet. Almost all of the diseases that occur naturally have been reproduced experimentally using diets deficient in selenium and/or vitamin E. Conversely, the lesions can usually be prevented with selenium and vitamin E supplementation. In certain instances, as for example in hand-fed dairy calves, the incorporation of excessive quantities of polyunsaturated fatty acids was a major factor in the experimental disease and this led to the conclusion that certain myopathic agents were necessary to produce the lesion, which is no longer tenable. The presence of polyunsaturated fatty acids in the diet may cause a conditioned vitamin E deficiency because the vitamin acts as an antioxidant. In the case of naturally occurring muscular dystrophy in calves, lambs and foals on pasture, the myopathic agent, if any, is unknown and selenium is protective. However, selenium is not protective against the muscular dystrophy associated with the feeding of cod liver oil to calves.

Selenium is an essential nutrient for animals and diseases due to selenium inadequacy in livestock are of worldwide distribution.

Biological functions of selenium and vitamin E

Glutathione peroxidases and tissue peroxidation

Selenium is a biochemical component of the enzyme glutathione peroxidase (GSH-PX). The activity of the enzyme in erythrocytes is positively related to the blood concentration of selenium in cattle, sheep, horses, and pigs and is a useful aid for the diagnosis of selenium deficiency and to determine the selenium status of the tissues of these animals. The enzyme from the erythrocytes of both cattle and sheep contains 4 g atoms of

Control Selenium and vitamin E supplementation of diet, strategic oral and/or parenteral vitamin E and selenium to pregnant dams or young animals on pasture.
Plasma GSH-PX protects cellular membranes and lipid-containing organelles from peroxidative damage by inhibition and destruction of endogenous peroxides, acting in conjunction with vitamin E to maintain integrity of these membranes.  

Hydrogen peroxide and lipid peroxides are capable of causing irreversible denaturation of essential cellular proteins, which leads to degeneration and necrosis. GSH-PX catalyzes the breakdown of hydrogen peroxide and certain organic hydroperoxides produced by glutathione during the process of redox cycling. This dependence of GSH-PX activity on the presence of selenium offers an explanation for the interrelationship of selenium, vitamin E and sulfur-containing amino acids in animals. The sulfur-containing amino acids may be precursors of glutathione, which in turn acts as a substrate for GSH-PX and maintains sulfhydryl groups in the cell. Selenium is also a component of several other proteins such as selenoprotein P, selenoflagellin, Se-transport proteins and the bacterial enzymes, formate dehydrogenase, and glycine reductase. Selenium also facilitates significant changes in the metabolism of many drugs and xenobiotics. For example, selenium functions to counteract the toxicity of several metals such as arsenic, cadmium, mercury, copper, silver, and lead.

The arachidonic cascade, phagocytosis, and the immune response

Glutathione peroxidase may be involved in the arachidonic acid cascade. Eicosanoids are important mediators of immune and reproductive function.

Vitamin E

Vitamin E is an antioxidant that prevents oxidative damage to sensitive membrane lipids by decreasing hydroperoxide formation. The vitamin has a central role in protection of cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondrial, endoplasmic reticulum, and plasma membranes.

Interrelationships between selenium and vitamin E

An important interrelationship exists between selenium, vitamin E and the sulfur-containing amino acids in preventing some of the nutritional diseases caused by their deficiency. If vitamin E prevents fatty acid hydroperoxide formation and the sulfur amino acids (as precursors of GSH-PX) and selenium are involved in peroxide destruction, these nutrients would produce a similar biochemical result, that is, lowering of the concentration of peroxides or peroxide-induced products in the tissues. Protection against oxidative damage to susceptible non-membrane proteins by dietary selenium, but not by vitamin E, might explain why some nutritional diseases respond to selenium but not to vitamin E. On the other hand, certain tissues or subcellular components may not be adequately protected from oxidant damage because they are inherently low in GSH-PX even with adequate dietary selenium. Damage to such tissues would be expected to be aggravated by diets high in unsaturated fatty acids and to respond adequately to vitamin E but not to selenium. The variations in GSH-PX activity between certain tissues, such as liver, heart, skeletal, and myocardial muscles, would explain the variations in the severity of lesions between species.

There are both selenium-dependent GSH-PX and non-selenium-dependent GSH-PX activities in the tissues and blood. The non-selenium-dependent enzyme does not contain selenium and does not react with hydrogen peroxide but shows activity toward organic hydroperoxide substrates. The spleen, cardiac muscle, erythrocytes, brain, thymus, adipose tissue, and striated muscles of calves contain only the selenium-dependent enzyme. The liver, lungs, adrenal glands, testes, and kidney contain both enzymes. Hepatic tissue contains the highest level of non-selenium-dependent enzyme.

Vitamin E can prevent a toxic reaction to oral iron (ferrous sulfate) or iron dextran 1M. When 0.1 ppm of selenium and 50 IU vitamin E/kg are added to the gestation of horses from 0.1 to 10 days of age, plasma GSH-PX protects cellular membranes and lipid-containing organelles from peroxidative damage by inhibition and destruction of endogenous peroxides, acting in conjunction with vitamin E to maintain integrity of these membranes. GSH-PX catalyzes the breakdown of hydrogen peroxide and certain organic hydroperoxides produced by glutathione during the process of redox cycling. This dependence of GSH-PX activity on the presence of selenium offers an explanation for the interrelationship of selenium, vitamin E and sulfur-containing amino acids in animals. The sulfur-containing amino acids may be precursors of glutathione, which in turn acts as a substrate for GSH-PX and maintains sulfhydryl groups in the cell. Selenium is also a component of several other proteins such as selenoprotein P, selenoflagellin, Se-transport proteins and the bacterial enzymes, formate dehydrogenase, and glycine reductase. Selenium also facilitates significant changes in the metabolism of many drugs and xenobiotics. For example, selenium functions to counteract the toxicity of several metals such as arsenic, cadmium, mercury, copper, silver, and lead.

The arachidonic cascade, phagocytosis, and the immune response

Glutathione peroxidase may be involved in the arachidonic acid cascade. Eicosanoids are important mediators of immune and reproductive function.

Vitamin E

Vitamin E is an antioxidant that prevents oxidative damage to sensitive membrane lipids by decreasing hydroperoxide formation. The vitamin has a central role in protection of cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondria, endoplasmic reticulum, and plasma membranes.

Interrelationships between selenium and vitamin E

An important interrelationship exists between selenium, vitamin E and the sulfur-containing amino acids in preventing some of the nutritional diseases caused by their deficiency. If vitamin E prevents fatty acid hydroperoxide formation and the sulfur amino acids (as precursors of GSH-PX) and selenium are involved in peroxide destruction, these nutrients would produce a similar biochemical result, that is, lowering of the concentration of peroxides or peroxide-induced products in the tissues.

Protection against oxidative damage to susceptible non-membrane proteins by dietary selenium, but not by vitamin E, might explain why some nutritional diseases respond to selenium but not to vitamin E. On the other hand, certain tissues or subcellular components may not be adequately protected from oxidant damage because they are inherently low in GSH-PX even with adequate dietary selenium. Damage to such tissues would be expected to be aggravated by diets high in unsaturated fatty acids and to respond adequately to vitamin E but not to selenium. The variations in GSH-PX activity between certain tissues, such as liver, heart, skeletal, and myocardial muscles, would explain the variations in the severity of lesions between species.

There are both selenium-dependent GSH-PX and non-selenium-dependent GSH-PX activities in the tissues and blood. The non-selenium-dependent enzyme does not contain selenium and does not react with hydrogen peroxide but shows activity toward organic hydroperoxide substrates. The spleen, cardiac muscle, erythrocytes, brain, thymus, adipose tissue, and striated muscles of calves contain only the selenium-dependent enzyme. The liver, lungs, adrenal glands, testes, and kidney contain both enzymes. Hepatic tissue contains the highest level of non-selenium-dependent enzyme.

Vitamin E can prevent a toxic reaction to oral iron (ferrous sulfate) or iron dextran 1M. When 0.1 ppm of selenium and 50 IU vitamin E/kg are added to the gestation of horses from 0.1 to 10 days of age, plasma GSH-PX protects cellular membranes and lipid-containing organelles from peroxidative damage by inhibition and destruction of endogenous peroxides, acting in conjunction with vitamin E to maintain integrity of these membranes. GSH-PX catalyzes the breakdown of hydrogen peroxide and certain organic hydroperoxides produced by glutathione during the process of redox cycling. This dependence of GSH-PX activity on the presence of selenium offers an explanation for the interrelationship of selenium, vitamin E and sulfur-containing amino acids in animals. The sulfur-containing amino acids may be precursors of glutathione, which in turn acts as a substrate for GSH-PX and maintains sulfhydryl groups in the cell. Selenium is also a component of several other proteins such as selenoprotein P, selenoflagellin, Se-transport proteins and the bacterial enzymes, formate dehydrogenase, and glycine reductase. Selenium also facilitates significant changes in the metabolism of many drugs and xenobiotics. For example, selenium functions to counteract the toxicity of several metals such as arsenic, cadmium, mercury, copper, silver, and lead.

The arachidonic cascade, phagocytosis, and the immune response

Glutathione peroxidase may be involved in the arachidonic acid cascade. Eicosanoids are important mediators of immune and reproductive function.
most common deficiency diseases of farm livestock in the USA. In the Czech Republic, the incidence of selenium deficiency in cattle is high and most frequently diagnosed in heifers, feeder bulls, grazed beef cattle, and dairy cows in the dry period. Surveys of live cattle in the Czech Republic and in cattle tissues obtained at slaughter have found significant deficiency of selenium. Poor selenium status, as assessed from blood, muscle, and liver selenium concentrations, was found in 80%, 70%, and 73% of the tested animals, respectively. White muscle disease has occurred in lambs in Turkey where the levels of selenium in the hay and soil are deficient. The mean values of selenium in the soil and hay were 0.03 ppm and 0.07 ppm, respectively.

NMD is endemic in grazing goats on the Mexican plateau because of selenium deficiency in the soil and forages. In two different locations of the plateau, the concentration of selenium in the soil was 0.047 and 0.051 ppm, in the forages 0.052 and 0.077 ppm, in the serum of goats, 0.02 and 0.21 ppm, respectively. The pH of the soil was 6.1 and 5.9, respectively. The mean concentration of selenium in the serum of kids with clinical signs of NMD was 36% lower compared with kids from the same farm which were normal.

Based on bulk tank milk selenium concentrations compared with serum selenium concentrations in dairy herds in Prince Edward Island, Canada, 59% of the herds were at some point marginal or deficient in selenium, which places them at risk of disease and suboptimal production. The periods of greatest risk were in the fall and winter when 5% and 4%, respectively, of herds fell in the range of true deficiency. Herds in which selenium supplementation was provided from a commercial dairy concentrate, were over 4 times more likely to be selenium-adequate than herds not using this method and adjusted average daily milk yield was 7.6% greater in herds determined to be selenium-adequate when compared with selenium-marginal herds.

Soils and therefore the pastures they carry, vary widely in their selenium content, depending largely on their geological origin. In general, soils derived from rocks of recent origin, e.g. the granitic and pumice sands of New Zealand, are notably deficient in selenium. Soils derived from igneous rocks are likely to be low in selenium. Sedimentary rocks, which are the principal parent material of agricultural soils, are rich in selenium. Forage crops, cereal grains, and corn grown in these areas are usually low in selenium content (below 0.1 mg/kg dry matter, DM), compared with the concentration in crops (above 0.1 mg/kg DM) grown in areas where the available soil selenium is much higher and usually adequate. The disease occurs in pigs, usually in association with other more serious diseases, such as mulberry heart disease and hepatitis dietetica.

Selenium in soil, plants and animals

Selenium in soils. Soils containing <0.5 mg/kg of selenium are likely to support crops and pastures with potentially inadequate selenium concentrations (<0.05 mg/kg DM).

Selenium in plants. Plants vary in their uptake of selenium but selenium is not a requirement for plant growth. The selenium content of different pasture species on the same soil type does vary widely but slow growing and more deeply rooting species contained slightly higher concentrations. In New Zealand, the most deficient soils consist of rhyolitic pumice in the central volcanic plateau of the North Island. Peat soils in the Waikato River Valley are also deficient. North Island coastal sands and stony soils in the several locations are considered to be selenium-responsive, while most of the South Island is at least marginally deficient.

In the USA, the States of the Pacific North-west and of the north-eastern and south-western seaboard are generally low in selenium. In Canada, western prairie grains generally contain relatively high levels of selenium, whereas in the eastern provinces, soils and feedstuffs usually have low selenium concentrations. Most soils in the Atlantic provinces of Canada are acidic and, consequently, the forages are deficient in selenium. Most forage samples contain less than 0.10 mg/kg DM of selenium and enzootic nutritional muscular dystrophy is common throughout the region.

Surveys in the UK found that the selenium status may be low in sheep and cattle fed locally produced feedstuffs without any mineral supplementation. In some surveys, up to 50% of farms are low in selenium, which places a large number of animals at risk. There are also differences in the selenium concentrations of different feeds grown in the same area. For example, in some areas 75% of cattle fed primarily corn silage, or 50% of the cattle fed sedge hay, might be receiving diets inadequate in selenium.

Several factors influence the availability of soil selenium to plants.

- **Soil pH:** alkalinity encourages selenium absorption by plants — and the presence of a high level of sulfur, which competes for absorption sites with selenium in both plants and animals, are two factors reducing availability.
The level of α-tocopherol in pasture declines by up to 90% as it matures. Levels as low as 0.7 mg/kg DM have been reported in dry summer pastures grazed by sheep. The α-tocopherol content of ryegrass and clover pasture ranges from 22 to 350 mg/kg DM and 90–210 mg/kg DM, respectively. After harvesting and storage, the α-tocopherol content of pasture and other crops may fall further, sometimes to 0. Preservation of grain with propionic acid does not prevent the decline. Thus, the dietary intake of α-tocopherol by cattle and sheep may be expected to vary widely and lead to wide variations in tissue levels. The plasma vitamin E status of horses is highest from May to August in Canada when fresh grass is being grazed and lowest when the horses are being fed harvested or stored feed during the same period. Plasma vitamin E levels in dairy cows in the USA were higher during the summer and fall than during the winter and spring.15

Outbreaks of NMD may occur in yearling cattle fed on high-moisture grain treated with propionic acid as a method of inexpensive storage and protection from fungal growth. There is a marked drop in the vitamin E content of acid-treated grain and an increase in the levels of peroxides of fat, which is consistent with a loss of naturally occurring antioxidants such as the tocopherols (secondary vitamin E deficiency). In these situations, the levels of selenium in the feed were below 0.05 mg/kg DM, which is inadequate and emphasizes the interdependence of selenium and vitamin E. The α-tocopherol content of moist grain (barley and maize) stored for 6 months, with or without propionic acid, falls to extremely low levels of the vitamin, thus increasing the dietary requirements (a conditioned vitamin E deficiency) and the presence of myopathic agents in the oils may also contribute to the occurrence of the disease. A secondary vitamin E deficiency occurs when NMD develops on rations containing vitamin E in amounts ordinarily considered to be adequate, but the disease is prevented by further supplementation with the vitamin. The lack of specificity of vitamin E in the prevention of muscular dystrophy in some circumstances is indicated by its failure and by the efficiency of selenium, as a preventive agent in lambs on lush legume pasture.

Other myopathic agents in diet
Not all of the myopathic agents that may be important in the development of NMD in farm animals have been identified. Unsaturated fatty acids in fish and vegetable oils may be myopathic agents in some outbreaks of NMD of calves and lambs. Lupinosis-associated myopathy in sheep is a substantial skeletal muscle myopathy encountered in weaner sheep grazing lupin stubbles infected with the fungus Phomopsis spp.17 Affected sheep have a stiff gait, walk reluctantly, stand with their back humped and their feet under the body, and have difficulty getting to their feet.

Unaccustomed exercise
Historically, NMD occurred most commonly in rapidly growing, well-nourished beef calves 2–4 months of age, shortly following unaccustomed exercise. This was commonplace in countries where calves were born and raised indoors until about 6–8 weeks of age when they were turned out onto new pasture in the spring of the year. This has been a standard practice in small beef herds in the UK, Europe, and North America. A similar situation applies for ewes that lambed indoors up to 3 months of age, outbreaks of acute NMD and stiff-lamb disease may be associated with the driving of flocks long distances. A similar situation applies for calves that are moved long distances from calving grounds and early spring pastures to lush summer pastures. The wandering and bellowing that occurs in beef calves weaned at 6–8 months of age may precipitate outbreaks of subacute NMD. Degenerative myopathy of yearling cattle (feedlot cattle, housed yearling bulls and heifer replacements) is now being recognized with increased frequency. The disease resembles subacute NMD of calves and in the UK is often seen when yearlings are turned outdoors in the spring of the year after being housed during the winter and fed a poor quality hay or straw or propionic acid-treated grain. Unaccustomed exercise is a common precipitating factor. However, the disease has occurred in housed yearling bulls with no history of stress or unaccustomed exercise but whose diet was deficient in selenium and vitamin E.

In horses subjected to exercise, there is an increase in erythrocyte malondialdehyde, a product of peroxidation, but selenium supplementation has no beneficial effect. There is inconclusive evidence that a selenium-vitamin E deficiency causes NMD in adult horses. There is no evidence that paralytic myoglobinuria and the ‘tying-up’ syndrome are due to a deficiency of selenium and vitamin E.

Congenital nutritional muscular dystrophy
Congenital NMD is rare in farm animals. Isolated cases have been reported.18 Similarly, NMD can occur in calves and lambs only a few days of age but rarely. Selenium readily crosses the bovine placenta and fetal selenium is always higher than the maternal status.19 There is no evidence that the weak-calf syndrome is associated with selenium deficiency. Long-term parenteral supplementation with neither selenium alone nor in combination with vitamin E had any effect on the incidence of the weak-calf syndrome.

An investigation of aborted bovine fetuses with lesions of heart failure, specifically cardiac dilatation or hypertrophy along with a nodular liver and ascites compared with aborted fetuses without such lesions and non-aborted fetuses from the abattoir found myocardial necrosis and mean selenium levels of 5.5 µmol/kg in the fetuses with heart lesions, 6.5 µmol/kg in the fetuses without heart lesions and 7.5 µmol/kg selenium in the fetuses from the abattoir.10 This suggests that selenium deficiency in bovine fetuses may cause myocardial necrosis and heart failure.
Normal levels of selenium in liver and kidney tissue of bovine fetuses derived from the abattoir were 7.5 ± 5.2 μmol/kg and 44 ± 1.1 μmol/kg, respectively.

In pigs, NMD has been produced experimentally on vitamin E- and selenium-deficient rations but is usually only a part of the more serious complex of mulberry heart disease and hepatitis dietetica. Microangiopathy is most common in weaned pigs and may be particularly related to vitamin E deficiency.

There is conflicting evidence on the effect of the anti-oxidative vitamins C and E on the reproductive performance of sows. In some studies, increasing dietary vitamin E in the diet during gestation may have increased the litter size and reduced the pre-weaning piglet mortality. A similar response has been seen following intramuscular injection of sows with vitamin E and Se, but the injection of vitamin C has produced no improvement. A recent study has confirmed that there was no effect on reproductive performance of sows and growth performance of piglets when supplemented by both vitamin E and C. Vitamin E and Se given to immature gilts for flushing purposes led to the formation of fewer but larger corpora lutea after ovulation, probably due to the progression of a smaller number of follicles to the ovulatory stage. Vitamin E and the Se increased the development of the uterus but did not influence the number of piglets at farrowing.

VESD occurs naturally in rapidly growing pigs, usually during the post-weaning period (3 weeks to 4 months), particularly during the early finishing period. The lowest concentration of vitamin E in piglets was day 45 after farrowing but it may be that the Se status of the newborn piglets may be more important for their health than their vitamin E status. The first 3–4 weeks after weaning the move to the finishing house is the most dangerous period for a low vitamin E level and it is important to remember that there is considerable individual variation. Serum vitamin E declines after weaning and even with vitamin E supplementation it takes 2–3 days for levels to rise. There appears to be a temporary decreased absorption of the vitamin in the immediate post-weaning period and this in turn leads to the reduction of the stored vitamin E reserves. It is usually associated with diets deficient in both Se and vitamin E and those that may contain a high concentration of unsaturated fatty acids. Such diets include those containing mixtures of soybean, high-moisture corn and the cereal grains grown on soils with low levels of Se. The feeding of a basal ration of cull peas, low in Se and vitamin E, to growing pigs can cause the typical syndrome and low tissue levels of Se are present in pigs with spontaneously occurring hepatitis dietetica. It has been shown that feeding diets that contain linseed oil unfortunately reduced the vitamin E levels in the diet but increased the skatole levels. However, there are reports of naturally occurring mulberry heart disease of pigs in Scandinavia in which the tissue levels of Se and vitamin E are within normal ranges compared with normal pigs. In Ireland, in spite of supplementation of pig rations with vitamin E and Se at levels higher than that necessary to prevent experimental disease, spontaneous mulberry heart disease may still occur. Affected pigs have lower tissue vitamin E levels than control pigs, which suggests an alteration in α-tocopherol metabolism unrelated to dietary Se and PUFA contents.

The quality of the dietary fat does not necessarily influence blood vitamin E levels, but the presence of oxidized fat reduces the resistance of the red blood cells against peroxidation. The higher requirement for vitamin E by pigs fed oxidized fat may be due to the low vitamin E content in such fat. It has recently been shown that the inclusion of 0.3 ppm Se to the diet of post-weaning piglets resulted in better performance than non-Se supplemented diets irrespective of the level of vitamin E in the ration (up to 200 ppm).

Mulberry heart disease

This is the most common form of Se and vitamin E deficiency of pigs. It occurs most commonly in rapidly growing feeder pigs (60–90 kg) in excellent condition being fed on a high-energy diet low in vitamin E and Se. The true causal mechanism is not known but it can be prevented by supplementation with vitamin E. It can also occur when it would appear that the level in the diet and in the serum or tissues appear to be satisfactory. The diets most commonly inculminated are soybean, corn, and barley. Mean liver concentrations of vitamin E were lower in pigs with MHD than in pigs that died of causes other than MHD. The α-tocopherol content of corn is usually low and it is virtually absent from solvent-extracted soybean meal. Both are low in Se. The use of high-moisture corn may further exacerbate the tocopherol deficiency. The level of PUFAs in the diet was thought to be an important etiological factor but this is now not considered to be a
necessary prerequisite. Outbreaks of the disease may occur in which 25% of susceptible pigs are affected and the case mortality rate is about 90%. The disease has occurred in young piglets and in adult sows.

Hepatosis dietetica
Hepatosis dietetica appears to be less common than mulberry heart disease but the epidemiological characteristics are similar. It appears to be less common since the Se levels in supplements were raised to 0.3 ppm. It affects young growing pigs up to 3-4 months of age. NMD in pigs usually occurs in cases of mulberry heart disease and hepatosis dietetica but it has occurred alone in gilts.

Selenium-responsive disorders
A variety of diseases have been known as selenium-responsive disorders because they respond beneficially to the strategic administration of selenium. These include: ill-thrift in lambs and calves on pasture; lowered milk production in cows; white muscle disease in lambs, calves, and kids; lowered fertility and embryonic death in sheep and cattle; retained fetal membranes, metritis, poor uterine involution, and cystic ovaries in cows; subclinical mastitis and impaired immune function in cattle; and pre-maturity, perinatal death, and abortion in cattle. Of these, only ill-thrift, lowered fertility, lowered milk production, and white muscle disease have been reported in New Zealand. The literature on the roles of selenium deficiency in grazing ruminants in New Zealand and a rational approach to diagnosis and prevention has been reviewed.

The pathogenesis of these selenium-responsive diseases is not well understood but it would appear that the selenium deficiency is only marginal. Most investigations into selenium-responsive diseases have occurred in selenium-deficient areas in which diseases such as NMD of calves and lambs occur. The evidence that selenium deficiency in breeding ewes can result in a decline in reproductive performance has not been substantiated experimentally. Reproductive performance was not affected in ewes on a selenium-depleted diet.

Selenium-responsive unthriftiness in sheep has received considerable attention in New Zealand where the response to selenium administration has been most dramatic compared with Australia where the syndrome has also been recognized but where the response is much smaller. The oral administration of selenium to lambs in these areas results in greater body weight gains from weaning to 1 year of age compared with lambs not receiving selenium supplementation. The mean fleece weight of selenium-treated lambs is also greater.

The diagnosis of selenium-responsive unthriftiness depends on analyses of the soil, pasture and animal tissues for selenium and response trials to selenium supplementation. A deficiency state might be encountered when the selenium content of the soil is below 0.45 mg/kg, the pasture content below 0.02 mg/kg DM, the liver content below 21 μg/kg (0.27 μmol/kg) (WW), and wool concentrations below 50–60 μg/kg (0.63–0.76 μmol/kg). For the blood in selenium-responsive unthriftiness of sheep the following criteria are suggested:

- Mean blood selenium status (μg/dL)
  - Deficient = 1.0
  - Doubtful 1.1–1.9
  - Normal ≥2.0.

The GSH-PX activity is a good index of the selenium status of sheep with a selenium-responsive disease. If measured on a regular basis, it can provide an indication of the selenium status of grazing sheep in individual flocks. Single measurements of GSH-PX activity may fail to detect recent changes in grazing area, differences in pasture species and pasture composition and alterations in the physiological state of the animals.

Subclinical selenium insufficiency
Subclinical insufficiencies of selenium in grazing ruminants are widespread over large areas of southern Australia. The plasma concentrations of affected sheep flocks are low, there are no obvious clinical signs of insufficiency in the ewes and there are significant responses in wool production and fiber diameter to selenium supplementation. The incidence of estrus and fertility is not affected by selenium supplementation. Live weights at birth, in mid-lactation, and at weaning were increased in lambs born to selenium-supplemented and crossbred ewes and in lambs born as singletons. Clean fleece weight at 10 months of age was increased by 9.5% and fiber diameter by 0.3 μm in lambs born to ewes that had received supplementary selenium. Differences in fleece weight and live weight were not detected at 22 months, suggesting that subclinical selenium insufficiency in early life did not permanently impair productivity if selenium status subsequently increased.

Temporal variations in glutathione peroxidase activity in sheep can be used to identify seasons of the year with the highest risk of selenium deficiency. In the Mediterranean area, lambs born in the spring/summer are at higher risk to selenium-deficiency related diseases. Lambs born in autumn/winter are from ewes gestating during the summer, when supplementation with cereal grains is provided.

Selenium is a component of the 1 iodothyronine deiodinase, which catalyzes the extrathyroidal conversion of thyroxine (T4) to the more active tri-iodothyronine (T3). Sheep grazing pastures low in selenium frequently have higher circulating T4 and lower circulating T3 concentrations than sheep receiving selenium supplementation.

When ewes grazing pastures low in selenium were supplemented thiocyanate (to cause iodine insufficiency), iodide and selenium, there was no evidence of clinical deficiencies. Growth rates of lambs were not affected by thiocyanate of their dams during mid-pregnancy, but plasma T3 and T4 concentrations were depressed in ewes receiving thiocyanate. The iodide supplementation increased thyroid hormone concentrations in ewes, but depressed plasma T3 concentrations in lambs. Supplementation of sheep grazing pastures low in selenium with both selenium and thyroid hormones improved wool characteristics, live weight gain, and blood selenium, but there was no evidence of an interaction between the selenium and the hormones. Thus, it seems unlikely that the decline in the quantity of T3 produced, or of T4 utilized for T3 production, in selenium-deficient sheep is responsible for the observed differences in the productivity of selenium-deficient and supplemented sheep. The thyroids have a major role in regulating thermogenesis and lambs born to ewes supplemented with iodide tend to have higher rectal temperatures during cold stress. The thermoregulatory ability of the perinatal lamb is not adversely affected by subclinical selenium deficiency.

In a survey of the status of vitamin E and selenium of the livers of culled ewes and market lambs raised in Ontario, selenium was present at marginal levels in 3.3% of cull ewe samples and in 43% of market lamb samples. Vitamin E was low to deficient in 10% of cull ewe samples and in 90% of market lamb samples. In culled ewes, there was a strong relationship between selenium and vitamin E. A large percentage of samples with marginal selenium values had adequate vitamin E, which may indicate that the sheep had access to high levels of vitamin E but received inadequate levels of supplement containing selenium.

An evaluation of the trace mineral status of beef cows in Ontario found that 96% of culled cows were deficient in blood selenium. Based on analysis of serum samples from cattle in Iowa and Wisconsin, subclinical selenium deficiency is common in the cattle population. The serum levels may be adequate for reproductive performance but marginal for optimal resistance to mastitis or for adequate transfer of selenium to the calf.
Reproductive performance

The published information on the effects of vitamin E and selenium deficiency or of dietary supplementation with one or the other or both on reproductive performance in farm animals is conflicting and controversial. Reproductive performance is complex and dependent on the interaction of many factors. Reproductive inefficiency is likewise complex and it is difficult to isolate one factor like a deficiency of vitamin E or selenium as a cause of reproductive inefficiency. Conversely, it is difficult to prove that supplementation with these nutrients will ensure optimum reproductive performance.45

Sheep

The evidence about the effect of selenium and vitamin E deficiency on reproductive performance in sheep is conflicting. Observations in the 1960s concluded that selenium deficiency caused embryonic deaths 20–30 days after fertilization in ewes. But supplementation of ewes, low or marginal in selenium status, with selenium did not improve reproductive performance. Experimental studies using selenium-deficient diets in ewes have been unable to find any adverse effects of selenium depletion on ewe conception rates, embryonic mortality, or numbers of lambs born. The parenteral administration of selenium to pregnant ewes between 15 and 35 days after mating resulted in a reduced embryonic survival rate and is not recommended during the first month of pregnancy.46

Cattle

Vitamin E supplementation can have significant effects on the health and some aspects of fertility in lactating dairy cows.55 When used at four times the current recommendations. Vitamin E supplementation of dairy cows has its most beneficial effect of reducing the incidence of mastitis when used at rates of at least 1000 IU per day during the dry period and early lactation. The primary effect of vitamin E supplementation is on the immune system. The importance of selenium and vitamin E for the maintenance of optimum reproductive performance is not clear.47 The IM injection of dairy cattle with selenium and vitamin E 3 weeks prepartum did not have any effect on average days to first estrus or first service, average days to conception, services per conception, or number of uterine infusions required. The prepartum IM injection of vitamin E and selenium E 3 weeks prepartum increased the percentage of cows pregnant to first service, reduced the number of services per conception, decreased the incidence of retained placenta and reduced the interval from calving to conception. In a randomized field trial in a large dairy herd in the USA, oral supplementation of pregnant first-calf dairy heifers with selenium using a commercially available sustained-release intra-ruminal selenium bolus, increased blood selenium concentrations in treated animals at 30 days after treatment until after calving.48 However, based on data analyzed mid-lactation and late lactation, there were no differences between treated and control groups in somatic cell count, days not pregnant, total milk production, or times bred. The use of an intra-ruminal pellet of selenium at two different levels in dairy herds in New Zealand was evaluated in yearling heifers.49 The recommended dose was effective in elevating whole blood GSH-PX activity and selenium concentrations to over 10 times those of control animals. Milk production was increased and there was a trend to decreased somatic cell counts. There were no differences in calving-first-service or calving-conception intervals, or in the percentage of animals pregnant to first or all services. In other observations, following the treatment of dairy cows with oral selenium pellets there was an improvement in first service conception rate and significantly higher blood levels of GSH-PX. The inconsistent results obtained following the use of selenium and vitamin E in pregnant cows may be related to the selenium status of the animals; in some herds the blood levels are marginal and in others the levels are within the normal range.

Winter-fedor lactating Norwegian dairy cows were found to have an adequate plasma levels of vitamin E and marginal-to-adequate levels of blood selenium. Silage was the most important source of selenium, while cows were found to have an adequate to-adequate levels of blood selenium.55 Supplementation of the diet of cattle with selenium and vitamin E has been shown to inhibit: Resistance to infectious disease

Many studies have examined the role of selenium and vitamin E resistance to infectious disease. Most of the evidence is based on in vitro studies of the effects of deficiencies of selenium or vitamin E or supplementation with the nutrients on leukocyte responses to mitogens, or on the antibody responses of animals to a variety of pathogens. The status of selenium and vitamin E in an animal can alter antibody response, phagocytic function, lymphocyte response and resistance to infectious disease. The administration of vitamin E and selenium during the dry period can influence mammary gland health and milk cell counts in dairy ewes.58 In general, a deficiency of selenium results in immunosuppression and supplementation with low doses of selenium augments immunological functions. A deficiency of selenium has been shown to inhibit:

- Resistance to microbial and viral infections
- Neutrophil function
- Antibody production
- Proliferation of T and B lymphocytes
- Cytokine production

Vitamin E and selenium have interactive effects on lymphocyte responses to experimental antigens.59 Vitamin E supplementation of transport-stressed feedlot cattle is associated with reduced serum acute-phase protein concentrations compared with control animals.60 Supplementation of the diet of cattle arriving in the feedlot with vitamin E had beneficial effects on humoral immune response and recovery from respiratory disease.55
The parenteral administration of selenium and vitamin E during pregnancy in dairy cows has a positive effect on the increase of selenium and vitamin E concentrations in blood, increase of selenium and immunoglobulins concentrations in colostrum and an increase of T3 concentration in blood on the day of parturition. In addition, there was a trend toward a decreased incidence of clinical mastitis.

Neutrophil function
Selenium deficiency can affect the function of polymorphonuclear neutrophils (PMNs), which are associated with physiological changes in GSH-PX levels. In calves on an experimental selenium-deficient diet, the oxygen consumption and the activities of GSH-PX are lower than normal in neutrophils. The feeding of 80-120 mg of selenium/kg of mineral mixture provided ad libitum is an effective method of increasing blood selenium in a group of cattle and optimizing the humoral antibody response experimentally. It is suggested that blood selenium levels over 100 μg/L are necessary to maintain optimum immunocompetence in growing beef cattle. In selenium-deficient goats, the production of leukotriene B4, a product of neutrophil arachidonic acid lipoygenation and a potent chemotactic and chemokinetic stimulus for neutrophils, is decreased, resulting in dysfunction of the neutrophils. A deficiency of selenium in pregnant sows impairs neutrophil function and vitamin E deficiency impairs function of both neutrophils and lymphocytes, which may result in increased susceptibility of their piglets to infectious diseases. It is suggested that selenium supplementation be maintained at 0.3 mg/kg of the diet.

Neutrophils from postparturient dairy cows with higher levels of selenium have greater potential to kill microbes and cattle with greater superoxide production may have higher milk production. Vitamin E is a fat-soluble membrane anti-oxidant which enhances the functional efficiency of neutrophils by protecting them from oxidative damage following intracellular killing of ingested bacteria. Peripartum immunosuppression in dairy cows is multifactorial but is associated with endocrine changes and decreased intake of critical nutrients. Decreased phagocytes and intracellular killing by neutrophils occur in parallel with decreased dry matter intake and decreased circulating vitamin E. Since neutrophils are the primary mechanism of uterine defense and mammary health, the role of vitamin E on the health of dairy cows during the transition period have been examined. Compared with control cows given a placebo, the parenteral administration of vitamin E 1 week prepartum had no effect on the incidence of retained placentae, clinical mastitis, metritis, endometritis, ketosis, displaced abomasum or lameness. However, there was a decreased incidence of retained placenta in cows with marginal pretreatment vitamin E status. An increase in α-tocopherol of 1 μg/mL in the last week prepartum reduced the risk of retained placenta by 20%. In addition, serum non-esterified fatty acid concentration ≥ 0.5 mEq/L tended to increase the risk of retained placenta by 80% and in the last week pre-partum, a 100 ng/mL increase in serum retinol was associated with a 60% decrease in the risk of early lactation clinical mastitis.

Immune response
The effects of selenium deficiency and supplementation on the immune response of cattle to experimental infection with the infectious bovine rhinotracheitis virus and sheep to parainfluenza-3 virus, indicates that a deficiency can affect the humoral response and supplementation enhances the response. The administration of selenium either alone or in combination with vitamin E can improve the production of antibodies against E. coli in dairy cows. Pigs fed a vitamin E- and selenium-deficient diet develop an impaired cell-mediated immunity as measured by lymphocyte response to mitogenic stimulations. Supplementation of the diets of young pigs with selenium at levels above those required for normal growth have increased the humoral response, but not in sows. The wide variations in antibody responses that occur in these experiments indicate that there is a complex relationship between the selenium status of the host, humoral immune responses and protective immunity. The concept of using selenium supplementation to enhance antibody responses in sheep to vaccines is probably unfounded. However, the administration of sodium selenite to sheep vaccinated against enzootic abortion (Chlamydiophila abortus) increased the antibody response but not when given with vitamin E.

Vitamin E can stimulate the immune defense mechanisms in laboratory animals and cattle, experimentally. In most cases, the immunostimulatory effects of additional vitamin E are associated with supplementation in excess of levels required for normal growth. The parenteral administration to calves of 1400 μg of vitamin E weekly increases their serum vitamin E concentrations and lymphocyte stimulation indices. Similarly in growing pigs, a serum vitamin E concentration above 3 mg/L was necessary to achieve a significant response of the lymphocytes to stimulation with mitogens.

General resistance
These changes may render selenium-deficient animals more susceptible to infectious disease, but there is no available evidence to indicate that naturally occurring selenium and vitamin E deficiencies are associated with an increase in the incidence or severity of infectious diseases. Neutrophils from selenium-deficient animals lose some ability to phagocytose certain organisms, but how relevant this observation is in naturally occurring infections is unclear. Field studies of the incidence and occurrence of pneumonia in housed calves found that selenium status was not a risk factor.

Transfer of selenium and vitamin E to the fetus, colostrum, and milk
Selenium. In sheep, selenium is transferred across the placenta to the fetus and maternal selenium status during gestation is positively associated with fetal and newborn lamb selenium status. Supplementation of gestating ewes with selenium will improve the selenium status of the lambs at birth. However, after birth the selenium of the lamb is depleted quickly by about 18 days after birth. Thus, continued intake of selenium by the lamb is necessary to maintain normal selenium status during the postnatal period. The colostrum of ewes contains higher levels of selenium than ewe milk. The selenium content of ewe's milk decreases rapidly after parturition, reaching a stable level by 1 week past parturition. Supplementation of ewes during lactation results in higher milk selenium concentration and higher blood selenium in lambs. Supplementation of ewes has been shown to prevent nutritional myodegeneration in nursing lambs in selenium-deficient flocks.

There is a highly significant relationship between blood selenium of cattle and milk selenium concentration. As in sheep, in cattle, selenium is transferred across the placenta to the fetus and across the mammary barrier into the colostrum and milk.

Pigs. The maternal intake of selenium affects fetal liver selenium and newborn piglets have lower liver selenium concentrations compared with their dams, regardless of selenium intake of sows during gestation. Thus compared with cattle and sheep, the relatively high concentration of selenium needed in the diets of young rapidly growing pigs may be partially a function of limited placental transport or hepatic deposition of selenium and why the piglet is more susceptible to selenium deficiency than the sow.

Vitamin E. The transfer of vitamin E across the placenta to the fetus in sheep and cattle is limited. Plasma levels of vitamin E in the fetus and in newborn lambs
(before ingestion of colostrum) are lower than in the ewe. Vitamin E supplementation of the ewe in late gestation results in insignificant increases of the serum vitamin E in the lamb. However, supplementation of the ewe in the last month of pregnancy increases the vitamin E content of colostrum and milk. Colostrum of the ewe is a rich source of vitamin E for the neonatal lamb, containing 5-11 times more vitamin E than milk at 1 week post partum. The parenteral administration of sodium selenite to ewes at lambing increases the vitamin E content of milk of ewes over the first 5 weeks of lactation, indicating a potential positive effect of selenium repletion on vitamin E transfer to milk.

Neonatal morbidity and mortality

Based on some preliminary observations of the selenium content of hair samples of young calves, higher selenium levels in newborn calves may have some protective effect against morbidity due to neonatal disease. Similarly, neonatal piglets with high blood levels of GSH-PX activity may be more resistant to infectious diseases or other causes of neonatal mortality. Administration of vitamin E and selenium to dairy cows in late pregnancy resulted in the production of increased quantities of colostrum and the calves have increased quantities of GSH-PX at birth and 28 days of age, but the improved selenium status did not provide any improvement in passive immunity or growth. Supplementing selenium to beef cows grazing selenium-deficient pastures with a salt mineral mix containing 120 mg selenium/kg of mix increased the selenium status of the cows and increased the serum IgG concentration, or enhanced transfer of IgG from serum to colostrum and increased the selenium status of the calves. The parenteral administration of 0.1 mg Se and 1 mg of vitamin E/kg BW at mid-gestation did not affect the production of systemic or colostral antibodies. Supplementation of dairy cows at dry-off with selenium at 3 mg/d as selenite via an intramammary bolus resulted in sufficient transfer of selenium to meet a target concentration of more than 2.2 µg of selenium/g of liver DM in newborn calves.

Mastitis in dairy cattle

There is some evidence that a dietary deficiency of vitamin E may be associated with an increased incidence of mastitis in dairy cattle. An increased incidence of mastitis during the early stages of lactation coincides with the lowest plasma concentration of vitamin E. Supplementation of the diet of dairy cows beginning 4 weeks before and continuing for up to 8 weeks after parturition with vitamin E at 3000 IU/cow per day, combined with an injection of 5000 IU, 1 week before parturition, prevented the suppression of blood neutrophil and macrophage function during the early postpartum period compared with controls. The vitamin E prevented the suppression of blood neutrophils during the postpartum period. Cows in both the treated and control groups were fed diets containing selenium at 0.3 ppm of total dry matter. When selenium status in dairy cows is marginal, plasma concentrations of α-tocopherol should be at least 3 µg/mL. Cows receiving a dietary supplement of about 1000 IU/d of vitamin E had 30% less clinical mastitis than did cows receiving a supplement of 100 IU/d of vitamin E. The reduction was 88% when cows were fed 4000 IU/d of vitamin E during the last 14 days of the dry period.

The selenium status of dairy cows may also have an effect on the prevalence of mastitis and mammary gland health. Dairy herds with low somatic cell counts had significantly higher mean blood GSH-PX and higher whole blood concentrations of selenium than in herds with high somatic cell counts. The prevalence of infection due to Streptococcus agalactiae and Staphylococcus aureus was higher in herds with the high somatic cell counts compared with those with the low somatic cell counts. This suggests that phagocytic function in the mammary gland may be decreased by a marginal selenium deficiency. In a survey of cattle in herds in Switzerland, those with chronic mastitis had lower serum levels of selenium than healthy control herds. Experimental coliform mastitis in cattle is much more severe in selenium-deficient animals than selenium-adequate animals. The severity was in part due to the increased concentrations of eicosanoids.

Milk neutrophils from cows fed a selenium-deficient diet have significantly reduced capacity to kill ingested Escherichia coli and Staph. aureus, compared with cells from cows fed a selenium-supplemented diet. However, other experimental results are not as convincing.

Blood abnormalities

In young cattle from areas where NMD is endemic and particularly at the end of winter housing, the erythrocytes have an increased susceptibility to hemolysis following exposure to hypotonic saline. During clinical and subclinical white muscle disease in calves, there is a significant increase in both the osmotic and the peroxidative hemolysis of the erythrocytes. This defect is thought to be the result of alterations in the integrity of cell membranes of which tocopherols are an essential component. Abnormalities of the bone marrow associated with vitamin E deficiency in sheep have been described and abnormal hematological responses have been described in young growing pigs on an experimental selenium- and vitamin E-deficient diet. Vitamin E deficiency in sheep results in increased hemolytic susceptibility of erythrocytes, which may provide a basis for a single functional test for vitamin E deficiency in sheep.

Anemia characterized by a decreased packed cell volume, decreased hemoglobin concentration and Heinz body formation has been observed in cattle grazing on grass grown on peaty muck soils in the Florida everglades. Selenium supplementation corrected the anemia, prevented Heinz body formation, increased the body weight of cows and calves and elevated blood selenium.

Equine degenerative myeloencephalopathy

Equine degenerative myeloencephalopathy, which may have an inherited basis, has been associated with a vitamin E deficiency. The vitamin E status is low in some affected horses and supplementation with the vitamin was associated with a marked reduction in the incidence of the disease. However, serum vitamin E and blood GSH-PX activities determined in horses with histologically confirmed diagnosis of the disease compared with age-matched controls failed to reveal any differences and the findings did not support a possible role for vitamin E deficiency as a cause. Foals sired by a stallion with degenerative myeloencephalopathy and with neurological deficits consistent with the disease during their first year of life had lower plasma levels of α-tocopherol when the levels were determined serially beginning at 6 weeks to 10 months of age than age-matched controls. Absorption tests with vitamin E revealed that the lower α-tocopherol levels were not due to an absorption defect.

Equine motor neuron disease

This is a neurodegenerative disease of the somatic lower motor neurons resulting in a syndrome of diffuse neuromuscular disease in the adult horse. Case-control studies found the mean plasma vitamin E concentrations in affected horses were lower than that of control horses. Adult horses are affected with the risk peaking at 16 years of age. In addition to the role of vitamin E depletion, other individual and farm-level factors, contribute to the risk of developing the disease.

Generalized steatitis

Steatitis in farm animals and other species may be associated with vitamin E and/or selenium deficiency. Most cases in horses have involved nursing or recently weaned foals. Generalized steatitis in the foal has...
been described as either generalized cachexia due to steatitis alone, or as a primary myopathy or myositis with steatitis of secondary importance. The terms used have included steatitis, generalized steatitis, fat necrosis, yellow fat disease, polymyositis, and muscular dystrophy. The relationships between steatitis and vitamin E and selenium deficiency in the horse are not clear and there may be none. Many more clinical cases must be examined in detail before a cause–effect relationship can be considered.

PATHOGENESIS

The literature on the antioxidant roles of selenium and vitamin E have been reviewed. Dietary selenium, sulfur-containing amino acids and vitamin E act synergistically to protect tissues from oxidative damage. GSH-PX, which is selenium-dependent, functions by detoxifying lipid peroxides and reducing them to non-toxic hydroxy fatty acids. Vitamin E prevents fatty acid hydroperoxide formation. High levels of PUFAs in the diet increase the requirements for vitamin E and, with an inadequate level of selenium in the diet, tissue oxidation occurs, resulting in degeneration and necrosis of cells. Vitamin E protects cellular membranes from lipoperoxidation, especially membranes rich in unsaturated lipids, such as mitochondrial, endoplasmic reticulum and plasma membranes. Thus, dietary PUFA are not a prerequisite for the disease. Diets low in selenium and/or vitamin E do not provide sufficient protection against the 'physiological' lipoperoxidation that occurs normally at the cellular level.

The relative importance of selenium, vitamin E and sulfur-containing amino acids in providing protection in each of the known diseases caused by their deficiency is not clearly understood. Selenium has a sparing effect on vitamin E and is an efficient prophylactic against muscular dystrophy of calves and lambs at pasture, but does not prevent muscular dystrophy in calves fed on a diet containing cod liver oil. The current understanding of the biochemical function of selenium and its relation to vitamin E and the mechanisms of action of selenium and vitamin E in protection of biological membranes has been reviewed.

Nutritional muscular dystrophy

A simplified integrated concept of the pathogenesis of the NMD would be as follows. Diets deficient in selenium and/or vitamin E permit widespread tissue lipoperoxidation leading to hyaline degeneration and calcification of muscle fibers. One of the earliest changes in experimental selenium deficiency in lambs is the abnormal retention of calcium in muscle fibers undergoing dystrophy and selenium supplementation prevents the retention of calcium. Unaccustomed exercise can accelerate the oxidative process and precipitate clinical disease. Muscle degeneration allows the release of enzymes, such as lactate dehydrogenase, aldolase and creatine phosphokinase, the last of which is of paramount importance in diagnosis. Degeneration of skeletal muscle is rapidly and successively followed by invasion of phagocytes and regeneration. In myocardial muscle, replacement fibrosis is the rule.

In calves, lambs, and foals, the major muscles involved are skeletal, myocardial and diaphragmatic. The myocardial and diaphragmatic forms of the disease occur most commonly in young calves, lambs, and foals, resulting in acute heart failure, respiratory distress, and rapid death, often in spite of treatment. The skeletal form of the disease occurs more commonly in older calves, yearling cattle, and older foals and results in weakness and recumbency, is usually less severe and responds to treatment. The biceps femoris muscle is particularly susceptible in calves and muscle biopsy is a reliable diagnostic aid.

In foals with NMD, there is a higher proportion of type IIC fibers and a lower proportion of type I and IIA fibers than in healthy foals. The type IIC fibers are found in fetal muscle and are undifferentiated and still under development. During the recovery period, fibers of types I, IIA, and IIB increase and the proportion of type IIC fibers decreases. A normal fiber type composition is present in most surviving foals 1–2 months after the onset of the disease.

Acute NMD results in the liberation of myoglobin into the blood, which results in myoglobinuric. This is more common in horses, older calves, and yearling cattle, than in young calves whose muscles have a lower concentration of myoglobin. Hence, the tendency to myoglobinuric will vary depending on the species and age of animal involved.

Subclinical selenium insufficiency

Selenium deficiency affects thyroid hormone metabolism and may explain the cause of ill-thrift. The conversion of the iodine-containing hormone, thyroxine (T4) to the more potent triiodothyronine (T3) is impaired in animals with low selenium status and iodothyroinediase is a selenoprotein which mediates this conversion.

VESD syndrome and others

The pathogenesis of mulberry heart disease, hepatitis dietica, exudative diathesis, and muscular dystrophy of pigs is not yet clear. Vitamin E and Se are necessary to prevent widespread degeneration and necrosis of tissues, especially liver, heart, skeletal muscle, and blood vessels. Se and vitamin E deficiency in pigs results in massive hepatic necrosis (hepatosis dietica), degenerative myopathy of cardiac and skeletal muscles, edema, microangiopathy, and yellowish discoloration of adipose tissue. Myocardial and hepatic calcium concentrations are increased in pigs with mulberry heart disease. In addition, there may be esophagogastric ulceration, but it is uncertain whether or not this lesion is caused by a Se and/or vitamin E deficiency. Anemia has also occurred and has been attributed to a block in bone marrow maturation, resulting in inadequate erythropoiesis, hemolysis or both. However, there is no firm evidence that anemia is a feature of Se and vitamin E deficiency in pigs. The entire spectrum of lesions has been reproduced experimentally in pigs with natural or purified diets deficient in Se and vitamin E, in which an antagonist was added to inactive vitamin E or Se. However, in some studies, the Se content of tissues of pigs that died from mulberry heart disease was similar to that of control pigs without the disease.

The extensive tissue destruction in pigs may account for the sudden death nature of the complex (mulberry heart disease and hepatitis dietica) and the muscle stiffness that occurs in some feeder pigs and sows of farrowing time with muscular dystrophy. The tissue degeneration is associated with marked increases in serum enzymes related to the tissue involved. An indirect correlation between vitamin E intake and peroxide hemolysis in pigs on a deficient diet suggests that lipoperoxidation is the ultimate biochemical defect in pigs and that vitamin E and Se are protective.

CLINICAL FINDINGS

Acute enzootic muscular dystrophy

Affected animals may collapse and die suddenly after exercise without any other premonitory signs. The excitement associated with the hand-feeding of dairy calves may precipitate peracute death. In calves under close observation, a sudden onset of dullness and severe respiratory distress, accompanied by a frothy or blood-stained nasal discharge, may be observed in some cases. Affected calves, lambs, and foals are usually thirsty and can swallow unless the tongue is affected. The heart rate is usually increased up to 150–200/min and often with arrhythmia, the respiratory rate is increased up to 60–72/min and loud breath sounds are audible over the entire
lung fields. The temperature is usually normal or slightly elevated. Affected animals commonly die 6–12 h after the onset of signs in spite of therapy. Outbreaks of the disease occur in calves and lambs in which up to 15% of susceptible animals may develop the acute form and the case fatality approaches 100%.

**Subacute enzootic muscular dystrophy**

This is the most common form in rapidly growing calves, 'white muscle disease' and in young lambs, 'stiff-lamb disease'. Affected animals may be found in sternal recumbency and unable to stand but some make an attempt to stand. If they are standing, the obvious signs are stiffness, trembling of the limbs, weakness and, in most cases, an inability to stand for more than a few minutes. The gait in calves is accompanied by rotating movements of the hocks and in lambs a stiff, goose-stepping gait. Muscle tremor is evident if the animal is forced to stand for more than a few minutes. On palpation the dorsolumbar, gluteal and shoulder muscle masses may be symmetrically enlarged and firmer than normal (although this may be difficult to detect). Most affected animals retain their appetite and will suck if held up to the dam or eat if hand-fed. Major involvement of the diaphragm and intercostal muscles causes dyspnea with labored and abdominal-type respiration. The temperature is usually in the normal range but there may be a transient fever (41°C, 105°F) due to the effects of myoglobinemia and pain. The heart rate may be elevated, but there are usually no rhythmical irregularities. Following treatment, affected animals usually respond in a few days and within 3–5 days they are able to stand and walk unassisted.

In some cases, the upper borders of the scapulae protrude above the vertebral column and are widely separated from the thorax. This has been called the 'flying scapula' and has occurred in outbreaks in heifers from 18 to 24 months of age within a few days after being turned out in the spring following loose-housing throughout the winter. The abnormality is due to bilateral rupture of the serratus ventralis muscles and has been reported in a red deer. Occasionally, the toes are spread and there is relaxation of carpal and metacarpal joints or knuckling at the fetlocks and standing on tip-toe, inability to raise the head, difficulty in swallowing, inability to use the tongue and relaxation of abdominal muscles. Choking may occur when the animals attempt to drink. In 'paralytic myoglobinuria' of yearling cattle, there is usually a history of recent turning out on pasture following winter housing. Clinical signs occur within 1 week and consist of stiffness, recumbency, myoglobinuria, hyperpnea, and dyspnea. Severe cases may die within a few days and some are found dead without premonitory signs. In rare cases, lethargy, anorexia, diarrhea and weakness are the first clinical abnormalities recognized, followed by recumbency and myoglobinuria.

**Congenital muscular dystrophy** has been described in a newborn calf. The calf was still recumbent 13 h after birth, had increased serum creatine kinase and decreased serum vitamin E and selenium levels. Recovery occurred following supportive therapy and vitamin E and selenium.

**Subcapsular liver rupture in lambs** has been associated with vitamin E deficiency in lambs usually under 4 weeks of age. Affected lambs collapse suddenly, become limp, and die within a few minutes or several hours after the onset of weakness.

**In foals, muscular dystrophy** occurs most commonly during the first few months of life and is common in the first week. The usual clinical findings are failure to suck, recumbency, difficulty in rising and unsteadiness and trembling when forced to stand. The temperature is usually normal but commonly there is polyneura and tachycardia. The disease in foals may be characterized by an acute, fulminant syndrome, which is rapidly fatal, or a subacute syndrome characterized by profound muscular weakness. Failure of passive transfer, aspiration pneumonia, and stunting are frequent complications. In the subacute form, mortality rates may range from 30 to 45%.

**In adult horses with muscular dystrophy**, a stiff gait, myoglobinuria, depression, inability to eat, holding the head down low, and edema of the head and neck are common. The horse may be presented initially with clinical signs of colic.

**In pigs, muscular dystrophy** is not commonly recognized clinically because it is part of the more serious disease complex of mulberry heart disease and hepatitis dietetica. However, in outbreaks of this complex, sickening piglets, feeder pigs and sows after farrowing, may exhibit an uncoordinated, staggering gait suggestive of muscular dystrophy.

**Subclinical nutritional muscular dystrophy** occurs in apparently normal animals in herds at the time clinical cases are present. The serum levels of creatine phosphokinase levels may be elevated in susceptible animals for several days before the onset of clinical signs; following treatment with vitamin E and selenium the level of serum enzymes returns to normal. Grossly abnormal electrocardiograms occur in some animals and may be detectable before clinical signs are evident.

**Vitamin E selenium deficiency in pigs**

Usually they occur separately but rarely MHD and HD occur together and even more rarely, you may find that there is NMD as well. There is a suspicion that the occurrence of two or more together has recently become more common but this in fact may be due to the greater awareness of both conditions. Two or more requires the supplementation with both Vitamin E and Se.

**Mulberry heart disease**

Usually seen in pigs from a few weeks to 4 months of age. These pigs are nearly always the best of the group and it may be that this rate of growth increases the demand for vitamin E and Se. In mulberry heart disease, affected animals are commonly found dead without premonitory signs. More than one pig may be found dead. When seen alive, animals show severe dyspnea, cyanosis and recumbency and forced walking can cause immediate death. In some outbreaks, about 25% of pigs will show a slight inappetence and inactivity, these are probably in the subclinical stage of the disease. The stress of movement, inclement weather, or transportation will precipitate further acute deaths. The temperature is usually normal, the heart rate rapid and irregularities may be detectable. The feces are usually normal. A good 'classical outbreak' has been described.

**Hepatosis dietetica**

In hepatitis dietetica, most pigs are found dead. Very few cases show other signs. In occasional cases, before death there will be dyspnea, severe depression, vomiting, staggering, diarrhea and a state of collapse. Some pigs are icteric. Outbreaks also occur similar to the pattern in mulberry heart disease. Muscular dystrophy is almost a consistent necropsy finding in both mulberry heart disease and hepatitis dietetica but is usually not recognized clinically because of the seriousness of the two latter diseases. Clinical muscular dystrophy has been described in gilts at 11 months of age. About 48 h after farrowing, there was muscular weakness, muscular tremors, and shaking. This was followed by collapse, dyspnea, and cyanosis. There were no liver or heart lesions. In experimental Se and vitamin E deficiency in young growing pigs, a subtle stiffness occurs along with a significant increase in the creatinine phosphatase (CPK) and serum glutamic-oxaloacetic transaminase (SGOT) values.

**CLINICAL PATHOLOGY**

**Myopathy**

Plasma creatine kinase (CK)

This is the most commonly used laboratory aid in the diagnosis of NMD. The enzyme is highly specific for cardiac and skeletal...
muscle and is released into the blood following unaccustomed exercise and myodegeneration. In cattle and sheep, its half-life is 2-4 h and plasma levels characteristically decline quickly unless there is continued myodegeneration, but remain a good guide to the previous occurrence of muscle damage for a period of about 3 days. The normal plasma levels of CK (IU/L) are: sheep 52 ± 10; cattle 26 ± 5; horses 58 ± 6; and pigs 226 ± 43. In cattle and sheep with NMD, the CK levels will be increased usually above 1000 IU/L, commonly increased to 5000-10 000 IU/L to monitor recovery of animals treated for nutritional myopathy.

The levels of both enzymes will be increased usually above 1000 IU/L, but is not as reliable as the CK because muscle degeneration is still progressive or has occurred within the last 2 days. Measurement of plasma CK activity could be used to monitor recovery of animals treated for nutritional myopathy.

Aspartate aminotransferase (AST) activity is also an indicator of muscle damage, but is not as reliable as the CK because increased AST levels may also indicate liver damage. The AST activity remains elevated for 3-10 days because of a much longer half-life than CK. In acute muscular dystrophy, the AST activity remains elevated for 3-10 days because of a much longer half-life than CK.

The magnitude of the increase in AST and CK is directly proportional to the extent of muscle damage. Both are elevated initially; an elevated AST and declining CK would suggest that muscle degeneration is no longer active. The levels of both enzymes will be increased slightly in animals that have just been turned out and subjected to unaccustomed exercise, horses in training and in animals with ischemic necrosis of muscle due to recumbency caused by diseases other than muscular dystrophy. However, in acute muscular dystrophy, the levels are usually markedly elevated.

Selenium status

Information on the critical levels of selenium in soil and plants is accumulating gradually, the estimations are difficult and expensive. Most field diagnoses are made on the basis of clinicopathological findings, the response to treatment and control procedures using selenium. The existence of NMD is accepted as presumptive evidence of selenium deficiency, which can now be confirmed by analyses of GHS-PX and the concentrations of selenium in soil, feed samples, and animal tissues. Tentative critical levels of the element are as follows:

- **Forages and grains**: A content of 0.1 mg/kg DM is considered adequate
- **Soil**: Soils containing less than 0.5 mg/kg are likely to yield crops inadequate in selenium concentration
- **Animal tissues, blood, and milk**: The concentration of selenium in various tissues is a reliable indicator of the selenium status of the animal. There is a positive correlation between the selenium content of feed and the selenium content of the tissues and blood of animals ingesting that feed and the values fluctuate with the dietary intake of the element. Three tests can be used to assess selenium status in cattle and sheep: serum and whole blood selenium and glutathione peroxidase activity. Serum selenium responds more rapidly to the administration of selenium than whole blood selenium. There is a similar delay in glutathione peroxidase activity to selenium supplementation. Blood or serum selenium status is most consistently measured at the herd-level. Interlaboratory differences in thresholds for deficiency exist and results should be considered based on laboratory-specific guidelines. The recommended blood selenium reference ranges for New Zealand livestock have been used in several publications (see Table 30.7).

Reference ranges for selenium and vitamin E in serum, blood, and liver of sheep and goat in the USA are available. Selenium status in horses in New Zealand, the reference ranges for blood used for selenium status in horses are: adequate >1600 nmol/L (128 mg/mL); marginal 450-1600 nmol/L (36-128 mg/mL); and deficient <450 nmol/L (36 mg/mL).

Kidney cortex and liver

Normal liver selenium concentrations range from 1.2 to 2.0 µg/g DM, regardless of species or age. Levels of 3.5-5.3 µg/g (44-67 nmol/g) DM in the kidney cortex and 0.90-175 µg/g (11-22 nmol/g) DM in the liver of cattle are indicative of adequate selenium. Levels of 0.6-1.4 µg/g (8-18 nmol/g) in the kidney cortex and 0.07-0.60 µg/g (0.9-8 nmol/g) in the liver represent a deficient state.

The selenium content of bovine fetal liver samples collected at an abattoir contained 0.77 µg/mL WW and 0.13 µg/mL WW, from dairy breeds and beef breeds of cattle, respectively. Mean liver selenium levels from aborted bovine fetuses with myocardial lesions were 5.5 µmol/kg, 6.5 µmol/kg in fetuses without myocardial lesions and 7.5 µmol/kg in fetuses from the abattoir, which suggests that selenium deficiency may be the cause of abortion.

**Blood and milk**

Blood and milk levels of selenium are used as indicators of selenium status in cattle and the effect of dietary supplementation. Serum selenium values increase gradually with age from starting ranges for neonates of 50-80 ng/mL for calves and sheep and 70-90 for foals and pigs. Expected or normal values for adults are in the ranges of 70-100 for cattle, 120-150 for sheep, 130-160 for horses, and 180-220 for pigs.

Dams of affected calves have blood levels of 1.7 ng/mL (22 nmol/L) (blood) and 4.9 ng/mL (62 nmol/L) (milk); their calves have blood levels of 5-8 ng/mL (63-102 nmol/L). Normal selenium-supplemented cows have 19-48 ng/mL (241-609 nmol/L) in blood and 10-20 ng/mL (127-253 nmol/L) in milk and their calves have blood levels of 33-61 ng/mL (419-774 nmol/L). Mean selenium concentrations in the blood of normal mares have been 26-27 ng/mL (329-342 nmol/L). In Thoroughbred horses, selenium concentrations in serum range from 39.5 to 118.5 ng/mL (40-160 nmol/L) (0.5-2.0 µmol/L) and there is significant differences between various stables of horses.

Bulk tank milk

The bulk tank milk selenium levels are closely related to the mean herd blood and milk levels and have the potential to be a low-cost, non-invasive means of evaluating herd selenium levels in order to determine selenium deficiency in the dairy herd. Bulk tank selenium concentrations are an accurate reflection of the herd selenium status over the range of selenium intakes typical of dairy herds in an area.

**Glutathione peroxidase**

There is a direct relationship between the GSH-PX activity of the blood and the selenium levels of the blood and tissues of cattle, sheep, horses, and pigs. The normal selenium status of cattle is represented by whole blood selenium concentration of 100 ng/mL (1270 nmol/L) and blood GSH-PX activity of approximately 30 mU/mg hemoglobin.

There is a high positive relationship (r = 0.87-0.958) between blood GSH-PX activity and blood selenium concentrations in cattle. Blood selenium levels less than 50 ng/mL are considered as selenium-deficient, while levels between 50 and 100 ng/mL (126.6 nmol/L) are marginal and greater than 100 ng/mL are adequate. Comparable whole blood levels of GSH-PX are deficient if less than 30 mU/mg.
hemoglobin, marginal if 30–60 mU/mg and adequate if greater than 60 mU/mg hemoglobin. There is some evidence of variation in GSH-PX activities between breeds of sheep; levels may also decrease with increasing age. Low levels in some breeds of sheep may also be a reflection of adaptation to low selenium intake because of low levels of selenium in the soil and forages.

The GSH-PX activity is a sensitive indicator of the level of dietary selenium intake and the response to the oral or parenteral administration of selenium. Because selenium is incorporated into erythrocyte GSH-PX only during erythropoiesis, an increase in enzyme activity of the blood will not occur for 4–6 weeks following administration of selenium. Plasma GSH-PX will rise more quickly and will continue to increase curvilinearly with increasing dietary selenium levels because it is not dependent on incorporation of the selenium into the erythrocytes. The liver and selenium concentration and serum GSH-PX activity may respond to changes in dietary selenium more rapidly than either whole blood selenium or erythrocyte GSH-PX activity. The response in GSH-PX activity may depend upon the selenium status of the animals at the time when selenium is administered. Larger increases in the enzyme activity occur in selenium-deficient animals. The GSH-PX activity in foals reflects the amount of selenium given to the mare during pregnancy.

The sandwich ELISA is a simplified method for the estimation of GSH-PX activity and selenium concentration in bovine blood and can be used for rapid screening of the selenium status of a large number of cattle. The GSH-PX activity of whole blood samples has been used to assess the selenium status of cattle in the Czech Republic.

The GSH-PX activity can be determined rapidly using a spot test which is semiquantitative and can place a group of samples from the same herd or flock into one of three blood selenium categories: deficient, low marginal and marginal adequate. A commercial testing kit known as the Ransel Kit is now available. Because of the instability of GSH-PX plasma, GSH-PX activity in sheep, cattle, and pigs should be measured in fresh plasma or stored at −20°C (−4°F). For absolute measurements, it is suggested that pigs plasma GSH-PX activity be measured immediately after separation from the blood cells, or be assayed within 24 h under specified laboratory conditions.

**Vitamin E status**

Vitamin E occurs in nature as a mixture of tocopherols in varying proportions. They vary widely in their biological activity so that chemical determination of total tocopherols is of much less value than biological assay. Tocopherol levels in blood and liver provide good information on the vitamin E status of the animal. However, because of the difficulty of the laboratory assays of tocopherols, they are not commonly done and insufficient reliable data are available. Analysis of liver from clinically normal animals on pasture reveal a mean α-tocopherol level of 20 mg/kg WW for cattle and 6 mg/kg WW for sheep. The corresponding ranges were 6.0–53 mg/kg WW for cattle and 1.8–17 mg/kg WW in sheep. The critical level below which signs of deficiency may be expected are 5 mg/kg WW for cattle and 2 mg/kg WW for sheep. Tocopherol levels in the serum of less than 2 mg/L in cattle and sheep are considered to be critical levels below which deficiency diseases may occur. However, if the diet contains adequate quantities of selenium, but not an excessive quantity of PUFAs, animals may thrive on low levels of serum tocopherols. In growing pigs, the serum vitamin E levels are between 2 and 3 mg/L. In summary, there are insufficient reliable data available on the vitamin E status on animals with NMD to be of diagnostic value.

The mean plasma vitamin E levels in clinically normal horses of various ages and breeds were 2.8 μg/mL. The optimal method for storing equine blood prior to α-tocopherol analysis is in an upright position in the refrigerator for up to 72 h. If a longer period is needed, the serum or plasma should be separated, blanketed with nitrogen gas and frozen in the smallest possible vial; the α-tocopherol in these samples will be stable at −16°C (3°F) for at least 3 months.

A summary of the GSH-PX activity, tocopherol and selenium levels in blood and body tissues of animals deficient in selenium appears in Table 30.6. Normal values are also tabulated for comparison. Both the abnormal and normal values should be considered as guidelines for diagnosis because of the wide variations in levels between groups of animals. The level of dietary selenium may fluctuate considerably, which may account for variations in GSH-PX. Selenium reference ranges to determine selenium status of sheep and cattle in New Zealand are shown in Table 30.7.

In the early stages of the subclinical form of NMD in lambs, there may be a decrease in serum selenium and glutathione peroxidase activity and an increase in the activity of aspartate aminotransferase (AST), creatine kinase (CK), and lactate dehydrogenase (LDH) compared with healthy lambs. The LDH-isoenzyme activity is useful for detection of subclinical forms of NMD because of significant increases in the activity of the LDH₂-muscle fraction.

**Farmed red deer**

Reference range data for liver and blood selenium in red deer are limited. White muscle disease has occurred in young deer with blood and liver selenium concentrations of 84–140 nmol/L and 240–500 nmol/kg fresh tissue, respectively. No growth rate response to selenium supplementation occurred in 1-year-old deer when blood selenium concentrations were less than 130 nmol/L, the range in which a growth rate response would be expected in sheep.
Pigs

An increase in the activity of several plasma enzymes occurs in Se and vitamin E deficiencies of pigs. The measurement of AST, CPK, lactic acid dehydrogenase, and isocitrate dehydrogenase can be used to detect the onset of degeneration of skeletal and myocardial muscles and liver. However, these are not commonly used for diagnostic purposes because of the acuteness of the illness. The determination of the levels of Se in feed supplies, tissues, and blood of affected pigs is much more useful as an aid to diagnosis and for guidelines for supplementation of the diet.

In Se-vitamin E deficiency in pigs, serum Se values of less than 2.5 ng/mL (3.2 nmol/L), hepatic Se of less than 0.10 mg/kg (1.3 μmol/kg), plasma α-tocopherol values of <0.40 μg/mL and hepatic α-tocopherol concentrations of <0.75 μg/g of tissue are common. In a recent study, the vitamin E level was <2 ppm in 25% of pigs with gross and microscopic lesions of MHD. In a recent study results suggested that supplementation with a surfactant level of vitamin E reduced the response to endotoxin, i.e. a reduced response to the peak levels of IL-6.

The diagnostic criteria for the VESD complex in pigs in New Zealand indicate that liver vitamin E concentrations >10 μmol/kg are adequate, with <2.5 μmol/kg associated with deficiency. Corresponding estimates for serum vitamin E are >2.5 μmol/L and <0.8 μmol/L, respectively. Liver Se concentrations of >2200 nmol/kg are adequate, with 1100–2200 nmol/kg being in the marginal range and <1100 nmol/kg being deficient. Deficiency levels for blood are in the range of 400–1500 nmol/L. These values must be interpreted along with the concentration of PUFAs in the diet.

There is a close relationship between blood vitamin E and resistance of erythrocytes against lipid peroxidation. The supplementation of the diet of pigs with vitamin E will increase both the serum levels of vitamin E and the resistance of the erythrocytes to lipid peroxidation.

**NECROPSY FINDINGS**

The gross appearance of the muscle lesions is quite constant, but the distribution of affected muscles varies widely in different animals. Affected groups of skeletal muscle are bilaterally symmetrical and contain localized white or gray areas of degeneration and necrosis. These areas may be in streaks, involving a large group of muscle fibers that run through the center of the apparently normal muscle or as a peripheral boundary around a core of normal muscle. In the diaphragm, the distribution of damaged bundles gives the tissue a radially striated appearance. The affected muscle is friable and edematous and may be mineralized. Secondary pneumonia often occurs in cases where the muscles of the throat and chest are affected. In cases with myocardial involvement, white areas of degeneration are visible, particularly under the endocardium of the left ventricle in calves and of both ventricles in lambs. The lesions may extend to involve the interventricular septum and papillary muscles and have a gritty character consistent with mineralization. Pulmonary congestion and edema is common.

Histologically, the muscle lesions in all species are non-inflammatory. Hyaline degeneration is followed by coagulation necrosis and variable degrees of mineralization.

Other than a variable degree of muscular atrophy, gross lesions are not seen in horses with equine motor neuron disease. Confirmation of the diagnosis relies on histological identification of characteristic degeneration and loss of motor neurons of the spinal cord ventral horns. However, a very strong presumptive diagnosis can be achieved by microscopic confirmation of neurogenic atrophy in the sacrocaudalis dorsalis muscle or axonal degeneration in the spinal accessory nerve.

A generalized steatitis has been described in newborn foals less than 2 months of age. The microscopic appearance of this yellow-brown fat consists of necrotic fat infiltrated by neutrophils, macrophages and giant cells. Steatitis and nodular panniculitis have also been reported in a 3-year-old vitamin E/ selenium-deficient mare. Supplemental vitamin E is believed to protect against steatitis in foals.

In mulberry heart disease the carcass is in good condition. All body cavities contain excessive amounts of fluid and shreds of fibrin. In the peritoneal cavity, the fibrin is often in the form of a lacy net covering all the viscera. The liver is enlarged, mottled and has a characteristic nutmeg appearance on the cut surface. The lungs are edematous and excessive fluid in the pleural cavities is accompanied by collapse of the ventral lung field. The pericardial sac is filled with gelatinous fluid interlaced with bands of fibrin. Beneath the epicardium and endocardium are multiple hemorrhages of various sizes. Usually, this hemorrhage is more severe on the right side of the heart. This gives the heart the typical mottled appearance which is caused by areas of necrosis and areas of hemorrhage. Histologically, the characteristic lesion is widespread myocardial congestion, hemorrhage, and myofiber degeneration. Multiple fibrinous microthrombi are within the myocardial capillaries and, occasionally, degenerative changes are visible in walls of small arterioles in many organs, including the heart. Malacia of cerebral white matter, or more rarely the molecular layer of the cerebellum, may occur and is attributable to microvascular damage. It should be stressed that, in some cases, the disease course is so rapid that morphologic changes are not discernible in the myocardial cells. Since it can be extremely difficult to distinguish mulberry heart disease from S suis septicemia histologically, it is prudent to also attempt bacteriologic culture when attempting to confirm the diagnosis.

In hepatitis dietetica, the liver is swollen and has a mottled to mosaic-like appearance throughout its lobes. Many of the lobules are distended and reddish in color. There is in fact an irregular distribution of hepatic necrosis and hemorrhage. The gall bladder may be edematous and there may also be myocardial necrosis and pulmonary edema. Typically, the disease course is so rapid that jaundice does not develop. Histologically, there is a distinct lobular distribution of hemorrhage, degeneration, and necrosis.

In NMD of pigs, the lesions are often only visible at the microscopic level and consist of areas of bilaterally distributed areas of muscular degeneration. The changes include hyalinization, loss of striations and fragmentation of myofibers. The sections are difficult to cut because of the presence of calcium in the myocytes.
A mild degree of NMD may accompany some cases of *hepatosis dietetica*.

**Samples for confirmation of diagnosis**
- **Toxicology** – 50 g liver (ASSAY (Se) (Vitamin E))
- **Histology** – formalin-fixed skeletal muscle (multiple sites), heart (both left and right ventricular walls), brain (including cerebral hemisphere) (LM). May require special stains to show the presence of calcium in the sections.
- **Bacteriology** (for mulberry heart disease only) – heart, liver, swab from pericardial sac (CULT).

### Differential Diagnosis

**Nutritional muscular dystrophy**

NMD is most common in young rapidly growing animals fed a selenium-vitamin E-deficient ration or whose dams were on a deficient, unsupplemented ration throughout the winter months. Characteristically, the disease is sudden in onset and several animals are affected initially or within a few days, particularly following unaccustomed exercise. In the acute form, generalized weakness and a state of collapse are common. In the subacute form, the major clinical findings are stiffness in walking, long periods of recumbency or total recumbency, inability to stand, a normal mental attitude and appetite and no abnormal neurological findings to account for the recumbency. The CP levels are markedly elevated.

**Calves and yearlings**

Acute enzootic muscular dystrophy in calves with myocardial involvement must be differentiated from other diseases causing generalized weakness, toxemia and shock. These include:
- **Septicemias**: Haemophilus septicemia resulting in weakness, recumbency and fever
- **Pneumonia**: Pneumonic pasteurellosis causing dyspnea, toxemia, fever and weakness.

**Subacute enzootic muscular dystrophy**

In which skeletal muscle lesions predominate must be differentiated from other diseases of young calves and yearlings characterized clinically by paresis and paralyzing. The subacute form is more common in yearlings and young cattle and is characterized by recumbency with other body systems being relatively within normal ranges. The other diseases include:
- **Musculoskeletal diseases**: Polyarthritis, traumatic or infectious myopathies (blackleg), osteodystrophy and fractures of long bones
- **Diseases of the nervous system**: Spinal cord compression, Hemophilus meningoencephalitis and myelitis, organophosphatic insecticide poisoning
- **Diseases of the digestive tract**: Carbohydrate engorgement resulting in lactic acidosis, shock, dehydration, and weakness.

### Lambs and kids

In lambs with 'stiff-lamb' disease, there is stiffness and a stifled gait, affected animals prefer recumbency, they are bright and alert and will suck the ewe if assisted. The serum levels of CPK and SGOT are also markedly elevated. Differentiation may be necessary from enzootic ataxia and swayback, but in these two diseases, stiffness is not characteristic but rather weakness and paresis.

**Foals**

In foals, NMD must be differentiated from acute diseases of the musculoskeletal and nervous system causing abnormal gait, weakness and recumbency. They include:
- Polyarthritis
- Meningitis
- Traumatic injury to the spinal cord.

**Mulberry heart disease**

Mulberry heart disease must be differentiated from other common causes of sudden death in pigs in which the diagnosis is made at necropsy and include:
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis and anthrax
- Porcine stress syndrome
- Gut edema
- Intestinal volvulus, heat exhaustion, suffocation during transportation.

### TREATMENT

Because of the overlapping functions of selenium and vitamin E and because it is not always possible to know the relative etiological importance of one nutrient or the other in causing some of the acute conditions already described, it is recommended that a combined mixture of selenium and α-tocopherol be used in treatment. α-Tocopherol is the potent form of the tocopherols and is available in a number of pharmaceutical forms, which also vary in their biological activity. It has become necessary to express the unitage of vitamin E in terms of international units of biological activity (1 IU:1 mg synthetic racemic α-tocopherol acetate. Natural D-α-tocopherol acetate 1 mg: 1 IU and natural D-α-tocopherol 1 mg: 0.92 IU).

**Nutritional muscular dystrophy**

For treatment of NMD in calves, lambs, and foals a mixture containing 3 mg selenium (as sodium or potassium selenite) and 150 IU/mL of DL-α-tocopherol acetate, given IM at 2 mL/45 kg BW is recommended. One treatment is usually sufficient. Animals with severe myocardial involvement will usually not respond to treatment and the case mortality rate is about 90%. However, all in-contact animals in the herd (calves, lambs, and foals) should be treated prophylactically with the same dose of selenium and vitamin E. They should be handled carefully during treatment to avoid precipitating acute muscular dystrophy. Animals with subacute skeletal muscular dystrophy will usually begin to improve by 3 days following treatment and may be able to stand and walk unassisted within 1 week.

Animals sometimes do not respond to either vitamin E or Se or treatment with both.

In outbreaks of mulberry heart disease, *hepatosis dietetica* and related Se and vitamin E deficiency diseases in pigs, all clinically affected pigs and all pigs at risk should be treated individually with a combination of Se and vitamin E parenterally at first to prevent any further sudden death. It can then be followed by oral administration.

### CONTROL

The control and prevention of the major diseases caused by selenium and vitamin E deficiencies can generally be accomplished by the provision of both nutrients to susceptible animals fed on deficient rations. The following points are relevant and applicable to most situations:

- Provide selenium and vitamin E
- Maternal transfer to newborn
- Selenium in milk supplements
- Dietary requirement of selenium
- High sulfate diets
- Glutathione peroxidase activity
- Different methods of supplementation.

Provide selenium and vitamin E

Over the years, both the vitamin E levels and Se levels in the diets have increased but particularly the former. This is in response to the more rapid growth rates of pigs but also the realization that pigs are coping with many more oxidative disease states. Outdoor pigs usually have sufficient of both unless the soil is Se deficient. A recent Chinese paper has suggested that dietary zinc at 85 mg/kg, Se at 0.4 mg/kg, and vitamin E at 45 IU/kg is appropriate for crossbred sows.

While Se alone is protective against a greater spectrum of diseases than is vitamin E, there are situations in which vitamin E is more protective. Both Se and vitamin E should be provided when the diets are deficient in both nutrients, but this may not apply in every situation. Most of the emphasis has been on Se supplementation at the expense of vitamin E, which is more expensive and less stable. Most injectable vitamin E and Se preparations are adequate in Se but insufficient in vitamin E.

There have been several attempts to supplement weaner pigs with a vitamin E preparation. Besides individual injections, it
is possible to supplement weaner pigs with water supplementation.109 Pigs will usually drink even if they are not eating. A recent study110 showed that the supplementation of drinking water with high doses of vitamin E (150 mg of DL-α-tocopherol acetate) was effective in maintaining serum vitamin E levels over the weaning period. This was even true when over the weaning period the intake of food was very low (it can be as low as 0.2–0.3 kg) and there is a temporary malabsorption in the intestine. It takes about 100 IU/L of water to provide a good vitamin E blood serum value.

Maternal transfer to newborn
Diseases caused by selenium deficiency are preventable by the administration of selenium to the dam during pregnancy or directly to the young growing animal. Selenium is transported across the placenta and provides protection for the neonate. Oral supplementation with selenium in beef cattle will provide enough to maintain blood levels in the dam and for adequate transfer to the fetus, which can sequester selenium when the levels are low in the dam. The colostrum of selenium-supplemented milk also contains an adequate amount of selenium to prevent severe selenium-deficiency diseases.68 However, by 7 days after parturition, the levels in milk may be inadequate to maintain adequate serum levels in calves. The strategic administration of selenium and vitamin E before the expected occurrence of the disease is also a reliable method of preventing the disease.

Selenium is potentially toxic
Se is toxic and any treatment and control program using it must be carefully monitored.111 Se injected into or fed to animals concentrates in liver, skeletal muscle, kidney, and other tissues and withdrawal periods before slaughter must be allowed. There is some concern that Se may be a carcinogen for man. The only tissues that appear likely to consistently accumulate more than 3–4 mg/kg of Se are the kidney and liver and these are very unlikely to constitute more than a very small part of the human diet. There have been no reports of untoward effects of Se on human health when it has been used at nutritional levels in food-producing animals. The incorporation of Se into commercially prepared feeds for some classes of cattle and pigs has been approved in some countries. A recent case in Norway showed the hazards of Se contamination in the case of an iron supplement.112 Se toxicosis has been fairly regularly reported.104–106

Pigs that are deficient may be more susceptible to other diseases. Pigs with NMD often have the appearance of pneumonic pigs because the diaphragm is weak and the pigs are dyspneic.

Deficient and small pigs may be more susceptible to the effects of iron and when this is given by injection there may be large numbers of dead piglets as a result of iron toxicity. In these cases, the heart lesions resemble those of MHD.

Selenium in milk supplies
The use of selenium in the diet of lactating dairy cows has caused concern about possible adulteration of milk supplies. However, the addition of selenium to the diets of lactating dairy cows at levels that are protective against the deficiency diseases does not result in levels in the milk that are hazardous for human consumption. The feeding of excessive quantities of selenium to dairy cattle would cause toxicity before levels became toxic for man.

Dietary requirement of selenium
The dietary requirement of selenium for both ruminants and non-ruminants is 0.1 mg/kg DM of the element in the diet. There may be nutritionally important differences in the selenium status between the same feeds grown in different regions and between different feeds within a region. Even within a region featuring high selenium concentrations, some feeds may contain levels of selenium below the 0.1 mg/kg minimum requirement for livestock. Thus a selenium analysis of feeds appears necessary in order to supplement livestock appropriately. Some geographical areas are known to be deficient in selenium and the feeds grown in these areas must be supplemented with selenium and vitamin E on a continuous basis. Some reports indicate that surveys have found that dairy producers are providing insufficient supplementation of selenium in the ration to meet the recommended selenium intake for lactating dairy cows.113 Long-term administration of organic selenium in the form of selenium yeast provides higher blood and tissue concentrations than repeated parenteral administration of recommended therapeutic doses of inorganic selenium.71

High sulfate diets
Avoidance of high sulfate diets is desirable, but provision of adequate Se overcomes the sulfate effect.

Glutathione peroxidase activity
Whole blood GSH-FiX activity is a way of monitoring Se status but is not as reliable in pigs as in sheep and cattle.

Pigs. In growing pigs, both Se and vitamin E at 30IU/kg DM of feed are necessary for the prevention of the diseases caused by diets deficient in vitamin E and Se. Supplementation of the diet of the sow will result in an adequate transfer to the piglets. Satisfactory protection of the diseases of pigs caused by vitamin E Se deficiency depends on the correct balance between Se, α-tocopherol, PUFAs in the diet and the presence of a suitable antioxidant to conserve the α-tocopherol.107

Different methods of supplementation
The prevention of the major diseases caused by selenium and vitamin E deficiencies can be achieved by different methods, including:
- Dietary supplementation in the feed or water supplies
- Individual parenteral injections
- Oral administration
- Pasture top-dressing.

The method used will depend on the circumstances of the farm, ease of administration, cost, the labor available, severity of the deficiency that exists and whether or not the animals are being dosed regularly for other diseases such as parasitism. The subcutaneous injection of barium selenate, the administration of an intra-ruminal pellet and the addition of selenium to the water supply were compared in cattle; each method was effective for periods ranging from 4 to 12 months.

Dietary supplementation
The inclusion of selenium and vitamin E in the feed supplies or salt and mineral mixes has been generally successful in preventing the major diseases caused by deficiencies of these two nutrients.

Selenium dose
Individual injections
Injections of Se and vitamin E have been used successfully for prevention, particularly in circumstances where the diet cannot be easily supplemented. Following IM injections of sodium selenite into calves, lambs, and piglets, the Se concentration of the tissues, particularly the liver, increases and then declines to reach preinjection levels in 23 days in calves and 14 days in lambs, and piglets. Adequate sources of vitamin E also must be provided. Injectable preparations of Se and vitamin E are usually adequate in Se and deficient in vitamin E and it may not be possible to correct a marginal deficiency of vitamin E in pregnant beef cattle, for example, by IM injection of a Se and vitamin E preparation which contains an inadequate concentration of vitamin E.118 The current label dose of injectable Se, 0.055 mg Se/kg BW, which is therapeutically adequate for NMD, is not sufficient for long-term Se supplementation of cattle on a Se-deficient diet.119 Copper and Se supplementation by parenteral administration can be combined when both deficiencies are present.110
Subcutaneous injections

Cattle and sheep. A slow-release preparation of barium selenate for SC injection is now available for use in cattle and sheep.89 A SC injection of 1 mg selenium/kg BW to pregnant ewes, the GSH-PX activity is increased and maintained at adequate levels for up to 5 months. There is adequate transfer of selenium to the lambs, providing protection for up to 12 weeks of age, which covers the period when lambs are at greatest risk. A dose of 1.2 mg selenium/kg BW provided adequate selenium status for as long as two consecutive lambing seasons. Barium selenate at 1 mg selenium/kg BW SC provides protection in young sheep for at least 3 months and is not associated with risk of selenium toxicity or unacceptable residues of selenium in tissues other than the site of injection.89 A dose of 1 mg selenium/kg BW (barium selenate) to cattle SC increased the GSH-PX activity within 4 weeks and was maintained at high levels for up to 5 months.

Pigs. The SC injection of barium selenate of pregnant sows at 0.5–1.0 mg selenium/kg BW resulted in a significant difference in GSH-PX activity in the piglets from treated sows compared with untreated controls. The SC injection of barium selenate at 2.5 mg selenium/kg BW into pigs weighing 20 kg also maintained blood levels of selenium and GSH-PX activity during the most rapid growing period. The relative safety of barium selenate is due to its slow rate of release from the site of injection. By comparison, when selenium is administered as a soluble salt, such as sodium selenite, acute toxicity may occur at doses of 0.45 mg selenium/kg BW. Treatment with barium selenate increases the concentration of selenium in blood, liver and muscle and persists for at least 4 months. One disadvantage of barium selenate is that a large residue persists at the site of injection for long periods. The use of sodium selenite also increases tissue and blood concentrations of selenium, but they begin to decline by 23 days. The bovine liver rapidly removes approximately 40% of injected selenium salts (soluble) from the systemic plasma, binds it to a plasma component and within 1 h of injection releases it back into circulation.

Farmed red deer. A long-acting barium sulfate given subcutaneously to red deer on pasture, at 0.5, 1.0, or 2.0 mg Se/kg BW, elevated blood selenium concentrations from 105 nmol/L pre-injection for at least 377 days with peak levels of 1894, 1395, and 818 nmol/L for high, medium, and low doses, respectively.112 Pastures contained 10–30 mg Se/kg DM. There was no significant difference in growth rate between treated and control deer. The preparation produced fewer and less severe subcutaneous tissue reactions than previous preparations. Young growing deer seem less sensitive to selenium deficiency as measured by weight gain, than sheep and cattle, suggesting that reference ranges for those species are not appropriate for deer.

Oral selenium and anthelmintics

Oral dosing using sodium selenite is sometimes combined with the administration of anthelmintics and vaccinations. The dose should approximate 0.044 mg/kg BW. A routine program in a severely deficient area comprises three doses of 5 mg of selenium (11 mg sodium selenite) each to ewes, one before mating, one at mid-pregnancy and one 3 weeks before lambing and four doses to the lambs. The first dose to lambs (of 1 mg) is given at docking and the others (2 mg each) at weaning and then at 3-month intervals. A 100-day controlled release anthelmintic capsule containing 13.9 mg of selenium will protect lambs from selenium deficiency for at least 180 days.113

Both selenium and cobalt can be incorporated into an anthelmintic program. The levels of GSH-PX activity may be monitored on a regular basis following the drenching with selenium and provide a good indication of selenium availability and selenium status of grazing sheep.

Pasture top-dressing

The application of sodium selenate as a top-dressing to pasture is now practiced and permitted in some countries. Top-dressing at the approved rate of 10 g selenium/ha is effective for 12 months and has a toxicity margin of safety of about 20 times. Sodium selenite is now used in preference to sodium selenite because only about one-fifth is required to raise the pasture level of selenium to the same concentrations provided by sodium selenite. Top-dressing severely deficient pumice soils in New Zealand prevented deficiency for at least 12 months, sheep were protected against white muscle in lambs and reproduction performance and weight gains were improved. It is recommended that sodium selenite be applied annually to all selenium-deficient soils at the rate of 10 g selenium/ha added to the superphosphate fertilizer, or as prills of sodium selenate alone. Top-dressing is an economical alternative to individual animal dosing, particularly in severely deficient areas with a high stocking rate. At the approved rate, no adverse effects are anticipated in human or animal health or on the environment.

Muscular dystrophy

Under most conditions, NMD of calves and lambs can be prevented by providing selenium and vitamin E in the diets of the cow or ewe during pregnancy at 0.1 mg/kg DM of actual selenium and α-tocopherol at 1 g/d per cow and 75 mg/d per ewe. If possible, the supplementation should be continued during lactation to provide a continuous source of selenium to the calves and lambs. Under some conditions the level of 0.1 mg/kg DM may be inadequate. In some circumstances, the optimal selenium concentration in the feed is considerably higher than 0.1 mg/kg DM and levels up to 1.0 mg/kg DM in the feed result in increases in GSH-PX activity which may be beneficial; however, the cost-effectiveness has not been determined. Pregnant ewes being fed on alfalfa hay may require selenium at a level of up to 0.2 mg/kg DM to prevent white muscle disease in their lambs. Young growing cattle, particularly beef cattle likely to receive hay and straw deficient in selenium and those which are fed high-moisture grain, should receive a supplement of selenium at the rate of 0.1 mg/kg DM and α-tocopherol at 150 mg/d per head. If selenium-supplemented concentrates are used as part of a feeding program for dairy cows, it is not necessary to provide additional selenium by parenteral injection.

Lambs are born with a low serum level of vitamin E but the concentration increases rapidly after the ingestion of colostrum.1 Supplementation of pregnant ewes with α-tocopherol, either as a single IM dose (500 mg 2 weeks before lambing) or orally (150 mg daily during 3–4 weeks before lambing) results in a marked increase in the levels of the vitamin in the serum and colostrum. The vitamin E concentration in colostrum was 5–11 times higher than in milk 1 week after lambing.

Vitamin E supplementation of the feed of weaner sheep by oral drench or feed additive is effective in increasing plasma α-tocopherol concentrations. This is the most practical method for housed sheep and prevents subclinical myopathy.114 The IM oily injection was slow to increase plasma levels of tocopherols and did not prevent myopathy in grazing experiments. Vitamin E supplements have no beneficial effects on wool quality or quantity in grazing sheep and unless certain flocks are susceptible to vitamin E deficiency myopathy it is not recommended.

Beef cattle and sheep

Salt-mineral mixture. NMD can be prevented in unweaned beef calves and lambs by the inclusion of selenium
(14.8 mg/kg) and vitamin E (2700 IU/kg) in the mineral supplement provided ad libitum to the pregnant cows and ewes on a selenium-deficient ration during the latter two-thirds of gestation and for the first month of lactation. Under most conditions this will provide selenium at 0.1 mg/kg DM in the diet.

The provision of sodium selenite in a salt-mineral mixture to provide 90 mg of selenium/kg salt-mineral mixture on a year-round basis, even under range conditions, increased GSH-PX activity levels into normal ranges in beef cows for 3 months when fed to extremely deficient animals. Calves of these cows had increased weaning weights and decreased incidence of infectious diseases, but the trial was uncontrolled. The provision of 30 mg selenium/kg salt-mineral mixture was insufficient to raise the GSH-PX activity levels to normal ranges. Bak blood selenium levels were achieved in weaned beef calves supplemented with 80 and 160 mg selenium/kg in free-choice salt-mineral mixtures for a period of 108 days. In some conditions selenium levels were achieved higher levels than those permitted in the feeds. Current recommendations indicate that selenium intake for lactating and gestating dairy cattle should range from 5 to 7 mg/d for adequate concentrations in serum or plasma which would range from 70 to 100 ng of selenium/mL serum. Such supplementation should result in improved selenium status of the newborn, improved concentration of selenium in colostrum and improved health of the calves. The effects of selenium supplementation in dairy cattle on reproductive performance is equivocal. Some studies over a period of two lactations revealed no effect on reproductive performance, while others report an improvement in dairy cattle in a district considered to be marginally deficient in selenium. Intakes of inorganic selenium as sodium selenite in amounts of 50 mg/d for 90 days or 100 mg/d for 28 days by adult dairy cows (10–30 times the nutritional requirement) did not cause any health problems. The toxic dose for cattle ranges from 0.25 to 0.5 mg/kg BW.

Milk replacers for dairy calves should contain a suitable antioxidant and be supplemented with 300 IU/kg DM of α-tocopherol acetate at the rate of 0.1 mg/kg DM of the milk replacer.

**Vitamin E.** Dietary or parenteral supplementation of vitamin E to dairy cows during the peripartum period has consistently improved the function of neutrophils and macrophages. However, the effects of supplementation of dry dairy cows with vitamin E in the feed or parenteral administration of vitamin E before parturition on the incidence of disease have been variable. The amount of supplemental vitamin E fed per day during the peripartum period has ranged from 1000 to 3000 IU/day. Feeding 1000 IU/day of supplemental vitamin E to dry cows when adequate selenium was supplemented reduced the incidence of retained placenta. The peripartum subcutaneous injection of dairy cows with 3000 IU of vitamin E, 1 week before expected calving had no significant difference on the incidence of retained placenta, clinical mastitis, metritis, endometritis, ketosis, displaced abomasum, or lameness. Vitamin E administered to cows with marginal pre-treatment vitamin E status had a reduced risk of retained placenta. In cows, with adequate serum vitamin E, there was no reduction in the incidence of any disease.

Based on health and immune function in cows, plasma concentrations of α-tocopherol in peripartum cows should be approximately 3 μg/mL. To maintain these blood values, dry cows and heifers fed stored forages during the last 60 days of gestation require approximately 1.6 IU of supplemental vitamin E/kg BW (approximately 80 IU/kg DM). Increased intake of vitamin E of cows and heifers during the prepartum period also increases the vitamin E in colostrum. Milk is not a major source of vitamin E but colostrum contains high concentrations of α-tocopherol (3 to 6 μg/mL). For lactating cows, being fed stored forages to reduce the incidence of mastitis, the recommendation for vitamin E is 0.8 IU/kg BW (approximately 20 IU/kg DM). When fresh forage is fed, there is less need for supplemental vitamin E. The intake of polyunsaturated fatty acids increases the vitamin E requirement and additional vitamin E may be required when protected unsaturated fats are fed.

**NMD in the neonate.** The injection of Se 0.06 mg/kg BW into piglets under 1 week of age, repeated at weaning time and into the sow 3 weeks before farrowing will be effective. The minimum lethal dose of Se for piglets is 0.9 mg/kg BW, which provides a reasonably wide range of safety. A high concentration of Se in the diet of pregnant sows in the last half of gestation has been associated with hemorrhagic lesions on the claws of newborn piglets.

While selenium alone is protective against a greater spectrum of diseases than is vitamin E, there are situations in which vitamin E is more protective. Both selenium and vitamin E should be provided when the diets are deficient in both nutrients, but this may not apply in every situation. NMD can occur in ruminants with vitamin E deficiency and an adequate selenium status. Most of the emphasis has been on selenium supplementation at the expense of vitamin E, which is more expensive and less stable. Most injectable vitamin E and selenium preparations are adequate in selenium but insufficient in vitamin E.

**Selenium responsive reproductive performance and growth.** Sheep In selenium deficient situations, reproductive performance of ewes may be improved by selenium or selenium and vitamin E. Survival of lambs, live weights
at birth and at weaning may be increased by selenium supplementation. Single injections of selenium before mating and lambing had no significant effects on estrus, fertility, prolificacy, and the number of lambs born and reared to 28 days in 2-year-old ewes. Two consecutive injections of selenium (before mating and lambing) significantly increased the incidence of estrus, fertility, and lamb body weight at 28 days and daily weight gains for 28 days in 3-year-old ewes compared with controls. The injection of selenium plus vitamin E did not significantly improve reproductive performance in 2- to 3-year-old ewes in the flock not considered selenium deficient.

Weak-calf syndrome
The parenteral injection of selenium and iodine to pregnant cattle in Ireland did not significantly reduce the incidence of the weak-calf syndrome, which is often attributed to a selenium deficiency.

Pigs
The injection of selenium 0.06 mg/kg BW into piglets under 1 week of age, repeated at weaning time and into the sow 3 weeks before farrowing will be effective. The minimum lethal dose of selenium for piglets is 0.9 mg/kg BW, which provides a reasonably wide range of safety. A high concentration of selenium in the diet of pregnant sows in the last half of gestation has been associated with hemorrhagic lesions on the claws of newborn piglets.

Horses
Little information is available on the need of horses for selenium but the optimum intake is 6 mg/week or 2.4 ¡g/kg BW daily. The oral supplementation of 1 mg selenium/d increases blood selenium concentrations above levels associated with myodegeneration in horses and foals. In New Zealand, for horses on pasture, the injection of barium selenate, at a dose of 0.5 mg Se/kg BW, asetically at a deep intramuscular site was efficacious in correcting the selenium status of mares grazing pasture with a selenium content of 0.01 to 0.07 mg/kg DM. Some local swelling will occur.

To ensure nutritional adequacy and to have an adequate safety margin, adult Standardbred horses should receive 600–1800 mg DL-Î±-tocopherol daily in their feed. The parenteral administration of vitamin E and selenium to mares in late pregnancy and to their foals beginning at birth, will increase blood selenium to adequate levels. In selenium-deficient areas or when mares are fed selenium-deficient hay, the prepartum injections of selenium and vitamin E are indicated followed by intermittent injection of the foals, or supplementation of the diet with selenium at 0.1 mg/kg DM.

Intra-ruminal selenium pellets

Sheep
Intra-ruminal selenium pellets, similar to those used in cobalt deficiency, have produced satisfactory blood levels of selenium for up to 4 years in ewes at pasture. A satisfactory pellet is composed of 0.5 g elemental selenium and finely divided metallic iron. The technique is efficient, but not completely, due to wide variations between animals in the absorption rate of the selenium. The average delivery of selenium is 1 mg/d and there is no danger of toxicity. In sheep grazing selenium-deficient pastures, the ruminal pellets increase the selenium status and weight gains compared with controls. About 15% of treated sheep reject the pellets within 12 months and in varying degrees the pellets acquire deposits of calcium phosphate. Sheep fed pellets recovered from sheep have low selenium levels, which suggests a low release of selenium from pellets that have been in the rumen of other sheep for several months. The peak levels of selenium occur 3 months after administration; there is a rapid decline in activity between 5 and 13 months. Sustained-released boluses containing sodium selenite, cobalt sulfate, potassium iodide, manganese sulfate, zinc oxide, and sulfate and vitamins A, D, and E have also been formulated to provide long-term maintenance of selenium.

A zinc, cobalt, and selenium soluble glass bolus administered to ram lambs increased the selenium status of the animals and increased sperm motility, percentage of live sperm and sperm responding to hypo-osmotic swelling test (an assay to determine plasma membrane permeability).

High density compressed pellets containing both sodium selenite and cobalt carbonate have been developed for cattle and sheep. The sheep pellet weighs 18 g and contain 4.6% selenium and 12.7% cobalt (828 mg Se and 2295 mg Co). In both beef cows and growing cattle, the boluses increased blood glutathione peroxidase activity for at least 1 year.

A sustained-release intra-reticular bolus is an osmotic pump designed to release 3 mg selenium into the reticulorumen. It is intended to provide selenium supplementation for 120 days in grown heifers and pregnant beef cattle.

Selenium toxicity and residues
Selenium intoxication can occur following the administration of toxic amounts of a selenium salt. The use of selenium selenite instead of sodium selenate and giving a dose of five times the intended dose resulted in a high mortality within several hours after administration. Animals deficient in selenium are more susceptible to selenium toxicosis than those that are selenium-adequate. The pharmacokinetics of selenium toxicity in sheep given selenium selenite parenterally has been examined. When oral preparations of selenium and monensin are given concurrently as part of a routine dietary management practice, there is greater risk of selenium intoxication than if the selenium is given alone. Administration of monensin sodium at a constant, safe dosage enhanced the toxicity of selenium as demonstrated by increased severity of the signs of intoxication, fatalities, tissue selenium concentrations and intensified gross, histopathological, and biochemical changes. There is some concern about selenium supplementation of beef cattle being a potential source of contamination for nearby aquatic systems, but there is no evidence that this has occurred.

Selenium responsiveness
The response to selenium supplementation is proportional to the degree of deficiency and supplementation of animals that have adequate selenium intakes is unlikely to significantly improve growth rate. In New Zealand, for selenium-deficient lambs, the potential for a growth response to selenium supplementation is strongly related to blood selenium concentration. Economically significant live weight gains of >10 g/d can occur when initial blood levels in the tissues at slaughter were not a risk for humans.

Use of the intra-ruminal selenium pellets in dairy cattle in New Zealand resulted in improved growth and milk production in herds where the selenium status was below the adequate range, but there was no effect on udder health and reproductive performance.

High density compressed pellets containing both sodium selenite and cobalt carbonate have been developed for cattle and sheep. For cattle, the pellets weigh 18 g and contain 4.6% selenium and 12.7% cobalt (828 mg Se and 2295 mg Co). In both beef cows and growing cattle, the boluses increased blood glutathione peroxidase activity for at least 1 year.

A sustained-release intra-reticular bolus is an osmotic pump designed to release 3 mg selenium into the reticulorumen. It is intended to provide selenium supplementation for 120 days in grown heifers and pregnant beef cattle.
selenium concentrations are <130 nmol/L. This is the basis for the development of reference curves using blood selenium concentration to diagnose selenium deficiency and predict growth responses to lambs.\(^8\)

Although many methods of supplementation of selenium are efficacious, they can differ widely in their cost and convenience of administration. The objective of any micronutrient supplementation program should be to optimize the return on investment.\(^9\) The least cost option which provides adequate supplementation for the required period should be recommended initially.

Veterinarians are the professionals in the best position to offer advice on cost-effectiveness supplementation.\(^9\) To retain this position, they must provide sound recommendations based on micronutrient analysis of animal tissue and defensible reference ranges which are supported by production response data. Monitoring micronutrient status in animal tissue should be encouraged so as to ensure that regulatory requirements are met and that deficiency and excess use are avoided. Circumvention of veterinary involvement in the diagnosis and treatment of micronutrient supplementation can lead to greater use of supplements when not indicated, higher costs to farmers and low cost-benefit ratios for the industry.

Depot and bolus preparations have revolutionized the treatment of deficiencies of cattle and sheep that are grazed extensively where there is little opportunity for frequent administration (Table 30.8). The relatively short duration of a single drench or injection of selenium salts such as sodium selenite should be noted. The use of fertilizer applications selenium prills is gaining widespread acceptance on farms with high stocking rates.

Dietary Deficiency of Phosphorus, Calcium, and Vitamin D and Imbalance of the Calcium:Phosphorus Ratio

A dietary deficiency or disturbance in the metabolism of calcium, phosphorus, or vitamin D, including imbalance of the calcium:phosphorus ratio, is the principal cause of the osteodystrophies. The inter-relation of these various factors is often very difficult to define and because the end result in all these deficiencies is so similar the precise etiological agent is often difficult to determine in any given circumstance.

In an attempt to simplify this situation, the diseases in this section have been dealt with in the following order:

- Calcium deficiency (hypocalciosis)
  - Primary: an absolute deficiency in the diet
  - Secondary: when the deficiency is conditioned by some other factor, principally an excess intake of phosphorus

- Phosphorus deficiency (hypophosphatosis)
  - Primary: an absolute deficiency in the diet
  - Secondary: when the deficiency is conditioned by some other factor; although in general terms an excessive intake of calcium could be such a factor, specific instances of this situation are lacking

Vitamin D deficiency (hypovitaminosis-D)
  - Primary: an absolute deficiency intake of the vitamin
  - Secondary: when the deficiency is conditioned by other factors of which excess carotene intake is the best known.

In different countries with varying climates, soil types and methods of husbandry, these individual deficiencies are of varying importance. For instance in South Africa, northern Australia, and North America the most common of the above deficiencies is that of phosphorus; vitamin D deficiency is uncommon. In Great Britain, Europe and parts of North America, a deficiency of vitamin D can also be of major importance. Animals are housed indoors for much of the year, they are exposed to little ultraviolet irradiation, and their forage may contain little vitamin D. Under such conditions, the absolute and relative amounts of calcium and phosphorus in the diet need to be greater than in other areas if vitamin D deficiency is to be avoided. In New Zealand, where much lush pasture and cereal grazing is used for feed, the vitamin D status is reduced not only by poor solar irradiation of the animal and plant sterols, but in addition, an anti-vitamin D factor is present in the diet possibly in the form of carotene.

Now that the gross errors of management with respect to calcium and phosphorus and vitamin D are largely avoided, more interest is devoted to the marginal errors; in these, diagnosis is not nearly so easy and the deficiency can be evident only at particular times of the year. The conduct of a response trial in which part of the herd is treated is difficult unless they are hand-fed daily; there are no suitable reticular retention pellets or long-term injections of calcium or phosphorus because the daily requirement is so high. Two methods suggest themselves:

1. Analysis of ash content of samples of spongy bone from the tuber coxae
2. The metabolic profile method.

The latter program may have some value as a monitoring and diagnostic weapon in the fields of metabolic disease, nutritional deficiency and nutritional excesses.

Absorption and metabolism of calcium and phosphorus

In ruminants, dietary calcium is absorbed by the small intestine according to body needs. Whereas young animals with high growth requirements absorb and retain calcium in direct relation to intake over a wide range of intakes, adult male animals, irrespective of intake, absorb only enough calcium to replace that lost by excretion into urine and intestine, retaining none of it. Calcium absorption is increased in adult animals during periods of high demand, such as pregnancy and lactation, or after a period of calcium deficiency, but a substantial loss of body stores of calcium appears to be necessary before this increase occurs. The dietary factors influencing the efficiency of absorption of calcium include the nature of the diet, the absolute and relative amounts of calcium and phosphorus present in the diet and the presence of interfering substances. Calcium of milk is virtually all available for absorption, but calcium of forage-containing diets has an availability of only about 50%.

References:
77. Putterford EBC, Pig J 1998; 42:144.
addition of grain to an all-forage diet markedly improves the availability of the calcium.

Phosphorus is absorbed by young animals from both milk and forage-containing diets with a high availability (80–100%), but the availability is much lower (50–60%) in adult animals. Horses fed diets containing adequate amounts of calcium and phosphorus absorb 50–65% of the calcium, and slightly less than 50% of the phosphorus present in a variety of feedstuffs. In grains, 50–65% of the phosphorus is in the phytate form which is utilizable by ruminants, but not as efficiently by non-ruminants like the horse and pig. An average availability of 70% has been assumed for phosphorus in early weaning diets for young pigs, and a value of 50% in practical cereal-based feeds as supplied to growing pigs, sows and boars.

The metabolism of calcium and phosphorus is influenced by the parathyroid hormone calcitomin and vitamin D. Parathyroid hormone is secreted in response to hypocalcemia and stimulates the conversion of 25-dihydroxycholecalciferol to 1,25-dihydroxycholecalciferol (1,25-DHCC). Parathyroid hormone and 1,25-DHCC together stimulate bone resorption and 1,25-DHCC alone stimulates intestinal absorption of calcium. Calcium enters the blood from bone and intestine, and when the serum calcium level increases above normal, parathyroid hormone is inhibited and calcitomin secretion stimulated. The increased calcitomin concentration blocks bone resorption and the decreased parathyroid hormone concentration depresses calcium absorption.

**CALCIUM DEFICIENCY**

Calcium deficiency may be primary or secondary, but in both cases, the end result is an osteodystrophy, the specific disease depending largely on the species and age of the animals affected.

**ETYLOGICAL**

A primary deficiency due to a lack of calcium in the diet is uncommon, although a secondary deficiency due to a marginal calcium intake aggravated by a high phosphorus intake is not uncommon. In ponies, such a diet depresses intestinal absorption and retention of calcium in the body and the resorption of calcium from bones is increased. The effects of reduced calcium intake and parathyroidectomy are understandably additive in pigs, but parathyroid insufficiency seems an unlikely natural phenomenon.

**EPIDEMIOLOGY**

Calcium deficiency is a sporadic disease occurring in particular groups of animals rather than in geographically limited areas. Although death does not usually occur, there may be considerable loss of function and disabling lesions of bones or joints.

Horses in training, cattle being fitted for shows, and valuable stud sheep are often fed artificial diets containing cereal or grass hays which contain little calcium and grains which have a high content of phosphorus. The secondary calcium deficiency that occurs in these circumstances is often accompanied by a vitamin D deficiency because of the tendency to keep animals confined indoors. Pigs are often fed heavy concentrate rations with insufficient calcium supplement. Dairy cattle may occasionally be fed similarly imbalanced diets, the effects of which are exaggerated by high milk production.

There are no well-established records of calcium deficiency in grazing sheep or cattle, but there are records of low calcium intake in feedlots accompanied by clinical osteodystrophy. There is also a well-recognized field occurrence of calcium deficiency in young sheep in southeast Australia. Outbreaks can affect many sheep and are usually seen in winter and spring, following exercise or temporary starvation. In most outbreaks the characteristic osteoporosis results from a long-term deprivation of food due to poor pasture growth. Occasional outbreaks occur on green oats used for grazing. The calcium intake in some cases is as low as 3–5 g/week in contrast to the requirement of 3–5 g/d.

High protein intake and rapid growth have been suggested as contributory factors in the development of skeletal problems in young horses. However, a concentration of dietary protein of 20%, which is significantly above the NRC recommended level of 14%, is neither helpful nor harmful to growing horses. The high protein intake did not affect the rate of growth, height, and circumference of cannon bones compared with horses receiving the lower 14% diet. The high protein diet did not result in hypercalcuria and did not affect calcium absorption or calcium retention.

In females there is likely to be a cycle of changes in calcium balance, a negative balance occurring in late pregnancy and early lactation and a positive balance in late lactation and early pregnancy and when lactation has ceased. The negative balance in late pregnancy is in spite of a naturally occurring increased absorption of calcium from the intestine at that time, at least in ewes.

**PATHOGENESIS**

The main physiological functions of calcium are the formation of bone and milk, participation in the clotting of blood and the maintenance of neuromuscular excitability. In the development of osteodystrophies, dental defects and tetany the role of calcium is well understood but the relation between deficiency of the element and lack of appetite, poor growth, loss of condition, infertility and reduced milk flow is not readily apparent. The disorientation of the animals to move about and graze and poor dental development may contribute to these effects.

Experimentally, feeding young lambs a diet low in calcium and phosphorus for 12 weeks results in soft and pliable ribs with thickening of the costochondral junctions, reduction in feed intake by about 34%, significant changes in plasma calcium and phosphorus concentrations and changes in dry matter digestibility. Feeding repletion diets results in complete remineralization of rib bones, but only partial remineralization of the metatarsal bones.

Nutritional factors other than calcium, phosphorus and vitamin D may be important in the production of osteodystrophies, which also occur in copper deficiency, fluorosis and chronic lead poisoning. Vitamin A is also essential for the development of bones, particularly those of the cranium.

**CLINICAL FINDINGS**

The clinical findings, apart from the specific syndromes described later, are less marked in adults than in young animals, in which there is decreased rate or cessation of growth and dental maldevelopment. The latter is characterized by deformity of the gums, poor development of the incisors, failure of permanent teeth to erupt for periods of up to 27 months and abnormal wear of the permanent teeth due to
There is a profound fall in serum calcium. Enamel, occurring principally in sheep, defective development of dentine and enamel, occurring principally in sheep.

A calcium deficiency may occur in lactating ewes and suckling lambs whose metabolic requirements for calcium are higher than in dry and pregnant sheep. There is a profound fall in serum calcium. Tetany and hyperirritability do not usually accompany hypocalcemia in these circumstances, probably because it develops slowly. However, exercise and fasting often precipitate tetanic seizures and parapletic paresis in such sheep. This is typical of the disease as it occurs in young sheep in southeast Australia. Attention is drawn to the presence of the disease by the occurrence of tetany, convulsions and paresis but the important signs are ill-thrift and failure to respond to anthelmintics. Serum calcium levels will be as low as 5.6 mg/dL (1.4 mmol/L). There is lameness, but fractures are not common even though the bones are soft. A simple method for assessing this softness is compression of the frontal bones of the skull with the thumbs. In affected sheep, the bone can be felt to fluctuate.

Pigs fed on heavy concentrate rations may develop a hypocalemic tetany, which responds to treatment with calcium salts. Tetany may also occur in young growing cattle in the same circumstances.

Inappetence, stiffness, tendency of bones to fracture, disinclination to stand, difficult parturition, reduced milk flow, loss of condition, and reduced fertility are all non-specific signs recorded in adults.

**SPECIFIC SYNDROMES**

**Primary calcium deficiency**

No specific syndromes are recorded.

**Secondary calcium deficiency**

Rickets, osteomalacia, osteodystrophia fibrosa of the horse and pig and degenerative arthropathy of cattle are the common syndromes in which secondary calcium deficiency is one of the specific causative factors. In sheep, rickets is seldom recognized, but there are marked dental abnormalities. Rickets has been produced experimentally in lambs by feeding a diet low in calcium.

**CLINICAL PATHOLOGY**

Because of the effect of the other factors listed above on body constituents, examination of specimens from living animals may give little indication of the primary cause of the disturbance. For example, hypocalcemia need not indicate a low dietary intake of calcium. Data on serum calcium and phosphorus and plasma phosphatase levels, radiographical examination of bones and balance studies of calcium and phosphorus retention are all of value in determining the presence of osteodystrophic disease, but determination of the initial causative factor will still depend on analysis of feedstuffs and comparison with known standard requirements. The levels of serum calcium may be within the normal range in most cases. However, in spite of evidence to the contrary it seems that calcium deficiency is followed, at least in sheep, by a marked fall in serum calcium levels to as low as 3.5 mg/dL (0.87 mmol/L).

In an uncomplicated nutritional deficiency of calcium in sheep, there is only a slight reduction in the radiopacity of bone, in contrast to sheep with a low phosphorus and vitamin D status which show marked osteoporosis. The response to dietary supplementation with calcium is also of diagnostic value.

**NECROPSY FINDINGS**

True primary calcium deficiency is extremely rare but when it does occur, severe osteoporosis and parathyroid gland hypertrophy are the significant findings. The cortical bone is thinned and the metaphyseal trabeculae appear reduced in size and number. The ash content of the bone is low because the bone is resorbed before it is properly mineralized.

Calcium deficiency secondary to other nutritional factors is common and typically induces the form of osteodystrophy known as osteodystrophia fibrosa (see subsequent description). In most instances, the confirmation of a diagnosis of hypocalcinosis at necropsy includes an analysis of the diet for calcium, phosphorus, and vitamin D content.

**Samples for confirmation of diagnosis**

- **Toxicology** – long bone (ASSAY (ash)); feed (ASSAY (Ca) (P) (Vit D))
- **Histology** – formalin-fixed section of long bone (including metaphysis), parathyroid (LM).

**DIFFERENTIAL DIAGNOSIS**

A diagnosis of calcium deficiency depends upon proof that the diet is, either absolutely or relatively, insufficient in calcium, that the lesions and signs observed are characteristic and that the provision of calcium in the diet alleviates the condition. The diseases that may be confused with calcium deficiency are described under the diagnosis of each of the specific disease entities described below.

The close similarity between the dental defects in severe calcium deficiency of sheep and those occurring in chronic fluorosis may necessitate quantitative estimates of fluorine in the teeth or bone to determine the cause.

**TREATMENT**

The response to treatment is rapid and the preparations and doses recommended below are effective as treatment. Parenteral injections of calcium salts are advisable when tetany is present. When animals have been exposed to dietary depletion of calcium and phosphorus over a period of time, it is necessary to supplement the diet with calcium and phosphorus during dietary repletion.

**CONTROL**

The provision of adequate calcium in the diet, the reduction of phosphorus intake where it is excessive and the provision of adequate vitamin D are the essentials of both treatment and prevention. Some examples of estimated minimum daily requirements for calcium, phosphorus, and vitamin D are set out in Table 30.9. These are estimated minimum requirements and may need to be increased by a safety factor of 10% to allow for variation in individual animal requirements, the biological availability of nutrients in the feedstuffs and the effect which total amount of feed intake has on absolute intake of minerals. For example, the use of complete pig rations on a restricted basis may require that the concentration of both calcium and phosphorus be increased in order for that ration to deliver the actual total quantity of calcium and phosphorus necessary to meet a particular requirement for growth, pregnancy, or lactation. The information in Table 30.9 is presented merely as a guideline. When investigating a nutritional problem of formulating rations, it is recommended that the most recently available publications on the nutrient requirements of domestic animals be consulted.

Ground limestone is most commonly used to supplement the calcium in the ration, but should be prepared from calcite and not from dolomite. Variations in availability of the calcium in this product occur with variations in particle size, a finely ground preparation being superior in this respect. Bone meal and dicalcium phosphate are more expensive and the additional phosphorus may be a disadvantage if the calcium:phosphorus ratio is very wide. Alfalfa, clover, and molasses are also good sources of calcium but vary in their content. The optimum calcium:phosphorus ratio is within the range of 2:1 to 1:1. In cattle, absorption of both elements is better at the 2:1 ratio. For optimum protection against the development of urolithiasis in sheep a ratio of 2:2.5 calcium to 1 phosphorus is recommended.

The dustiness of powdered limestone can be overcome by dampening the feed or adding the powder mixed in molasses. Addition to salt or a mineral mixture is subject to the usual disadvantage that not all animals partake of it readily when it is provided free-choice, but this method of
supplementation is often necessary in pastured animals. High-producing dairy cows should receive the mineral mixture in their ration as well as having access to it in boxes or in blocks.

### REFERENCES

### PHOSPHORUS DEFICIENCY

Phosphorus deficiency is usually primary and is characterized by pica, poor growth, infertility and, in the later stages, osteodystrophy. Hypophosphatemia in dairy cattle is also associated with increased fragility of red blood cells and postparturient hemoglobinuria.

#### Etiology

Phosphorus deficiency is usually primary under field conditions but may be exacerbated by a deficiency of vitamin D and possibly by an excess of calcium.

#### Epidemiology

Geographical occurrence

In contrast to calcium deficiency, a dietary deficiency of phosphorus is widespread under natural conditions. It has a distinct geographical distribution depending largely upon the phosphorus content of the parent rock from which the soils of the area are derived, but also upon the influence of other factors, such as excessive calcium, aluminum, or iron, which reduce the availability of phosphorus to plants. Large areas of grazing land in many countries are of little value for livestock production without phosphorus supplementation. In New Zealand, for example, where fertilization of pasture with superphosphate has been practiced for many years, phosphorus deficiency may still occur in dairy herds because of inadequate maintenance of...
application over several years. There is evidence also that the quality of the superphosphate declined over a period of several years. Soil reserves of phosphorus may also be low because of high phosphate retention soils. Animals in affected areas mature slowly and are inefficient breeders and additional losses due to botulism and defects and injuries of bones may occur. Apart from areas in which frank phosphorus deficiency is seen, it is probable that in many other areas a mild degree of deficiency is a limiting factor in the production of meat, milk, and wool.

Heavy leaching by rain and constant removal by cropping contribute to phosphorus deficiency in the soil and the low phosphorus levels of the plant cover may be further diminished by drought conditions. Pastures deficient in phosphorus are classically also deficient in protein.

**Cattle**

The literature on phosphorus nutrition of grazing cattle has been reviewed. The degree of naturally occurring phosphorus deficiency in grazing cattle, the lack of uniformity in response to phosphorus supplementation and the suggested phosphorus requirements have resulted in considerable confusion in the United States and worldwide. Much of the confusion arises because animals have the ability to draw on skeletal phosphorus reserves when dietary phosphorus levels are inadequate. The mechanisms which control skeletal phosphorus withdrawal, the conditions which trigger withdrawal and the extent of withdrawal without affecting animal performance are not well understood.

The earliest report of naturally occurring phosphorus deficiency in grazing cattle was at Amaoedsvlakte in the Northern Cape of South Africa. The disease was called aphosphorosis and animals with the disease demonstrated a dehydrated appetite characterized by the desire to eat wood, bones, rocks, and other such materials. In severe deficiencies, cattle often died from botulism from eating bones from old carcasses contaminated with *Clostridium botulinum*. In advanced states of aphosphorosis, animals developed a stiffness in the forelegs referred to as 'stysiekte' in South Africa, 'creeps' in Texas and 'pegleg' in Australia.

A primary dietary deficiency of phosphorus in dairy cattle within the first several weeks of lactation can result in postpartum hemoglobinuria. In high-producing dairy cows, small restrictions in dietary phosphorus intake compared with National Research Council recommendations can result in acute recumbency in early lactation.

Under range conditions, milking cows are most commonly affected, but under intensive conditions, it is the dry and young stock receiving little supplementation which will be affected. The incidence of the disease varies; it is most common in animals at pasture during drought seasons but can also be a serious problem in housed cattle fed on hay only.

A survey of the mineral status of bones of cattle at abattoirs in western New South Wales, Australia, found evidence of osteodystrophy based on ash density. They represented cattle attempting to grow in a poor season, often female and in poor body fat condition and light in body weight and mostly from red soils known to be deficient in phosphorus.

The dietary requirements of phosphorus are given in Table 30.10. Cattle constantly grazing pasture in the southern hemisphere appear to require somewhat less phosphorus in their diet (0.20% is probably adequate) than do higher-producing, partly housed livestock. The dietary requirements of phosphorus recommended by the National Research Council for beef cows weighing 450 kg may exceed the basic requirements. Over a period of several gestations a daily allowance of 12 g of phosphorus/day/animal was adequate for beef cows. Cattle given a phosphorus-deficient diet did not develop detectable signs of phosphorus deficiency until they had been on a severely deficient diet for 6 months.

**Sheep and horses**

Sheep and horses at pasture are much less susceptible to the osteodystrophy of phosphorus deficiency than are cattle and their failure to thrive on phosphorus-deficient pasture is probably due in part to the low protein content of the pasture. In fact, there has been no clear demonstration of a naturally occurring phosphorus deficiency in sheep, nor is there any record of infertility in sheep caused by phosphorus deficiency. There is some limited evidence that the serum inorganic phosphorus levels in Thoroughbred racehorses may be related to certain feeding regimens and to racing performance. Horses fed cubed or pelleted dietary supplement have serum inorganic phosphate concentrations consistently below an accepted mean of 1.032 mmol/L. It is suggested that a rapid rate of passage of the ingesta may affect absorption of phosphorus. Other observations indicate that some of the best track performers had significantly lower inorganic serum phosphorus concentrations compared with some of the worst performers.

**Pigs**

A primary deficiency can occur in pigs kept in confinement and not provided with sufficient dietary phosphorus. Lactating sows are more commonly affected than growing pigs. In some situations, in the cereal grains, the phytate levels are high and phytase levels so low, rickets and osteomalacia are common in the pig population.

**Secondary phosphorus deficiency**

This is of minor importance compared with the primary condition. A deficiency of vitamin D is not necessary for the development of osteodystrophy, although with suboptimal phosphate intake deficiency of this vitamin becomes critical. Excessive intake of calcium does not result in secondary phosphorus deficiency, although it may cause a reduction in weight gains, due probably to interference with digestion and may contribute to the development of phosphorus deficiency when the intake is marginal. The presence of phytic acid in plant tissues, which renders phosphate unavailable to carnivora, is a major consideration in pigs but of only minor importance in herbivora, except that increasing intakes of calcium may reduce the availability of phytate phosphorus even for ruminants. Rock phosphates containing large amounts of iron and aluminum have been shown to be of no value to sheep as a source of phosphorus. A high intake of magnesium, such as that likely to occur when magnesium is fed to prevent lactation tetany, may cause hypophosphatemia if the phosphorus intake of dairy cows is already low.

All figures are on a dry matter (DM) basis and soil phosphate is citrate-soluble.
Hypophosphatemia has been induced in pigs by experimental supplementation of their diets with aluminum hydroxide. After 3 weeks, severe hypophosphatemia, intense hypercalcemia, decreased growth rate, and a lower concentration of bone phosphorus in cattle of all ages a reduction in bone strength necessary for normal activities, such as grazing. Bone phosphorus also functions as an important reservoir for resorption when body requirements temporarily exceed dietary intake. From 17 to 42% of bone could be resorbed in cattle and sheep in times of phosphorus deficiency.

Phosphorus is also essential for a broad range of enzymatic reactions, especially those concerned with energy metabolism and transfer. Phosphorus is also essential for the transfer of genetic information and is a vital component of various buffering systems. Phospholipids are necessary for maintenance of cell wall structure and integrity and as a integral components of myelin.

Rumen microbes have a phosphorus requirement apart from the animal's requirement which must be met for optimum rumen microbial activity to occur. Phosphorus is essential for the laying down of adequately mineralized bones and teeth and a deficiency will result in their abnormal development. Inorganic phosphate, which may be ingested as such, or liberated from esters during digestion or in intermediary metabolism, is utilized in the formation of proteins and tissue enzymes and is withdrawn from the plasma inorganic phosphate for this purpose.

Experimentally, female beef cattle fed diets containing <6 g of phosphorus/day developed an insidious and subtle complex syndrome characterized by weight loss, rough hair coat, abnormal stance, and lameness. Spontaneous fractures occurred in the vertebrae, pelvis, and ribs. Some affected bones were severely demineralized and the cortical surfaces were porous, chalky white, soft, and fragile. The osteoid tissue was not properly mineralized.

Experimental acute depletion of phosphorus in cattle results in a marked decline in serum inorganic phosphorus and affected animals display an avid appetite for old bones. The signs include:

- Failure to gain weight and maintain body condition
- Reduced bone weight
- Osteopenia radiographically
- Evidence of reduced bone formation.

Prolonged phosphorus deficiency was associated with increased plasma concentrations of total calcium and 1,25-dihydroxyvitamin D and reduced plasma concentrations of parathyroid hormone.

The pathophysiological effects of low dietary phosphorus in pigs have been examined. Determination of the serum concentrations of parathyroid hormone, 1,25-(OH)2 D and osteocalcin were monitored in Roman Landrace pigs originating from herds with dietary P deficiency. Serum P concentrations were negatively correlated with those of 1,25-(OH)2 D. In lactating animals and sucklings, the linear relationships were not present. Serum P concentrations positively correlated with those of PTH and 1,25-(OH)2 D concentrations were negatively correlated. The serum concentrations of 1,25-(OH)2 D and osteocalcin were positively correlated. Milk P concentrations ranging from 3.10 to 7.49 mmol/L were correlated positively with urinary P concentrations ranging from 0.26 to 11.37 mmol/L. In conclusion, similar to other species, P homeostasis is achieved in pigs by feedback mechanisms between P, PTH, and 1,25-(OH)2 D and osteocalcin production is induced by 1,25-(OH)2 D.

Inorganic phosphate also plays an important role in the intermediary metabolism of carbohydrate and of creatine in the chemical reactions occurring in muscle contraction. This may be of importance in those cows that are recumbent after calving and have hypophosphatemia. The loss of phosphorus in the phospholipids of milk due to the onset of profuse lactation may be the crucial factor in the development of postparturient hemoglobinuria. An increased susceptibility to bloat has been postulated as an effect of phosphorus deficiency.

**CLINICAL FINDINGS**

Primary phosphorus deficiency is common only in cattle. Young animals grow slowly and develop rickets. In adults there is an initial subclinical stage followed by osteomalacia. In cattle of all ages a reduction in voluntary intake of feed is a first effect of phosphorus deficiency and is the basis of most of the general systemic signs. Retarded growth, low milk yield, and reduced fertility are the earliest signs of phosphorus deficiency. For example, in severe phosphorus deficiency in range beef cattle, the calving percentage has been found to drop from 70 to 20%. Although it is claimed that relative infertility occurs in dairy heifers on daily intakes of less than 40 g of phosphate, the infertility being accompanied by anestrus, subestrus, and irregular estrus and delayed sexual maturity this has not been borne out by other experimental work, which indicates that fertility is independent of the calcium or phosphorus content or the calcium:phosphorus ratio of the diet in cattle. The effects of malnutrition on fertility are likely to be general and the infertility may often be related to lack of total energy intake rather than to specific deficiency. The development and wear of teeth are not greatly affected, in contrast with the severe dental abnormalities that occur in a nutritional deficiency of calcium. However, malocclusion may result from poor mineralization and resulting weakness of the mandible.

In the experimental production of phosphorus deficiency in beef cows, several months on a deficient diet are necessary before clinical signs develop. The clinical signs included general unthriftness, marked body weight loss, reduced feed consumption, reluctance to move, abnormal stance, bone fractures, and finally impaired reproduction. The detectable signs of phosphorus deficiency developed in the following sequence:

1. Loss of body weight and condition
2. Decreased whole blood phosphorus associated with increased whole blood calcium concentration
3. Allotriophagia
4. Abnormal stance, locomotion and recumbency.

In a severely deficient area, a characteristic conformation develops and introduced cattle revert to the district type in the next generation. The animals have a leggy appearance with a narrow chest and small girth, the pelvis is small, and the bones are fine and break easily. The chest is slabsided due to weakness of the ribs and the hair coat is rough and staring and lacking in pigment. In areas of severe deficiency, the mortality rate may be high due to starvation, especially during periods of drought when deficiencies of phosphorus, protein and vitamin A are exaggerated. Osteophagia is common and may be accompanied by a high incidence of botulism. Cows in late pregnancy often become recumbent and, although they continue to eat, are unable to rise. Such animals present a real problem in drought seasons because many animals in the area may be affected at the same time. Parenteral injections of phosphorus salts are ineffective and the only treatment that may be of benefit is to terminate the pregnancy by cesarean section.

Acute recumbency in high-producing dairy cows on a marginally phosphorus-deficient diet may become recumbent in early lactation. Affected animals are recumbent and cannot stand. They may be bright and alert and their vital signs are within normal range.
Although sheep and horses in phosphorus-deficient areas do not develop clinically apparent osteodystrophy they are often of poor stature and unthrifty and may develop perverted appetites. An association between low blood phosphorus and infertility in mares has been suggested but the evidence is not conclusive. The principal sign in affected sows is posterior paralysis.

**CLINICAL PATHOLOGY**

**Serum phosphorus**

Blood levels of phosphorus are not a good indicator of the phosphorus status of an animal because they can remain at normal levels for long periods after cattle have been exposed to a serious deficiency of the element. Serum inorganic phosphorus levels are affected by such factors as age of animal, milk yield, stage of pregnancy, season of year, breed, feeding patterns, and dietary phosphorus. The times of sampling in a herd must be standardized to reduce the effect of diurnal variation in serum concentrations of inorganic phosphorus. Attention is drawn to the need to use standard methods of collection because of the effect that technique can have on phosphorus levels in blood. In cattle, the recommended procedure is to collect blood from the coccygeal vein and preserve it in buffered trichloroacetic acid. Hair does not reflect the status either. However, a marked hypophosphatemia is a good indicator of a severe phosphorus deficiency. The mild-to-moderate deficiencies, which are the most common ones, are usually accompanied by normal blood levels of phosphorus. Generally, clinical signs occur when blood levels have fallen from the normal of 4.5–9 mg/dL (1.3–1.7 mmol/L) to 1.5–3.5 mg/dL (0.5–1.2 mmol/L) and a response to phosphate supplementation in body weight gain can be anticipated in cattle that have blood inorganic phosphorus levels of less than 4 mg/dL (1.3 mmol/L). Levels may fall as low as 1 mg/dL (0.3 mmol/L) or less in severe clinical cases. Serum levels of calcium are usually unaffected.

**Phosphorus content of diet**

Estimation of the mineral content in pasture and drinking water is a valuable aid in diagnosis, but has major difficulty in representing what the animal has actually been taking in. A technique has been devised for determining phosphorus intake of sheep by estimating the phosphorus content of feces. A pool of three pellets from each of 30 sheep is used as a sampling technique.

**Bone ash concentrations**

Determination of total bone ash concentrations and bone calcium and phosphorus concentrations from sample of rib can provide useful diagnostic information and comparison to normal values. There is usually a marked deterioration in the radiopacity of the bones. However, the bone content of phosphorus is still considered the most accurate indication of phosphorus status.

**NECROPSY FINDINGS**

The necropsy findings are those of the specific diseases, rickets and osteomalacia.

**DIFFERENTIAL DIAGNOSIS**

A diagnosis of phosphorus deficiency depends upon evidence that the diet is lacking in phosphorus and that the lesions and signs are typical of those caused by phosphorus deficiency and can be arrested or reverted by the administration of phosphorus. Differentiation from those diseases that may resemble rickets and osteomalacia is dealt with under those headings.

**TREATMENT**

The preparations and doses recommended under control can be satisfactorily used for the treatment of affected animals. In cases where the need for phosphorus is urgent, as in postparturient hemoglobinuria and in cases of parturient paresis complicated by hypophosphatemia, the intravenous administration of sodium acid phosphate (30 g in 300 mL distilled water) is recommended.

**CONTROL**

Phosphorus (P) deficiencies in grazing livestock can be prevented by direct treatment of the animal through supplementing the diet or the water supply, or indirectly by approximate fertilizer treatment of the soils. Hand-fed animals are supplemented with P in their diets.

**Phosphorus requirements**

Cattle

The phosphorus requirements for cattle in various stages of the production cycle have varied widely worldwide. Accurate P requirements must be established for all classes of cattle grazing under various conditions before producers can determine whether diets are adequate in P to meet animal needs or whether P supplements must be provided to optimize production. Apparent P requirements vary for a variety of reasons: differences among breeds of cattle, P availability in the feed, whether animals are pen fed or free grazing, possible interactions between nutrients, and the effects of disease and parasitism.

Dairy cattle

There is widespread belief among producers and consultants that reproductive performance in dairy cows can be improved by feeding phosphorus above recommended levels. The current NRC recommendations for early lactation (90 days in milk) diets are 0.36% P (DM basis) for cows milking 45 kg/d and 0.35% P for cows milking 35 kg/d. The NRC recommends up to 0.42% for the highest producing cows during the first few weeks of lactation.

Several studies indicate that dietary P at 0.38 to 0.40% is sufficient for high producing dairy cows. This concentration of P can be obtained with no supplementation or minimum supplementation of P, depending on feed ingredients. Dietary P at 0.31% can support high milk production but cannot sustain comparable high yield when cows proceed into late lactation. Cows conserve P when fed diets low in P by reducing P excretion in feces and urine. They may experience some negative balance in the first few weeks of lactation due to mobilization of P from bone, but this mobilized P can be restored in later lactation.

However, there has been a lack of information about the minimum intake level of P on which dairy cows can maintain health and milk production. In essence, the current requirements developed in various countries are mainly based on studies with non-lactating sheep and goats.

**Environmental implications of phosphorus feeding of livestock**

In the European Union and the USA, phosphorus (P) losses from dairy manure to the environment are becoming a more severe pollution problem. Ideally, P is recycled into the soil/plant/animal system from which only the P incorporated into the animal system escapes. In a sustainable dairy farming system, the amount of P expelled in the form of manure must be limited to that amount which crops need for maximum growth. However, due to high livestock intensities, overapplication of P from manure occurs, leading to P accumulation in the soil and finally leaching, thus causing eutrophication of lakes. Reducing P intake by dairy cows and thus also that excreted in the manure will contribute to reducing environmental pollution.

In Delaware County of New York, more P enters dairy farms than is exported in milk, meat, or crops sold, thus resulting in a net annual accumulation of P on the farm ranging from 19 to 41 kg/cow. Purchased feed is the single largest source of imported P on dairy farms, accounting for 65–85% of the 28–51 kg imported annually per cow for typical commercial dairy herds in New York. Similar amounts...
have been reported for dairy farms in the Netherlands. 

Dairy farms in the states of New York, Pennsylvania, Delaware, Maryland, and Virginia, fed P to lactating cows averaging 34% above the NRC recommendations. In 84% of the survey farms, ration formulation was provided by professionals rather than producers themselves. Most producers were feeding more P than cows needed because it was recommended by these consultants. Surveys in the USA show that dairy diets are formulated to contain approximately 0.45–0.50% P (DM basis), an amount that is about 20% in excess. This oversupplementation of P is costing the US dairy industry about US$100 million (in 1999). Most lactating dairy cow diets could have their P content reduced by 20%. This would result in a 25–30% reduction in P content of manure and a similar reduction in the amount of land required to accommodate the manure. Phosphorus is the most expensive nutrient in typical mineral-vitamin formulations for dairy cattle. Feeding a diet containing 0.45% P versus one containing 0.55% would save about $0.05/cow daily; for a 100 cows over 1 year, would save about $1825.00.

Three factors which lead to excessive feeding of P include the notion that increasing P intake would improve reproduction, the absence of lactation trials showing the absolute minimum of P required to support milk production and the aggressive marketing of P supplements.

Simulation models of the long-term effects of changes in feeding, cropping, and other production strategies on P loading and the economics of 100-cow and 800-cow dairy farms in south-eastern New York found that the most easily implemented change was to reduce the supplemented mineral P fed to that required to meet the current NRC recommended amounts, which would provide an annual increase in farm profit of about $22.00 per cow. Dairy farms in some areas can maintain a long-term P balance by feeding P according to the NRC requirements, a cropping strategy and land base use supplies all of the forage needed; all animals are fed a high forage diet; replacement heifers are produced on the farm.

The effects of feeding low amounts of phosphorus to high yielding dairy cows has been examined. Lactating dairy cows were fed diets containing 67, 80, and 100%, respectively, of the phosphorus requirements recommended by the Dutch Committee on Mineral Nutrition for a period of 21 months. Nearly 5 months after the beginning of the feeding trial, the milk yield and milk lactose content of the 67% group decreased significantly. After 2 years, on the 80% diet, postparturient hemoglobinuria occurred in one high producing cow. It was concluded that rations for high yielding dairy cows should not contain phosphorus content lower than 3.0 g/kg DM. The P supply with the 80% ration was considered to be just sufficient.

The supplementation of dietary P above levels recommended by the NRC (0.38% considered adequate or 0.48% excessive) did not improve duration or intensity of estrus in dairy cows under Wisconsin conditions. Large lactation studies have shown that feeding P in excess of 0.37% of diet DM, which corresponds closely to the NRC P requirement, did not affect milk production, milk composition, or animal health.

Digestion studies and P retention data also support the NRC recommendations. Biochemical markers of bone turnover in the dairy cow during lactation and the dry period are being used to measure bone formation and resorption during a complete lactation in dairy cattle.

Based on calculation of P losses and the true absorption coefficient using data on saliva production, saliva-P content, and the efficiency of P absorption under conditions in the Netherlands, the P requirement recommended for dairy cows: P requirement (g/d per 600 kg cow) = \(19 + 1.43 \times \text{kg milk. The recommendation is up to 22% lower than the current recommendation for high yielding dairy cows used in the UK.}

The overfeeding of P has important environmental implications. Phosphorus excretion increases linearly as P intake is increased above the requirement. Once P requirements are met, all of the excess dietary P is excreted in the feces. This excess P accumulates in the environment, primarily by the recycling of manure to land as fertilizer for crop production. The surface runoff of this excess P promotes the eutrophication of surface waters. (Eutrophication is the accidental or deliberate promotion of excessive growth of one kind of organism to the disadvantage of other organisms in the ecosystem.) Therefore, close monitoring of P inputs in the livestock industry is important to reduce the risk of eutrophication of lakes and streams. Reducing dietary intake closer to requirement will require frequent and accurate feed analysis, quantification of dry matter intake and ration management to ensure that formulated diets are mixed and delivered to the cows properly. Phosphorus reduction will be achieved by precision of feeding of dairy cattle. Portable and rapid tests are now available to determine the level of P in dairy cattle manure. These hand-held tools can yield real-time measurements of dissolved P and total P in manure.

As part of the US Environmental Protection Agency’s concentrated animal feeding operation (CAFO) final rule, all CAFOs will be required to develop and implement a nutrient management plan. The emphasis on better management of nutrients appropriately targets a critical environmental issue associated with animal production. The concentration of animals in livestock feeding operations, often separate from feed grain production, requires importing of substantial quantities of feed nutrients. Due to inefficiencies of nutrient utilization in livestock production, quantities of nitrogen and phosphorus in manure greater than can be utilized in local crop production often result. In a survey of 994 dairy farms in Pennsylvania, only 20% of the farms reported manure nutrient testing, compared with over 90% which did soil testing. Farm advisors and their services can be of vital importance in assisting producers make conscientious management decisions for enhanced nutrient utilization. Ration balancing involved the services of feed and mineral representatives on 85% of the farms, independent consultants on 12% and veterinarians only on 5% of farms. Nutrient management strategies and efforts must address the specific needs of farms with different animal densities and nutrient balances in order to be effective and applicable on the majority of farms.

Under field conditions, the difficulty usually encountered is that of providing phosphorus supplements to large groups of cattle grazing under extensive range conditions. The new recommendations for dairy cattle in 2001, are to provide phosphorus at 0.36–0.4% of dry matter intake. These are lower than the previous recommendation of 0.5% of dry matter intake.

Bone meal, dicalcium phosphate, disodium phosphate, and sodium pyrophosphate may be provided in supplementary feed or by allowing free access to their mixtures with salt or more complicated mineral mixtures. The availability of the phosphorus in feed supplements varies and this needs to be taken into consideration when compounding rations. The relative biological values for young pigs in terms of phosphorus are: dicalcium phosphate or rock phosphate 83%, steamed bone meal 56%, and colloidal clay or soft phosphate 34%. It is suggested that in deficient areas adult dry cattle and calves up to 150 kg BW should receive 225 g bone meal/week, growing stock over 150 kg BW 350 g/week, and lactating cows 1 kg weekly, but experience in particular areas may indicate the need.
for varying these amounts. The top-dressing of pasture with superphosphate is an adequate method of correcting the deficiency and has the advantage of increasing the bulk and protein yield of the pasture, but is often impractical under the conditions in which the disease occurs.

The addition of phosphate to drinking water is a much more satisfactory method provided the chemical can be added by an automatic dispenser to water piped into troughs. Adding chemicals to fixed tanks introduces errors in concentration, excessive stimulation of algal growth, and precipitation in hard waters. Monosodium dihydrogen phosphate (monosodium orthophosphate) is the favorite additive and is usually added at the rate of 10-20g/20L of water. Superphosphate may be used instead but is not suitable for dispensers, must be added in larger quantities (50 g/20 L) and may contain excess fluoride. A reasonably effective and practical method favored by Australian dairy farmers is the provision of a supplement referred to as ‘super juice’. Plain superphosphate at a rate of 2.5 kg in 40 L of water is mixed and stirred vigorously in a barrel. When it has settled for a day the ‘super juice’ is ready for use and is administered by skimming off the supernatant and sprinkling 100-200 mL on the feed of each cow.

Beef cattle
The literature on the phosphorus nutrition of grazing beef cattle in the USA and other parts of the world has been reviewed. There has been a notable lack of research into the P requirements of grazing beef cattle of various age groups, under varying soil and forage conditions which has created considerable confusion and disagreement about the P requirements. The effects of P fertilizer on forage P levels and seasonal changes in P concentration are well understood, but the availability of P in different forage species, at different stages of maturity and grown under different management schemes and environmental conditions is not well understood.

Feedlot Cattle
The phosphorus requirement of finishing feedlot calves is 0.16% of diet dry matter (DM) or 14.2 g/d. Typical grain-based feedlot cattle diets do not require supplementation of inorganic mineral P to meet P requirements. Plasma P, performance and bone characteristics indicate that P requirements are less than the predicted requirements and should be modified. Supplementation of mineral P in finishing diets is an unnecessary economic and environmental cost for beef feedlot producers and should continue.

Pigs
The estimated dietary requirements for phosphorus for maximum growth and feed efficiency of pigs at 3–5, 5–10, 10–20, 20–50, 50–80, and 80–120kg, as a percentage of diet (90% DM) are 0.70, 0.65, 0.60, 0.55, 0.45, and 0.40%, respectively. The form in which phosphorus exists in natural feedstuffs influences the efficiency of its utilization. In cereal grains, grain by-products, and oilseed meals, about 60–75% of the phosphorus is organically bound in the form of phytate which is poorly available to the pig. The biological availability of P in cereal grains is variable ranging from less than 15% in corn to approximately 50% in wheat which has naturally occurring phytase enzyme. The phosphorus in inorganic phosphorus supplements also varies in bioavailability: The P in ammonia, calcium, and sodium phosphates is highly available.

Toxicity of supplements
The use of phosphate supplements in the diet is not without hazards. Phosphoric acid is directly toxic and should not be used and monosodium phosphate is unpalatable to many animals; the depression of appetite that results may discount the improved feed utilization it provides. Superphosphate used as fertilizer can cause toxicosis in ruminants.

Clinical signs in sheep include teeth grinding, diarrhea, nervous system depression, apparent blindness, stiffness, and ataxia and high fatality rate.

VITAMIN D DEFICIENCY
Vitamin D deficiency is usually caused by insufficient solar irradiation of animals or their feed and is manifested by poor appetite and growth and in advanced cases by osteodystrophy.

Synopsis
Etiology Lack of ultraviolet solar irradiation and/or deficiency of preformed vitamin D in diet.
Epidemiology Uncommon because diets are supplemented. Occurs in animals in countries with relative lack of UV irradiation especially in winter months; animals raised indoors for long periods. May occur in young grazing animals in winter months. May be antivitamin D factor.
Signs Reduced productivity; poor weight gain; reduced reproductive performance. Rickets in young; osteomalacia in adults.
Clinical pathology Serum calcium and phosphorus. Plasma vitamin D.
ETIOLOGY

A lack of ultraviolet solar irradiation of the skin, coupled with a deficiency of preformed vitamin D complex in the diet, leads to a deficiency of vitamin D in tissues.

EPIDEMIOLOGY

Although the effects of clinically apparent vitamin D deficiency have been largely eliminated by improved nutrition, the subclinical effects have received little attention. For example, retarded growth in young sheep in New Zealand and southern Australia during winter months has been recognized for many years as responding to vitamin D administration.

However, general realization of the importance of this subclinical vitamin D deficiency in limiting productivity of livestock has come only in recent years. This is partly due to the complexity of the relations between calcium, phosphorus, and the vitamin and their common association with protein and other deficiencies in the diet. Much work remains to be done before these individual dietary essentials can be assessed in their correct economic perspective.

Ultraviolet irradiation

The lack of ultraviolet irradiation becomes important as distance from the equator increases and the sun’s rays are filtered and refracted by an increasing depth of the earth’s atmosphere. Cloudy, overcast skies, smoke-laden atmospheres, and winter months exacerbate the lack of irradiation. The effects of poor irradiation are felt first by animals with dark skin (particularly pigs and some breeds of cattle) or heavy coats (particularly sheep), by rapidly growing animals and by those that are housed indoors for long periods.

The concentration of plasma vitamin D3 recorded in grazing sheep varies widely throughout the year. During the winter months in the UK, the levels in sheep fall below what is considered optimal, while in the summer months the levels are more than adequate.

There is a marked difference in vitamin D status between sheep with a long fleece and those that have been recently shorn, especially in periods of maximum sunlight. The higher blood levels of vitamin D in the latter group are probably due to their greater exposure to sunlight. Pigs reared under intensive farming conditions and animals being prepared for shows are small but important susceptible groups.

Dietary vitamin D

The importance of dietary sources of preformed vitamin D must not be underestimated. Irradiated plant sterols with anti-rachitic potency occur in the dead leaves of growing plants. Variation in the vitamin D content of hay can occur with different methods of curing. Exposure to irradiation by sunlight for long periods causes a marked increase in anti-rachitic potency of the cut fodder, whereas modern hay-making technique with its emphasis on rapid curing tends to keep vitamin D levels at a minimum. Grass ensilage also contains very little vitamin D.

Based on a survey of the concentrations of vitamin D in the serum of horses in the UK, the levels may be low.

In the absence of a dietary supplement containing vitamin D, the concentration of 25-OH D3 and 25-OH D2 are, respectively, a reflection of the absorption of vitamin D2 from the diet and of biosynthesis of vitamin D3.

Information on the vitamin D requirements of housed dairy cattle is incomplete and contradictory. It appears, however, that in some instances natural feedstuffs provide less than adequate amounts of the vitamin for optimum reproductive performance in high-producing cows.

Grazing animals

The grazing of animals, especially in winter time, on lush green feed including cereal crops, leads to a high incidence of rickets in the young. An antivitamin D factor is suspected because calcium, phosphorus and vitamin D intakes are usually normal, but the condition can be prevented by the administration of calciferol. Carotene, which is present in large quantities in this type of feed, has been shown to have antivitamin D potency but the existence of a further rachitogenic substance seems probable. The rachitogenic potency of this green feed varies widely according to the stage of growth and virtually disappears when flowering commences. Experimental overdosing with vitamin A causes a marked retardation of bone growth in calves. Such overdosing can occur when diets are supplemented with the vitamin and may produce clinical effects.

The importance of vitamin D to animals is now well-recognized and supplementation of the diet where necessary is usually performed by the livestock owner. Occasional outbreaks of vitamin D deficiency are experienced in intensive systems where animals are housed and in areas where specific local problems are encountered, e.g. rickets in sheep on green cereal pasture in New Zealand.

PATHOGENESIS

Vitamin D is a complex of substances with anti-rachitogenic activity. The important components are as follows:

Vitamin D3 (cholecalciferol) is produced from its precursor 7-dehydrocholesterol in mammalian skin and by natural irradiation with ultraviolet light.

Vitamin D2 is present in sun-cured hay and is produced by ultraviolet irradiation of plant sterols. Calciferol or viosterol is produced commercially by the irradiation of yeast. Ergosterol is the provitamin.

Vitamin D4 and D5 occur naturally in the oils of some fish.

Vitamin D produced in the skin or ingested with the diet and absorbed by the small intestine is transported to the liver. In the liver, 25-hydroxycholecalciferol is produced, which is then transported to the kidney where at least two additional derivatives are formed by 1α-hydroxylase.

One is 1,25-dihydroxycholecalciferol (DHCC) and the other is 24,25-DHCC. Under conditions of calcium need or calcium deprivation the form predominantly produced by the kidney is 1,25-DHCC. At present, it seems likely that 1,25-DHCC is the metabolic form of vitamin D most active in eliciting intestinal calcium transport and absorption and is at least the closest known metabolite to the form of vitamin D functioning in bone mineralization. The metabolite also functions in regulating the absorption and metabolism of the phosphate ion and especially its loss from the kidney. A deficiency of the metabolite may occur in animals with renal disease, resulting in decreased absorption of calcium and phosphorus, decreased mineralization of bone, and excessive losses of the minerals through the kidney. A deficiency of vitamin D per se is governed in its importance by the calcium and phosphorus status of the animal.

Because of the necessity for the conversion of vitamin D to the active metabolites, there is a lag period of 2–4 days following the administration of the vitamin parenterally before a significant effect on calcium and phosphorus absorption can occur. The use of synthetic analogs of the active metabolites such as 1α-hydroxycholecalciferol (an analog of 1,25-DHCC) can increase the plasma concentration of calcium and phosphorus within 12 h following administration and has been recommended for the control of parturient paresis in cattle.
Maternal status
Maternal vitamin D status is important in determining neonatal plasma calcium concentration. There is a significant correlation between maternal and neonatal calf plasma concentrations of 25-OH D$_2$, 25-OH D$_3$, 24,25-(OH)$_2$D$_2$, 24,25-(OH)$_2$D$_3$, and 25,26-(OH)$_3$D$_3$. This indicates that the vitamin D metabolite status of the neonate is primarily dependent on the 25-OH D status of the dam. The maternal serum concentrations of calcium, phosphorus, and magnesium do not determine concentrations of these minerals found in the newborn calf. The ability of the placenta to maintain elevated plasma calcium or phosphorus in the fetus is partially dependent on maternal 1,25-(OH)$_2$D$_2$ status. Parenteral cholecalciferol treatment of sows before parturition is an effective method of supplementing neonatal piglets with cholecalciferol via the sow’s milk and its metabolite via placenta transport.

Calcium:phosphorus ratio
When the calcium:phosphorus ratio is wider than the optimum (1:1 to 2:1), vitamin D requirements for good calcium and phosphorus retention and bone mineralization are increased. A minor degree of vitamin D deficiency in an environment supplying an imbalance of calcium and phosphorus might well lead to disease, whereas the same degree of vitamin deficiency with a normal calcium and phosphorus intake could go unsuspected. For example, in growing pigs, vitamin D supplementation is not essential provided calcium and phosphorus intakes are rigidly controlled, but under practical circumstances, this may not be possible.

The minor functions of the vitamin include maintenance of efficiency of food utilization and a calorigenic action, the metabolic rate being depressed when the vitamin is deficient. These actions are probably the basis for the reduced growth rate and productivity in vitamin D deficiency. Some evidence suggests that vitamin D may have a role in the immune system. Local production of 1,25-(OH)$_2$D$_2$ by monocytes may be important in the immune function, particularly in the parturient dairy cow.

CLINICAL FINDINGS
The most important effect of lack of vitamin D in farm animals is reduced productivity. A decrease in appetite and efficiency of food utilization cause poor weight gains in growing stock and poor productivity in adults. Reproductive efficiency is also reduced and the overall effect on the animal economy may be severe.

In the late stages lameness, which is most noticeable in the forelegs, is accompanied in young animals by bending of the long bones and enlargement of the joints. This latter stage of clinical rickets may occur simultaneously with cases of osteomalacia in adults. An adequate intake of vitamin D appears to be necessary for the maintenance of fertility in cattle, particularly if the phosphorus intake is low. In one study in dairy cattle, the first ovulation after parturition was advanced significantly in vitamin D-supplemented cows.

CONTROL Supplementation
The administration of supplementary vitamin D to animals by adding it to the diet or by injection is necessary only when exposure to sunlight or the provision of a natural ration containing adequate amounts of vitamin D is impractical.

A total daily intake of 7–12 IU/kg BW is optimal. Sun-dried hay is a good source, but green fodders are generally deficient in vitamin D. Fish liver oils are high in vitamin D, but are subject to deterioration on storage, particularly with regard to vitamin A. They have the added disadvantage of losing their vitamin A and D content in premixed feed, of destroying vitamin E in these feeds when they become rancid and of seriously reducing the butterfat content of milk. Stable water-soluble vitamin A and D preparations do not suffer from these disadvantages. Irradiated dry yeast is probably a simpler and cheaper method of supplying vitamin D in mixed grain feeds.

Stable water-soluble preparations of vitamin D are now available and are commonly added to the rations of animals being fed concentrate rations. The classes of livestock that usually need dietary supplementation include:

Calves raised indoors on milk replacers
Pigs raised indoors on grain rations
Beef cattle receiving poor quality roughage during the winter months
Cattle raised indoors for prolonged periods and not receiving sun-cured forage containing adequate levels of vitamin D. These include calves raised as herd replacements, yearling cattle fed concentrate rations, bulls in artificial insemination centers and purebred bulls maintained indoors on farms
Feedlot lambs fed grain rations during the winter months or under totally covered confinement
Young growing horses raised indoors or outdoors on rations that may not contain adequate concentrations of calcium and phosphorus. This may be a problem in rapidly growing, well-muscled horses receiving a high level of grain.

Because there is limited storage of vitamin D in the body, compared to the storage of vitamin A, it is recommended that daily dietary supplementation be provided when possible for optimum effect.

In situations where dietary supplementation is not possible, the use of single IM injections of vitamin D$_2$ (calciferol) in oil will protect ruminants for 3–6 months.
dose of 11,000 units/kg BW is recommended and should maintain an adequate vitamin D status for 3–6 months.

In mature non-pregnant sheep weighing about 50 kg, a single IM injection of 6000 IU/kg body weight produced concentrations of 25-hydroxyvitamin D₃ at adequate levels for 3 months. The parenteral administration of vitamin D₃ results in both higher tissue and plasma levels of vitamin D₃ than does oral administration and IV administration produces higher plasma levels than does the IM injection. The timing of the injection should be selected so that the vitamin D status of the ewe is adequate at the time of lambing. The vitamin D₃ status of lambs can be increased by the parenteral administration of the vitamin to the pregnant ewe.

Dosing pregnant ewes with 30,000 IU of vitamin D₃ in a rapidly available form, approximately 2 months before lambing, provides a safe means of increasing the vitamin D status of the ewe and the newborn lambs by preventing seasonally low concentrations of 25-hydroxyvitamin D₃. In adult sheep there is a wide margin of safety between the recommended requirement and the toxic oral dose, which provides ample scope for safe supplementation if such is desirable. In adult sheep given 20 times the recommended requirements for 16 weeks there was no evidence of pathological calcification. Oral dosing with 30–45 units/kg BW is adequate, provided treatment can be given daily. Massive oral doses can also be used to give long-term effects, e.g. a single dose of 2 million units is an effective preventive in cattle receiving a single dose of 11,000 units/kg BW is recommended and should maintain an adequate vitamin D status for 3–6 months. In mature non-pregnant sheep weighing about 50 kg, a single IM injection of 6000 IU/kg body weight produced concentrations of 25-hydroxyvitamin D₃ at adequate levels for 3 months. The parenteral administration of vitamin D₃ results in both higher tissue and plasma levels of vitamin D₃ than does oral administration and IV administration produces higher plasma levels than does the IM injection. The timing of the injection should be selected so that the vitamin D status of the ewe is adequate at the time of lambing. The vitamin D₃ status of lambs can be increased by the parenteral administration of excessive quantities of the vitamin.

In cattle, large parenteral doses of vitamin D₃ 15–17 million IU, results in prolonged hypercalcemia, hyperphosphatemia and large increases in plasma concentrations of vitamin D₃ and its metabolites. Clinical signs of toxicity occur within 2–3 weeks and include marked anorexia, loss of body weight, dyspnea, tachycardia, loud heart sounds, weakness, recumbency, torticollis, fever and a high case fatality rate. Pregnant cows 1 month before parturition are more susceptible than non-pregnant cows.

In pigs, severe toxicity in pigs occurs at a daily oral dose of 50,000–70,000 IU/kg BW. Signs include a sudden onset of anorexia, vomiting, diarrhea, dyspnea, apathy, aphonia, emaciation, and death. Clinical signs are commonly observed within 2 days after consumption of the feed containing excessive vitamin D₃. At necropsy, hemorrhagic gastritis and mild interstitial pneumonia are commonly present. Arteriosclerosis with calcification of the heart base vessels may also be visible macroscopically in poisoned cattle. Osteoporosis with multiple fractures has been observed in subacute to chronic hypervitaminosis D in pigs. Histologically, there is widespread soft tissue mineralization, with a predilection for the lung and gastric mucosa, as well as elastin-rich tissue, such as blood vessels. Changes in bone vary with the duration of exposure to toxic levels of the vitamin.

Assay of the various metabolites of vitamin D in tissues is difficult. The diagnosis is therefore usually confirmed by correlating microscopic changes with a history of exposure to toxic levels of vitamin D.

**Samples for confirmation of diagnosis**
- **Toxicology** – 500 g of suspect feed (ASSAY (Vit D))
- **Histology** – formalin-fixed lung, stomach/abomasum, proximal aorta, lung, bone (LM)

**REFERENCES**

**RICKETS**
Rickets is a disease of young, growing animals characterized by defective calcification of growing bone. The essential lesion is a failure of provisional calcification with persistence of hypertrophic cartilage and enlargement of the epiphyses of long bones and the costochondral junctions (so-called 'rachitic rosary'). The poorly mineralized bones are subject to pressure distortions.

**Synopsis**

**Etiology**
Deficiencies of any or combination of calcium, phosphorus, and vitamin D.

**Epidemiology**
Young growing animals. No longer common. In calves on phosphorus-deficient diets (range or housed). In grazing lambs due to lack of solar irradiation. Rare in foals and pigs.

**Signs**
Stiff gait and lameness, enlargement of ends of long bones, curvature of long bones, prolonged periods of recumbency. Delayed dentition.

**Clinical pathology**
Elevated alkaline phosphatase, low serum calcium and phosphorus. Lack of density of bone radiographically.

**Necropsy findings**
Abnormal bones and teeth. Bone shafts are soft, epiphyses enlarged. Ratio of bone ash to organic matter is decreased.

**Diagnostic confirmation**
Histology of bone, especially epiphyses.

**Differential diagnosis list**
- Epiphysitis
- Congenital and acquired abnormalities
- Infectious synovitis.

**Treatment**
Vitamin D injections, calcium and phosphate orally.

**Control**
Supplement deficient diets with calcium, phosphorus, and vitamin D.
ETIOLOGY
Rickets is caused by an absolute or relative deficiency of any or a combination of calcium, phosphorus, or vitamin D in young, growing animals. The effects of the deficiency are also exacerbated by a rapid growth rate.

An inherited form of rickets has been described in pigs. It is indistinguishable from rickets caused by nutritional inadequacy.

EPIDEMIOLOGY
Clinical rickets is not as important economically as the subclinical stages of the various dietary deficiencies that produce it. The provision of diets adequate and properly balanced with respect to calcium, phosphorus and sufficient exposure to sunlight, are mandatory in good livestock production. Rickets is no longer a common disease because these requirements are widely recognized, but the incidence can be high in extreme environments, including purely exploitative range grazing, intensive feeding in fattening units and heavy dependence on lush grazing, especially in winter months.

Rickets is a disease of young, rapidly growing animals and occurs naturally under the following conditions.

Calves
Primary phosphorus deficiency in phosphorus-deficient range areas and vitamin D deficiency in calves housed for long periods are the common circumstances. Vitamin D deficiency is the most common form of rickets in cattle raised indoors for prolonged periods in Europe and North America. Grazing animals may also develop vitamin D deficiency rickets at latitudes where solar irradiation during winter is insufficient to promote adequate dermal photobiosynthesis of vitamin D₃ from 7-dihydrocholesterol. Rickets has occurred in yearling steers in New Zealand wintered on swede (Brassica napus) crop deficient in phosphorus.¹

In young, rapidly growing cattle raised intensively indoors a combined deficiency of calcium, phosphorus and vitamin D can result in leg weakness characterized by stiffness, reluctance to move, and retarded growth. In some cases, rupture of the Achilles tendon and spontaneous fracture occur.² The Achilles tendon may rupture at the insertion of, or proximal to, the calcaneus.

Lambs
Lambs are less susceptible to primary phosphorus deficiency than cattle, but rickets does occur under the same conditions. Green cereal grazing and, to a lesser extent, pasturing on lush ryegrass during winter months may cause a high incidence of rickets in lambs; this is considered to be a secondary vitamin D deficiency. An outbreak of vitamin D deficiency rickets involving 50% of lambs aged 6-12 months grazing new grass and rape occurred during the early winter months in Scotland.³ In the South Island of New Zealand, where winter levels of solar irradiation are low, rickets occurs in hoggets grazing green oats, or other green crops, which have been shown to contain high levels of rachitogenic carotenoids.⁴ A vitamin D responsive rickets has occurred in twin lambs 3-4 weeks of age.⁴

Pigs
Rickets in young pigs occurs in intensive fattening units where the effects of diet containing excessive phosphate (high cereal diets) are exacerbated by vitamin D and calcium deficiencies.

Foals
Rickets is uncommon in foals under natural conditions, although it has been produced experimentally.

PATHOGENESIS
Dietary deficiencies of calcium, phosphorus, and vitamin D result in defective mineralization of the osteoid and cartilaginous matrix of developing bone. There is persistence and continued growth of hypertrophic epiphyseal cartilage, increasing the width of the epiphyseal plate. Poorly calcified spicules of diaphyseal bone and epiphyseal cartilage yield to normal stresses, resulting in bowing of long bones and broadening of the epiphyses with apparent enlargement of the joints. Rapidly growing animals on an otherwise good diet will be first affected because of their higher requirement of the specific nutrients.

CLINICAL FINDINGS
The subclinical effects of the particular deficiency disease will be apparent in the group of animals affected and have been described in the earlier general section. Clinical rickets is characterized by:

- Stiffness in the gait
- Enlargement of the limb joints, especially in the forelegs
- Enlargement of the costochondral junctions
- Long bones show abnormal curvature, usually forward and outward at the carpus in sheep and cattle
- Lameness and a tendency to lie down for long periods.

Eruption of the teeth is delayed and irregular, and the teeth are poorly calcified with pitting, grooving, and pigmentation. They are often badly aligned and wear rapidly and unevenly. These dental abnormalities, together with thickening and softness of the jaw bones, may make it impossible for severely affected calves and lambs to close their mouths. As a consequence, the tongue protrudes and there is drooling of saliva and difficulty in feeding. In less severely affected animals, dental malocclusion may be a significant occurrence. Severe deformity of the chest may result in dyspnea and chronic ruminal tympany. In the final stages, the animal shows hypersensitvity, tetany, recumbency and eventually dies of inanition.

CLINICAL PATHOLOGY
The plasma alkaline phosphatase is commonly elevated, but serum calcium and phosphorus levels depend upon the causative factor. If phosphorus or vitamin D deficiencies are the cause, the serum phosphorus level will usually be below the normal lower limit of 3 mg/dL. The serum concentrations of 25-hydroxyvitamin D₃ and 25-hydroxyvitamin D₂ are markedly decreased in vitamin D-deficient rickets compared with the normal values of >5 ng/mL.³ Serum vitamin D concentrations as low as 0.4 ng/mL have been reported in lambs with vitamin D responsive rickets.⁴ Serum calcium levels will be low only in the final stages. In leg weakness of young, rapidly growing cattle, the serum concentration of 25-hydroxyvitamin D may be non-detectable and the serum levels of calcium and inorganic phosphorus may be low.⁵

Radiographic examination of bones and joints is one of the most valuable aids in the detection of rickets. Rachitic bones have a characteristic lack of density compared with normal bones. The ends of long bones have a 'woolly' or 'moth-eaten' appearance and have a concave or flat, instead of the normal convex, contour. Surgical removal of a small piece of costochondral junction for histological examination has been used extensively in experimental work and should be applicable in field diagnosis.

NECROPSY FINDINGS
Apart from general poorness of condition, the necropsy findings are restricted to abnormal bones and teeth. The bone shafts are softer and larger in diameter, due in part to the subperiosteal deposition of osteoid tissue. The joints are enlarged and on cutting, the epiphyseal cartilage can be seen to be thicker than usual. Histological examination of the epiphysis is desirable for final diagnosis. In sheep, the best results are obtained...
from an examination of the distal cartilages of the metacarpal and metatarsal bones. A valuable diagnostic aid is the ratio of ash to organic matter in the bones. Normally the ratio is three parts of ash to two of organic matter but in rachitic bone this may be depressed to 1.2, or 1.3 in extreme cases. A reduction below 45% of the bone weight as ash also suggests osteodystrophy. Because of the difficulty encountered in repeating the results of bone ash determinations, a standardized method has been devised in which the ash content of green bone is determined, using either the metacarpus or metatarsus and the ash content related to the age of the animal, as expressed by the length of the bone. Although normal standards are available only for pigs, the method suggests itself as being highly suitable for all species.

**Samples for confirmation of diagnosis**

- **Toxicology** – long bone (ASSAY (ash)); 500 g feed (ASSAY (Ca) (P) (Vit D))
- **Histology** – formalin-fixed long bone (including growth plate) (LM).

**Differential diagnosis**

Rickets occurs in young, rapidly growing animals and is characterized by stiffness of the gait and enlargement of the distal physes of the radius, tibia, third metacarpal and metatarsal bones and the proximal extremity of the proximal phalanx. There may or may not be deviation of the limbs caused by uneven growth rates in various growth plates. The suggested causes include improper nutrition, faulty conformation and hoof growth, muscle imbalance, overweight and compression of the growth plate. Recovery may occur spontaneously or require surgical correction.

**Rickets in pigs** is uncommon and the diagnosis may be difficult. The disease is usually suspected in young, rapidly growing pigs in which there is stiffness in the gait, walking on tiptoes, enlargements of the distal ends of long bones, and dietary evidence of a marginal deficiency of calcium or phosphorus. The radiographic and pathological findings may suggest a rickets-like lesion.

**Myosplasmal synovitis and arthritis** clinically resembles rickets of pigs. There is a sudden onset of stiffness of gait, habitual recumbency, a decrease in feed consumption, and enlargements of the distal aspects of the long bones which may or may not be painful, spontaneous recovery usually occurs in 10–14 days. The locomotor problems in young, growing pigs raised in confinement and with limited exercise must be considered in the differential diagnosis. In performance testing stations, up to 20% of boars may be affected with leg weakness. Rickets in lambs must be differentiated from chlamydial and erysipelis arthritus, which are readily diagnosed at necropsy.

**OSTEOMALACIA**

Osteomalacia is a disease of mature animals affecting bones in which endochondral ossification has been completed. The characteristic lesion is osteoporosis and the formation of excessive uncalcified matrix. Lameness and pathological fractures are the common clinical findings.

**Synopsis**

**Etiology** Absolute or relative deficiency of any one or combination of calcium, phosphorus, and vitamin D in adult animals.

**Epidemiology** Primarily in cattle and sheep on phosphorus-deficient diets. In feedlot animals due to excessive phosphorus without complementary calcium and vitamin D.

**Signs** Reduced productivity, lack of playing or eating, standing lameness, and growth retardation.

**Clinical pathology** Increased alkaline phosphatase, decreased serum phosphorus levels. Increased density of long bones radiographically.

**Necropsy findings** Decreased density of bones, erosions of articular cartilages.

**Diagnostic confirmation** Histology of bones.

**Differential diagnosis list**
- Chronic fluorosis
- Myosplasmal synovitis and arthritis
- Spinal cord compression

**Treatment** As for calcium, phosphorus, and vitamin D deficiency.

**Control** Adequate supplementation of diet.

**ETIOLOGY**

In general, the etiology and occurrence of osteomalacia are the same as for rickets except that the predisposing cause is not the increased requirement of growth but the drain of lactation and pregnancy.

**EPIDEMIOLOGY**

Osteomalacia occurs in mature animals under the same conditions and in the same areas as rickets in young animals, but is recorded less commonly. Its main occurrence is in cattle in areas seriously deficient in phosphorus. It is also recorded in sheep, again in association with hypophosphatemia. In pastured animals, osteomalacia is most common in cattle, and sheep raised in the same area are less severely affected. In feedlot animals, excessive phosphorus intake without complementary calcium and vitamin D is likely as a cause, especially if the animals are kept indoors. It also occurs in sows that have recently weaned their pigs after a long lactation period (6–8 weeks) while on a diet deficient usually in calcium. A marginal deficiency of both phosphorus and vitamin D will exaggerate the condition. Intensively-fed yearling cattle with inadequate mineral supplementation...
may be affected with spontaneous fractures of the vertebral bodies, pelvic bones and long bones, leading to recumbency. Simply handling the animals through a chute for routine activities such as tuberculin testing may precipitate the fractures

**PATHOGENESIS**

Increased resorption of bone mineral to supply the needs of pregnancy, lactation and endogenous metabolism leads to osteoporosis, and weakness and deformity of the bones. Large amounts of uncalcified osteoid are deposited about the diaphyses. Pathological fractures are commonly precipitated by sudden exercise or handling of the animal during transportation.

**CLINICAL FINDINGS**

**Ruminants**

In the early stages, the signs are those of phosphorus deficiency, including lowered productivity and fertility and loss of condition. Licking and chewing of inanimate objects begins at this stage and may bring their attendant ills of oral, pharyngeal, and esophageal obstruction, traumatic rickets, and botulism.

The signs specific to osteomalacia are those of a painful condition of the bones and joints and include a stiff gait, moderate lameness often shifting from leg to leg, cracking sounds while walking, and an arched back. The hindlegs are most severely affected and the hocks may be rotated inwards. The animals are disinclined to move, lie down for long periods and are unwilling to get up. The colloquial names ‘pegleg’, ‘creeps’, ‘stiffs’, ‘cripples’, and ‘bog-lame’ describe the syndrome aptly. The names ‘milkeg’ and ‘milck-lameness’ are commonly applied to the condition when it occurs in heavily milking cows. Fractures of bones and separation of tendon attachments occur frequently, often without apparent precipitating stress. In extreme cases, deformities of bones occur and when the pelvis is affected dystocia may result. Finally, weakness leads to permanent recumbency and death from starvation.

**Pigs**

Affected sows are usually found recumbent and unable to rise from lateral recumbency or from the dog-sitting position. The shaft of one femur or the neck of the femur is commonly fractured. The fracture usually occurs within a few days following weaning of the pigs. The placing of the sow with other adult pigs usually results in some fighting and increased exercise, which commonly precipitates the pathological fractures.

**CLINICAL PATHOLOGY**

In general, the findings are the same as those for rickets, including increased serum alkaline phosphatase and decreased serum phosphorus levels. Radiographic examination of long bones shows decreased density of bone shadow.

**NECROPSY FINDINGS**

It can be difficult to discern any gross changes as the epiphyses are seldom enlarged and the altered character of cancellous bone may not be macroscopically visible. Cortical bone may be somewhat thinned and erosions of the articular cartilages have been recorded in cattle suffering from primary phosphorus deficiency. The parathyroid glands may be enlarged. Histologically, abnormal osteoid covers trabeculae and a degree of fibrous tissue proliferation is often evident. Analysis reveals the bones to be lighter than normal with a low ratio of ash to organic matter.

**SAMPLES FOR CONFIRMATION OF DIAGNOSIS**

**Toxicology** – long bone (ASSAY (ash); 500 g feed (ASSAY (Ca)) (P) (Vit D)).

**Histology** – formalin-fixed bone, parathyroid (LM).

**DIFFERENTIAL DIAGNOSIS**

The occurrence of non-specific lameness with pathological fractures in mature animals should arouse suspicion of osteomalacia. There may be additional evidence of subnormal productivity and reproductive performance and dietary evidence of a recent deficiency of calcium, phosphorus, or vitamin D.

A similar osteoporotic disease of cattle in Japan has been ascribed to a dietary deficiency of magnesium. The cattle are on high-concentrate, low-roughage diets, have high serum calcium and alkaline phosphatase levels, but a low serum magnesium level. The osteoporosis is observable at slaughter and clinical signs observed are those of intercurrent disease, especially ketosis, milk fever, and hypomagnesemia. Reproductive and renal disorders occur concurrently.

In cattle it must be differentiated from chronic fluorosis in mature animals, but the typical mottling and pitting of the teeth and the enlargements on the shafts of the long bones are characteristic. In some areas, e.g. northern Australia where the water supply is obtained from deep sub-artesian wells, the two diseases may occur concurrently. Analysis of water supplies and foodstuffs for fluorine may be necessary in doubtful cases.

In sows, osteomalacia with or without pathological fractures must be differentiated from spinal cord compression due to a vertebral body abscess and chronic arthritis due to erysipelas.

**TREATMENT AND CONTROL**

Recommendations for the treatment and control of the specific nutritional deficiencies have been described under their respective headings. Some weeks will elapse before improvement occurs and deformities of the bones are likely to be permanent.

**REFERENCE**

**OSTEODYSTROPHIA FIBROSA**

Osteodystrophia fibrosa is similar in its pathogenesis to osteomalacia, but differs in that soft, cellular, fibrous tissue is laid down as a result of the weakness of the bones instead of the specialized uncalcified osteoid tissue of osteomalacia. It occurs in horses, goats, and pigs.

**ETIOLOGY**

A secondary calcium deficiency due to excessive phosphorus feeding is the common cause in horses and probably also in pigs. The disease can be readily produced in horses on diets with a ratio of calcium:phosphorus of 1.2:9 or greater, irrespective of the total calcium intake. Calcium:phosphorus ratios of 1.0:9 to 1.4 have been shown to be preventive and curative. With a very low calcium intake of 2–3 g/d and a calcium:phosphorus ratio of 1:13 the disease may occur within 5 months. With a normal calcium intake of 26 g/d and a calcium:phosphorus ratio of 1:5, obvious signs appear in about 1 year, but shifting lameness may appear as early as 3 months. The disease is reproducible in pigs on similar diets to those described above and also on diets low in both calcium and phosphorus. The optimum calcium:phosphorus ratio is 1:2.1 and the intake for pigs should be within the range of 0.6–1.2% of the diet.

**EPIDEMIOLOGY**

Osteodystrophia fibrosa is principally a disease of horses and other Equidae and to a lesser extent of pigs. It has also occurred in goats. Among horses, those engaged in heavy city work and in racing are more likely to be affected because of the tendency to maintain these animals on unbalanced diets. The major occurrence is in horses fed a diet high in phosphorus and low in calcium. Such diets include cereal hays combined with heavy grain or bran feeding. Legume hays, because of their high calcium content, are preventive.

The disease may reach endemic proportions in army horses moved into new territories, whereas local horses, more used to the diet, suffer little. Although horses may be affected at any age after weaning it is the 2–7 year age group that suffer most, probably because they are the group most likely to be...
exposed to the rations that predispose to the disease.

A novel occurrence has been recorded of an endemic form of the disease affecting large numbers of horses at pasture. The dietary intake of calcium and phosphorus and their proportions, were normal. The occurrence was thought to be due to the continuous ingestion of oxalate in specific grasses. *Cenchrus ciliaris*, *Panicum maximum* var. *trichoglume*, Setaria aneup, *Bucharia mutica* and *Pennisetum clandestinum*.

**PATHOGENESIS**
Defective mineralization of bones follows the imbalance of calcium and phosphorus in the diet and a fibrous dysplasia occurs. This may be in response to the weakness of the bones or it may be more precisely a response to hyperparathyroidism stimulated by the excessive intake of phosphorus. The weakness of the bones predisposes to fractures and separation of muscular and tendinous attachments. Articular erosions occur commonly and displacement of the bone marrow may cause the development of anemia.

**CLINICAL FINDINGS**

**Horse**
As in most osteodystrophies, the major losses are probably in the early stages before clinical signs appear or on diets where the aberration is marginal. In horses, a shifting lameness is characteristic of this stage of the disease and arching of the back may sometimes occur. The horse is lame, but only mildly so and in many cases, no physical deformity can be found by which the seat of lameness can be localized. Such horses often creak badly in the joints when they walk. These signs probably result from relaxation of tendon and ligaments and appear in different limbs at different times. Articular erosions may contribute to the lameness. In more advanced cases severe injuries, including fracture and visible sprains of tendons, may occur but these are not specific to osteodystrophia fibrosa, although their incidence is higher in affected than in normal horses. Fracture of the lumbar vertebrae while racing has been known to occur in affected horses.

The more classical picture of the disease has largely disappeared because cases are seldom permitted to progress to this advanced stage. Local swelling of the lower and alveolar margins of the mandible is followed by soft, symmetrical enlargement of the facial bones, which may become swollen so that they interfere with respiration. Initially these bony swellings are firm and pyramidal and commence just above and anterior to the facial crests. The lesions are bilaterally symmetrical. Flattening of the ribs may be apparent and fractures and detachment of ligaments occur if the horse is worked. There may be obvious swelling of joints and curvature of long bones. Severe emaciation and anemia occur in the final stages.

**Pigs**
In pigs, the lesions and signs are similar to those in the horse and in severe cases, pigs may be unable to rise and walk, show gross distortion of limbs and enlargement of joints and the face. In less severe cases, there is lameness, reluctance to rise, pain on standing and bending of the limb bones, but normal facial bones and joints. With suitable treatment, the lameness disappears, but affected pigs may never attain their full size. The relationship of this disease to atrophic rhinitis is discussed under the latter heading.

**Goats**
An outbreak of the disease has been recorded in goats receiving a diet of wheat straw (60%) and 40% barley for 89 months. The ratio of calcium to phosphorus in the diet was 1.1.8. Affected goats were 9–10 months of age with a history of stunted growth, lameness, diarrhea, and tongue protrusion. Clinically there was symmetrical enlargement of the face and jaws, tongue protrusion, prominent eyeballs, and tremor. The enlarged bones were firm and painful on palpation. The hindlimbs were bent outwards symmetrically from the tarsal joints.

**CLINICAL PATHOLOGY**
There are no significant changes in blood chemistry in affected horses. However, a high incidence of lameness was recorded in goats receiving a diet of wheat straw (60%) and 40% barley for 89 months. The serum calcium level will tend to be lower than normal, the serum inorganic phosphorus higher than normal, and the alkaline phosphatase activity higher than normal. The levels of diagnostic alkaline phosphatase have not been determined. Affected horses may be unable to return their serum calcium levels to normal following the infusion of a calcium salt. Radiographic examination reveals increased translucency of bones.

**NECROPSY FINDINGS**
The entire skeleton is abnormal in this severe form of metabolic bone disease, but the change is most notable in the mandibular, maxillary, and nasal bones, which may appear thickened and distorted. The fleshy tissue that replaces normal cancellous bone in these sites is also present in the metaphyses of the long bones. Microscopically, there is proliferation of fibrous tissue and markedly increased osteoclast activity along thinned and abnormally oriented bony trabeculae. The parathyroid glands are enlarged. It must be remembered that osteodystrophia fibrosa is a lesion, not a disease. The pathway to this lesion usually involves a dietary imbalance in calcium and phosphorus, but the kidneys should also be examined to rule out the possibility of renal secondary hyperparathyroidism.

**Samples for confirmation of diagnosis**
- Toxicology – bone (ASSAY (ash)), 500 g feed (ASSAY (Ca) (P) (Vit D))

**Differential Diagnosis**
In the early stages, the diagnosis may be difficult because of the common occurrence of traumatic injuries to horses' legs. A high incidence of lameness in a group of horses warrants examination of the ration and determination of their calcium and phosphorus status. An identical clinical picture has been described in a mare with an adenoma of the parathyroid gland. In pigs, osteodystrophia fibrosa has been described in the case of hypovitaminosis A and experimentally as a result of manganese deficiency.

**TREATMENT AND CONTROL**
A ration adequately balanced with regard to calcium and phosphorus (calcium:phosphorus should be in the vicinity of 1:1 and not wider than 1:1.4) is preventive in horses and affected animals can only be treated by correcting the existing imbalance. Even severe lesions may disappear in time with proper treatment. Cereal hay may be supplemented with alfalfa or clover hay, or finely ground limestone (30 g daily) should be fed. Dicalcium phosphate or bone meal are not as efficient because of their additional content of phosphorus.

**REFERENCES**

**'BOWIE' OR 'BENTLEG'**
This is a disease of lambs of unknown etiology. There is a characteristic lateral curvature of the long bones of the front legs, but the lesions differ from those of rickets. It has been observed only on unimproved range pasture in New Zealand. The cause is unknown, although phosphorus deficiency has been suggested. Improvement of the pasture by top-dressing with superphosphate and sowin-injured grasses is usually followed by disappearance of the disease. Only suckling lambs are affected and cases occur only in the spring at a time when rickets does not occur. Up to 40% of a group of lambs may be affected without breed differences in incidence.
similar syndrome has been produced by the feeding of wild parsnip (Trachemene glaucifolia) and, experimentally, by the feeding of a diet low in both calcium and phosphorus.

The disease has also been reported from South Africa where it occurs primarily in ram lambs and develops from as early as 3 months up to 1 year of age.1 There is gradual bending of the forelimbs with hooves turned inwards and the carpal joints turned outwards. Animals of the South African Mutton Merino breed had significantly higher plasma phosphorus concentrations than those of the Merino and Dohne Merino breeds. The plasma calcium:phosphorus ratio was lower in affected lambs and their ewes and this converse ratio is thought to result in an induced plasma ionized calcium deficiency leading to improper calcification of bone.

Some tenderness of the feet and lateral curvature at the knees may be seen as early as 2-3 weeks of age and marked deformity is present at 6-8 weeks with maximum severity at weaning. The forelimbs are more commonly affected than the hindlimbs. Medial curvature occurs in rare cases. The sides of the feet become badly worn and the lateral aspects of the lower parts of the limbs may be injured and be accompanied by lameness. The lambs grow well at first, but by the time of weaning, affected lambs are in poor condition because of their inability to move about and feed properly. A rather similar syndrome has been observed in young Saanen bucks, but the condition showed a tendency to recover spontaneously.

At necropsy, in spite of the curvature of the limbs, there is no undue porosity and although the epiphyseal cartilages are thickened, they are supported by dense bone. There may be excessive synovial fluid in the joints and, in the later stages, there are articular erosions. Increased deposition of osteoid is not observed.

Supplementation of the diet with phosphorus or improvement of the pasture seems to reduce the incidence of the disease. Dosing with vitamin D or providing mineral mixtures containing all trace elements is ineffective.2

DEGENERATIVE JOINT DISEASE

Degenerative arthropathy occurs in cattle of all breeds, but reaches its highest incidence as a sporadic disease of young beef bulls. The disease has been identified as hip dysplasia because of the pre-existing shallow contour of the acetabulum. It is considered to be inherited as a recessive characteristic and exacerbated by rapid weight gain in young animals. The occurrence of the condition in these animals is usually associated with rearing on nurse cows, housing for long periods, provision of a ration high in cereal grains and byproducts (i.e. a high phosphorus:calcium ratio), and possibly with an inherited straight conformation of the hindlegs. Although the disease occurs in all beef breeds, there is a strong familial tendency which appears to be directly related to the rate of body weight gain and the straightness of the hindleg. If the potential for rapid weight gain is being realized in animals being force fed, the rate of occurrence appears to be dependent on their breeding and animals in the same herd that are allowed to run at pasture under natural conditions are either not affected or are affected at a much later age. Thus, animals in a susceptible herd may show signs as early as 6 months of age if they are heavily hand-fed and raised on dairy cow foster mothers. In the same herd, signs do not appear until 1-2 years of age if supplementary feeding is not introduced until weaning and not until 4 years if there is no significant additional feeding.

Clinically there is a gradual onset of lameness in one or both hindlegs. The disease progresses with the lameness becoming more severe over a period of 6-12 months. In some animals, there is a marked sudden change for the worse, usually related to violent muscular movements, as in breeding or fighting. In severely affected animals, the affected limb is virtually useless and, on movement, distinct crepitus can often be felt and heard over the affected joints. This can be accomplished by rocking the animal from side to side or having it walk while holding the hands over the hip joints.

An additional method of examination is to place the hand in the rectum close to the hip joint, while the animal is moved. Passive movement of the limb may also elicit crepitus, or louder clinking or clicking sounds. The hip joints are always most severely affected, but in advanced cases, there may be moderate involvement of the stifles and minimal lesions in other joints. Affected animals lie down most of the time and are reluctant to rise and to walk. The joints are not swollen, but in advanced cases, local atrophy of muscles may be so marked that the joints appear to be enlarged. There is a recorded occurrence in which the lesions were confined mainly to the front fetlocks.

Radiographic examination may provide confirmatory or diagnostic evidence.

At necropsy, the most obvious finding is extensive erosion of the articular surfaces, often penetrating to the cancellous bone and disappearance of the normal contours of the head of the femur or the epiphyses in the stifle joint. The synovial cavity is distended, with an increased volume of brownish, turbid fluid; the joint capsule is much thickened and often contains calcified plaques. Multiple, small exostoses are present on the periarticular surfaces. When the stifle is involved the cartilaginous menisci, particularly the medial one, are very much reduced in size and may be completely absent. In cattle with severe degenerative changes in the coxofemoral joint, an acetalabular osseous bulia may be present at the cranial margin of the obturator foramen.3

Degenerative joint disease of cattle is recorded on an endemic scale in Chile and is thought to be due to gross nutritional deficiency. The hip and tarsal joints are the only ones affected and clinical signs appear when animals are 8-12 months old. There is gross lameness and progressive emaciation. An inherited osteoarthritus is described under that heading. Sporadic cases of degenerative arthropathy, with similar signs and lesions, occur in heavy-producing, aged dairy cows and are thought to be caused by long-continued negative calcium balance. Rare cases also occur in aged beef cows but are thought to be associated with an inherited predisposition. In both instances the lesions are commonly restricted to the stifle joints.

REFERENCE
offspring of deficient dams. Vitamin A may also provide a protective effect against various infectious diseases and enhance many facets of the immune system.

Animals at pasture receive adequate supplies of the vitamin, except during prolonged droughts, but animals confined indoors and fed prepared diets may be deficient if not adequately supplemented. For example, a diet of dried sugar beet pulp, concentrates and poor quality hay can result in hypovitaminosis-A in confined beef cattle.

Ruminants on pasture
Primary vitamin A deficiency occurs in beef cattle and sheep on dry range pasture during periods of drought. Clinical vitamin A deficiency does not always occur under these conditions because hepatic storage is usually good and the period of deprivation not sufficiently long for these stores to reach a critically low level. Young sheep grazing natural, drought-stricken pasture can suffer serious depletion of reserves of the vitamin in 5–8 months, but normal growth is maintained for 1 year at which time clinical signs develop. Adult sheep may be on a deficient diet for 18 months before hepatic stores are depleted and the disease becomes evident. Cattle may subsist on naturally deficient diets for 5–18 months before clinical signs appear. However, during the annual dry season (October–June), herds of cattle, sheep and goats in the Sahelian region of West Africa are managed on dry grasses and shrubby lignaceous plants, which fail to provide maintenance levels of crude protein and vitamin A. These substandard conditions result in vitamin A deficiency characterized by night blindness, xerophthalminia, retarded growth rates, reproductive failures, and increased mortality. The pastoral herders associate the cure of night blindness with the consumption of green vegetation and will purposefully herd livestock into green vegetation areas when available. Certain ethnic groups of pastoral herders depend on ruminant milk as their principal source of vitamin A and night blindness in lactating and pregnant women as well as in young children appears after the onset of night blindness in their cattle and sheep during the latter half of the dry season. Therefore, increasing vitamin A levels in the milk of cows may alleviate the clinical signs of vitamin A deficiency in herder families.

Primary vitamin A deficiency is still relatively common in beef cattle that depend on pasture and roughage for the major portion of their diet. Beef calves coming off dry summer pastures at 6–8 months of age are commonly marginally deficient.

Maternal deficiency
A maternal deficiency of vitamin A can result in herd outbreaks of congenital hypovitaminosis-A in calves. In one such occurrence, out of 240 heifers fed a vitamin A-deficient ration, 89 calves were born dead; 47 were born alive but blind and weak and died within 1–3 days after birth. Blindness with dilated pupils, nystagmus, weakness, and incoordination were characteristic. In another occurrence in the UK, 25% of the calves born from maternally vitamin A deficient heifer dams had ocular abnormalities.

The status of the dam is reflected in that of the fetus only in certain circumstances, in that carotene, as it occurs in green feed, does not pass the placental barrier and a high intake of green pasture before parturition does not increase the hepatic stores of vitamin A in newborn calves, lambs, or kids and only to a limited extent in pigs. However, vitamin A in the alcohol form, as it occurs in fish oils, will pass the placental barrier in cows. Antepartum feeding of carotene and the alcohol form of the vitamin does, however, cause an increase in the vitamin A content of the colostrum. Young animals depend on the dam’s colostrum for their early requirements of the vitamin which is always highest in colostrum and returns to normal levels within a few days of parturition. Pigs weaned very early at 2–4 weeks may require special supplementation. Pregnant beef cows wintered on poor quality roughage commonly need supplementation with vitamin A throughout the winter months to insure normal development of the fetus and an adequate supply of the vitamin in the colostrum at parturition.

Adequacy of supplements
The addition of vitamin A supplements to diets may not always be sufficient to prevent deficiency. Carotene and vitamin A are readily oxidized, particularly in the presence of unsaturated fatty acids. Oil preparations are thus less satisfactory than dry or aqueous preparations, particularly if the feed is to be stored for any length of time. Pelleting of feed may also cause a serious loss up to 32% of the vitamin A in the original feedstuff.

Heat, light, and mineral mixes are known to increase the rate of destruction of vitamin A supplements in commercial rations. In one study, 47–92% of the vitamin A in several mineral supplements was destroyed after 1 week of exposure to the trace minerals, high relative humidity, sunlight and warm temperatures.

Feedlot cattle
The disease still occurs in feedlot cattle in some parts of North America when feedlot cattle are fed rations low in

ETIOLOGY
Vitamin A deficiency may be primary disease, due to an absolute deficiency of vitamin A or its precursor carotene in the diet, or a secondary disease in which the dietary supply of the vitamin or its precursor is adequate, but their digestion, absorption, or metabolism is interfered with to produce a deficiency at the tissue level.

EPIDEMIOLOGY
Primary vitamin A deficiency
Primary vitamin A deficiency is of major economic importance in groups of young growing animals on pasture or fed diets deficient in the vitamin or its precursors. In the UK, primary vitamin A deficiency occurs in housed cattle fed a ration containing little or no green forage.
carotene or vitamin A over a period of several months. The onset of clinical signs in growing feedlot cattle is typically seen 6–12 months after feeding a diet deficient in carotene or vitamin A. Small farm feedlots may feed their cattle a cereal grain such as barley and barley straw with no vitamin supplementation or inadequate supplementation. Grains, with exception of yellow corn, contain negligible amounts of carotene and cereals hay is often a poor source. Any hay cut late, leached by rain, bleached by sun, or stored for long periods loses much of its carotene content. The carotene content of yellow corn also deteriorates markedly with long storage. Moreover, under conditions not yet completely understood, the conversion by ruminants of carotene present in feeds such as silage may be much less complete than was formerly thought.

In feedlot cattle, the disease is most common in steers fed the same ration as heifers which may remain clinically normal. It is suggested that sexual dimorphism may be due to the production of vitamin A by the corpus luteum of heifers.

Pigs
Young pigs on a deficient diet may show signs after several months, but as in other animals, the length of time required before signs appear is governed to a large extent by the status before depletion commences. As a general rule it can be anticipated that signs will appear in pigs fed deficient rations for 4–5 months, variations from these periods probably being due to variations in the vitamin A status of the animal when the deficient diet is introduced. Congenital defects occur in litters from deficient sows, but the incidence is higher in gilts with the onset of clinical signs after several months, but as in other species, there is a sensitivity indicator than ocular changes because of interference with regeneration of visual purple.

Secondary vitamin A deficiency
Secondary vitamin A deficiency may occur in cases of chronic disease of the liver or intestines because much of the conversion of carotene to vitamin A occurs in the intestinal epithelium and the liver is the main site of storage of the vitamin. Highly chlorinated naphthalenes interfere with the conversion of carotene to vitamin A and animals poisoned with these substances have a very low vitamin A status. The intake of inorganic phosphorus also affects vitamin A storage, low phosphate diets facilitating storage of the vitamin. This may have a sparing effect on vitamin A requirements during drought periods when phosphorus intake is low and an exacerbating effect in stall-fed cattle on a good grain diet. However, phosphorus deficiency may lower the efficiency of carotene conversion. Vitamins C and E help to prevent loss of vitamin A in feedstuffs and during digestion. Additional factors which may increase the requirement of vitamin A include high environmental temperatures, a high nitrate content of the feed, which reduces the conversion of carotene to vitamin A and rapid rate of gain. Both a low vitamin A status of the animal and high levels of carotene intake may decrease the biopotency of ingested carotene.

The continued ingestion of mineral oil, which may occur when the oil is used as a preventive against bloat in cattle, may cause a depression of plasma carotene and vitamin A esters and the carotene levels in serum fat. Deleterious effects on the cattle are unlikely under the conditions in which it is ordinarily used because of the short period for which the oil is administered and the high intake of vitamin A and carotene.

PATHOGENESIS
Vitamin A is essential for the regeneration of the visual purple necessary for dim-light vision, for normal bone growth and for maintenance of normal epithelial tissues. Deprivation of the vitamin produces effects largely attributable to disturbance of these functions. The same tissues are affected in all species. However, there is a difference in tissue and organ response in the different species and particular clinical signs may occur at different stages of development of the disease. The major pathophysiological effects of vitamin A deficiency are as follows.

Night vision
Ability to see in dim light is reduced because of interference with regeneration of visual purple.

Cerebrospinal fluid pressure
An increase in CSF pressure is one of the first abnormalities to occur in hypovitaminosis-A in calves. It is a more sensitive indicator than ocular changes and, in the calf, it occurs when the vitamin A intake is about twice that needed to prevent night blindness. The increase in CSF pressure is due to impaired absorption of the CSF due to reduced tissue permeability of the arachnoid villi and thickening of the connective tissue matrix of the cerebral dura mater. The increased CSF pressure is responsible for the syncope and convulsions, which occur in calves in the early stages of vitamin A deficiency. The syncope and convulsions may occur spontaneously or be precipitated by excitement and exercise. It is suggested that the CSF pressure is increased in calves with subclinical deficiency and that exercise further increases the CSF pressure to convulsive levels.

Bone growth
Vitamin A is necessary to maintain normal position and activity of osteoblasts and osteoclasts. When deficiency occurs there is no retardation of endochondral bone growth, but there is incoordination of bone growth in that shaping, especially the finer molding of bones, does not proceed normally. In most locations this has little effect but may cause serious damage to the nervous system. Overcrowding of the cranial cavity occurs with resulting distortion and herniations of the brain and an increase in CSF pressure up to four to six times normal. The characteristic nervous signs of vitamin A deficiency, including papilledema, incoordination and syncope, follow. Compression, twisting and lengthening of cranial nerves and herniations of the cerebellum into the foramen magnum, causing weakness and ataxia and of the spinal cord into intervertebral foraminae results in damage to nerve roots and localizing signs referable to individual peripheral nerves. Facial paralysis and blindness due to constriction of the optic nerve, are typical examples of this latter phenomenon. The effect of excess vitamin A on bone development by its interference with vitamin D has been discussed elsewhere. Dwarfism in a group of pigs in a swine herd was suspected to be due to vitamin toxicity.

Epithelial tissues
Vitamin A deficiency leads to atrophy of all epithelial cells, but the important effects are limited to those types of epithelial tissue with a secretory as well as a covering function. The secretory cells are without power to divide and develop from undifferentiated basal epithelium. In vitamin A deficiency these secretory cells are gradually replaced by the stratified, keratinizing epithelial cells common to non-secretory epithelial tissues. This replacement of secretory epithelium by keratinized epithelium occurs chiefly in the salivary glands, the urogenital tract (including placenta but not ovaries or renal tubules) and the paracoelar glands and teeth (disappearance of odontoblasts from the enamel organ). The secretion of thyroxine is markedly reduced. The mucosa of the stomach is not markedly affected. These changes in epithelium
lead to the clinical signs of placental degeneration, xerophthalmia and corneal changes.

Experimental vitamin A deficiency in lambs results in changes in the epithelium of the small intestine characterized by vesicular microvillar degeneration and disruption of the capillary endothelium. Diarrhea did not occur.

Embryological development
Vitamin A is essential for organ formation during growth of the fetus. Multiple congenital defects occur in pigs and rats and congenital hydrocephalus in rabbits on maternal diets deficient in vitamin A. In pigs, administration of the vitamin to depleted sows before the 17th day of gestation prevented the development of eye lesions but administration on the 18th day failed to do so. A maternal deficiency of vitamin A in cattle can result in congenital hypovitaminosis-A in the calves, characterized by blindness with dilated pupils, nystagmus, weakness, and incoordination. Constriction of the optic canal with thickening of the dura mater results in ischemic necrosis of the optic nerve and optic disc edema resulting in blindness. Retinal dysplasia also occurs. Thickening of the occipital and sphenoid bones and doming of the frontal and parietal bones with compression of the brain also occur. Dilated lateral ventricles may be present and associated with increased CSF pressure.

Immune mechanisms
The effects of vitamin A and β-carotene on host defense mechanisms have been uncertain and controversial for many years. Some workers claim that the incidence and severity of bacterial, viral, rickettsial and parasitic infections are higher in vitamin A-deficient animals. It is possible that vitamin A and β-carotene afford protection against infections by influencing both specific and non-specific host defense mechanisms. The protective effect of vitamin A may be mediated by enhanced polymorphonuclear neutrophil function but this effect is also influenced by the physiological status of the animal such as lactation status in dairy cattle. Experimentally, a severe vitamin A deficiency in lambs is associated with alterations in immune function, but the exact mechanism is unknown.

CLINICAL FINDINGS
In general, similar syndromes occur in all species, but because of species differences in tissue and organ response, some variations are observed. The major clinical findings are set out below.

Night blindness
Inability to see in dim light (twilight or moonlit night) is the earliest sign in all species, except in the pig in which it is not evident until plasma vitamin A levels are very low. This is an important diagnostic sign.

Xerophthalmia
True xerophthalmia, with thickening and clouding of the cornea, occurs only in the calf. In other species a thin, serous mucoid discharge from the eyes occurs, followed by corneal keratinization, clouding and sometimes ulceration, and photophobia.

Changes in the skin
A rough, dry coat with a shaggy appearance and splitting of the bristle tips in pigs is characteristic, but excessive keratinization, such as occurs in cattle poisoned with chlorinated naphthalenes, does not occur under natural conditions of vitamin A deficiency. Heavy deposits of bran-like scales on the skin are seen in affected cattle. Dry, scaly hooves with multiple, vertical cracks are another manifestation of skin changes and are particularly noticeable in horses. A seborrheic dermatitis may also be observed in deficient pigs but is not specific to vitamin A deficiency.

Body weight
Under natural conditions, a simple deficiency of vitamin A is unlikely to occur and the emaciation commonly attributed to vitamin A deficiency may be largely due to multiple deficiencies of protein and energy. Although inappetence, weakness, stunted growth and emaciation occur under experimental conditions of severe deficiency, in field outbreaks severe clinical signs of vitamin A deficiency are often seen in animals in good condition. Experimentally, sheep maintain their body weight under extreme deficiency conditions and with very low plasma vitamin A levels.

Reproductive efficiency
Loss of reproductive function is one of the major causes of loss in vitamin A deficiency. Both the male and female are affected. In the male, libido is retained but degeneration of the seminiferous tubules causes reduction in the number of motile, normal spermatozoa produced. In young rams, the testicles may be visibly smaller than normal. In the female, conception is usually not interfered with, but placental degeneration leads to abortion and the birth of dead or weak young. Placental retention is common.

Nervous system
Signs related to damage of the nervous system include:

- Paralysis of skeletal muscles due to damage of peripheral nerve roots
- Encephalopathy due to increased intracranial pressure
- Blindness due to constriction of the optic nerve canal.

These defects occur at any age but most commonly in young, growing animals and they have been observed in all species except horses.

Paralysis
The paralytic form is manifested by abnormalities of gait due to weakness and incoordination. The hindlegs are usually affected first and the forelegs later. In pigs, there may be stiffness of the legs, initially with a stilted gait or flaccidity, knuckling of the fetlocks and sagging of the hindquarters. Complete limb paralysis occurs terminally.

Convulsions
Encephalopathy, associated with an increase in CSF pressure, is manifested by convulsions, which are common in beef calves at 6–8 months, usually following removal from a dry summer pasture at weaning time. Spontaneously, or following exercise or handling, affected calves will collapse (syncope) and during lateral recumbency a clonic-tonic convolution will occur, lasting for 10–30 s. Death may occur during the convolution or the animal will survive the convolution and lie quietly for several minutes, as if paralyzed, before another convolution may occur. Affected calves are usually not blind and the menace reflex may be slightly impaired or hyperactive. Some calves are hyperesthetic to touch and sound. During the convolution there is usually ventroflexion of the head and neck, sometimes opisthotonos and, commonly, tetanic closure of the eyelids and retraction of the eyeballs. Outbreaks of this form of hypovitaminosis-A in calves have occurred and the case fatality rate may reach 25%. The prognosis is usually excellent; treatment will effect a cure in 48 h but convulsions may continue for up to 48 h following treatment.

Seizures and acute deaths attributable to hypovitaminosis-A and hypovitaminosis-D have occurred in feeder pigs fed ground red wheat and whole milk and housed in a barn with no exposure to sunlight. Lethargy, inappetence, diarrhea, and vomiting and progression to convulsions were characteristic.

Blindness
The ocular form of hypovitaminosis-A occurs usually in yearling cattle (12–18 months old) and up to 2–3 years of age. These animals have usually been on marginally deficient rations for several months. Night blindness may or may not have been noticed by the owner. The cattle have usually been fed and housed for long periods in familiar surroundings and the clinical signs of night blindness may have been subtle and not noticeable.
The first sign of the ocular form of the disease is blindness in both eyes during daylight. Both pupils are widely dilated and fixed and will not respond to light. Optic disc edema may be prominent and there may be some loss of the usual brilliant color of the tapetum. Varying degrees of peripapillary retinal detachment, papillary and peripapillary retinal hemorrhages, and disruption of the retinal pigment epithelium may also be present. The menace reflex is usually totally absent, but the palpebral and corneal reflexes are present. The animal is aware of its surroundings and usually eats and drinks, unless placed in unfamiliar surroundings. The CSF pressure is increased in these animals, but not as high as in the calves described earlier. Convulsions may occur in these cattle if forced to walk, or if loaded onto a vehicle for transportation. The prognosis for the ocular form with blindness is unfavorable and treatment is ineffective because of the degeneration of the optic nerves. Exophthalmos and excessive lacrimation are present in some cases.

**Congenital defects**

These have been observed in piglets and calves. In calves, the defects are limited to congenital blindness due to optic nerve constriction and encephalopathy. In piglets, complete absence of the eyes (anophthalmos), or small eyes (microphthalmos), incomplete closure of the fetal optic fissure, degenerative changes in the lens and retina, and an abnormal proliferation of mesenchymal tissue in front of and behind the lens are some of the defects encountered. Ocular abnormalities in newborn calves from maternally vitamin A deficient heifers included corneal dermoid, microphthalmos, aphakia (absence of lens) and in some cases, both eyes covered by hairless skin.

Other congenital defects attributed to vitamin A deficiency in pigs include cleft palate and harelip, accessory ears, malformed hindlegs, subcutaneous cysts, abnormally situated kidneys, cardiac defects, diaphragmatic hernia, aplasia of the genitalia, internal hydrocephalus, herniations of the spinal cord, and generalized edema. Affected pigs may be stillborn, or weak and unable to stand, or may be quite active. Weak pigs lie on their sides, make slow paddling movements with their legs, and squawk plaintively.

**Other diseases**

Increased susceptibility to infection is often stated to result from vitamin A deficiency. The efficacy of colostrum as a preventive against diarrhea in calves was originally attributed to its vitamin A content, but the high antibody content of colostrum is most important. Anasarca. Edema of the limbs and brisket have been associated with vitamin A deficiency in feedlot cattle, especially steers. The pathogenesis is not understood. The edema can be extensive, include all four limbs, ventral body wall and extending to the scrotum. Heifers were unaffected.

**CLINICAL PATHOLOGY**

**Plasma vitamin A**

Vitamin A levels in the plasma are used extensively in diagnostic and experimental work. Plasma levels of 20 μg/dL are the minimal concentration for vitamin A adequacy. Papilledema is an early sign of vitamin A deficiency which develops before nystagmus and at plasma levels below 18 μg/dL. Normal serum vitamin A concentrations in cattle range from 25 to 60 μg/dL. In pigs, levels of 11.0 μg/dL have been recorded in clinical cases, with normal levels being 23–29 μg/dL. In experimental vitamin A deficiency in lambs, serum levels declined to 6.8 μg/dL (normal lambs at 45.1 μg/dL).

The clinical signs may correlate with the serum concentrations of vitamin A. In one outbreak, feedlot cattle with serum concentrations between 8.89 and 18.05 μg/dL had only lost body weight, those between 4.87 and 8.88 μg/dL had varying degrees of ataxia and blindness and those below 4.88 μg/dL had convulsions and optic nerve constriction.

Clinical signs can be expected when the levels fall to 5 μg/dL. For complete safety, optimum levels should be 25 μg/dL or above.

**Plasma retinol**

Some information on the plasma retinol values in stabilized Thoroughbred horses is available. The mean plasma level of retinol in 71 horses 2–3 years of age was 18.5 μg/dL. The serum retinol levels in racing Trotters in Finland are lower than in Thoroughbreds during the summer months, which is a reflection of the quality of the diets.

**Plasma carotene**

Plasma carotene levels vary largely with the diet. In cattle, levels of 150 μg/dL are optimum and, in the absence of supplementary vitamin A in the ration, clinical signs appear when the levels fall to 9 μg/dL. In sheep, carotene is present in the blood in very small amounts even when animals are on green pasture.

**Hepatic vitamin A**

A direct relationship between plasma and hepatic levels of vitamin A need not exist since plasma levels do not commence to fall until the hepatic stores are depleted. A temporary precipitate fall occurs at parturition and in acute infections in most animals. The secretion of large amounts of carotene and vitamin A in the colostrum of cows during the last 3 weeks of pregnancy may greatly reduce the level of vitamin A in the plasma.

Hepatic levels of vitamin A and carotene can be estimated in the living animal from a biopsy specimen. Biopsy techniques have been shown to be safe and relatively easy, provided a proper instrument is used. Hepatic levels of vitamin A and carotene should be of the order of 60 and 4.0 μg/g of liver, respectively. These levels are commonly as high as 200–800 μg/g. Critical levels at which signs are likely to appear are 2 and 0.5 μg/g for vitamin A and carotene, respectively.

**Cerebrospinal fluid**

CSF pressure is also used as a sensitive indicator of low vitamin A status. In calves, normal pressures of less than 100 mm of saline rise after depletion to more than 200 mm. In pigs, normal pressures of 80–145 mm rise to above 200 mm in vitamin A deficiency. An increase in pressure is observed at a blood level of about 7 μg vitamin A/dL plasma in this species. In sheep, normal pressures of 55–65 mm rise to 70–150 mm when depletion occurs. In the experimentally induced disease in cattle, there is a marked increase in the number of cornified epithelial cells in a conjunctival smear and distinctive bleaching of the tapetum lucidum as viewed by an ophthalmoscope. These features may have value as diagnostic aids in naturally occurring cases.

**NECROPSY FINDINGS**

Gross changes are rarely observed at necropsy. Careful dissection may reveal a decrease in the size of the cranial vault and of the vertebral. Compression and injury of the cranial and spinal nerve roots, especially the optic nerve, may be visible. In outbreaks in which night blindness is the primary clinical sign, atrophy of the photoreceptor layer of the retina is evident histologically, but there are no gross lesions.

Congenital ocular abnormalities in newborn calves from vitamin A deficient heifer dams included aphakia, absence of a uveal tract and aqueous humour, microphthalmos, bony outgrowths of the occipital bone, compression of the cerebellum and cardiac abnormalities similar to the tetralogy of Fallot.

Squamous metaplasia of the interlobular ducts of the parotid salivary gland is strongly suggestive of vitamin A deficiency in pigs, calves, and lambs, but the change is transient and may have disappeared 2–4 weeks after the intake of vitamin A is increased. This microscopic change is

---

**Diseases associated with deficiencies of fat-soluble vitamins**

Hepatic levels of vitamin A and carotene can be estimated in the living animal from a biopsy specimen. Biopsy techniques have been shown to be safe and relatively easy, provided a proper instrument is used. Hepatic levels of vitamin A and carotene should be of the order of 60 and 4.0 μg/g of liver, respectively. These levels are commonly as high as 200–800 μg/g. Critical levels at which signs are likely to appear are 2 and 0.5 μg/g for vitamin A and carotene, respectively.
most marked and occurs first, at the oral end of the main parotid duct. Abnormal epithelial cell differentiation may also be observed histologically in a variety of other sites such as the tracheal, esophageal, and ruminal mucosae, preputial lining, pancreatic ducts, and urinary epithelium. Hypovitaminosis-A has also been associated with an increased incidence of pituitary cysts in cattle. Secondary bacterial infections, including pneumonia and otitis media, are also common, due at least in part to the decreased barrier function of the lining epithelium.

The abnormalities that occur in congenitally affected pigs have already been described.

Samples for confirmation of vitamin A deficiency
- Toxicology – 50 g liver, 500 g feed
- Histology – formalin-fixed parotid salivary gland (including duct), rumen, pituitary, pancreas, brain (including optic nerves), cerebral spinal cord (including nerve roots); Bouin’s-fixed eye (LM).

**Differential diagnosis**

When the characteristic clinical findings of vitamin A deficiency are observed, a deficiency of the vitamin should be suspected if green feed or vitamin A supplements are not being provided. The detection of papilledema and testing for night blindness are the easiest methods of diagnosing early vitamin A deficiency in ruminants. Incoordination, paralysis, and convulsions are the early signs in pigs. Increase in CSF pressure is the earliest measurable change in both pigs and calves. Laboratory confirmation depends upon estimations of vitamin A in plasma and liver, the latter being most satisfactory. Unless the disease has been in existence for a considerable time, response to treatment is rapid. For confirmation at necropsy, histological examination of parotid salivary gland and assay of vitamin A in the liver, are suggested.

The salient features of the differential diagnosis of diseases of the nervous system of cattle are summarized in Table 32.3.

**Cattle**

Convulsive form of vitamin A deficiency in cattle must be differentiated from:
- Polioencephalomalacia: characterized by sudden onset of blindness, headpressing, and tonic-clonic convulsions, usually in grain-fed animals but also in pastured animals ingesting an excess of sulfate in water and grass
- Hypomagnesemetic tetany: primarily in lactating dairy cattle on pasture during cool windy weather; characterized by hyperesthesia, clumping tonic-clonic convulsions, normal eyesight and tachycardia, and loud heart sounds

- Lead poisoning: in all age groups, but most commonly in pastured calves in the spring, characterized by blindness, tonic-clonic convulsions, champing of the jaw, head-pressing, and rapid death
- Rabies: in all age groups, characterized by bizarre mental behavior, gradually progressive ascending paralysis with ataxia leading to recumbency, drooping saliva, inability to swallow, normal eyesight, and death in 4–7 days.

**Ocular form of vitamin A deficiency in cattle** must be differentiated from those diseases of cattle characterized by central or peripheral blindness:
- Central blindness: Polioencephalomalacia
- Lead poisoning: Meningoencephalitis.
- Peripheral blindness: Bilateral ophthalmitis due to ocular disease.

**Loss of body condition** in cattle, failure to grow and poor reproductive efficiency are general clinical findings not limited to vitamin A deficiency.

**Pigs**

Convulsive form of vitamin A deficiency in pigs must be differentiated from:
- Salt poisoning
- Pseudorabies
- Viral encephalomyelitis
- Organic arsenic poisoning.

**Paralytic form of vitamin A deficiency in pigs** must be differentiated from:
- Spinal cord compression due to vertebral body abscess.

**Congenital defects** similar to those caused by vitamin A deficiency may be caused by deficiencies of other essential nutrients, by inheritance or by viral infections in early pregnancy in all species. Maternal vitamin A deficiency is the most common cause of congenital defects in piglets. Final diagnosis depends upon the necropsy findings, analysis of feed and serum vitamin A of the dams.

**TREATMENT**

**Vitamin A**

Animals with curable vitamin A deficiency should be treated immediately with vitamin A at a dose rate equivalent to 10–20 times the daily maintenance requirement. As a rule, 440 IU/kg BW is the dose used. Parenteral injection of an aqueous rather than an oily solution is preferred. The response to treatment in severe cases is often rapid and complete, but the disease may be irreversible in chronic cases. Calves with the convulsive form due to increased CSF pressure will usually return to normal in 48 h following treatment. Cattle with the ocular form of the deficiency and that are blind will not respond to treatment and should be slaughtered for salvage.

**Hypervitaminosis-A**

Daily heavy dosing (about 100 times normal) of calves causes reduced growth rate, lameness, ataxia, paresis, exostoses on the planter aspect of the third phalanx of the fourth digit of all feet, and disappearance of the epiphyseal cartilage. Persistent heavy dosing in calves causes lameness, retarded horn growth and depressed CSF pressure. At necropsy, exostoses are present on the proximal metacarpal bones and the frontal bones are thin. Very high levels fed to young pigs may cause sudden death through massive internal hemorrhage and excessive doses during early pregnancy are reputed to result in fetal anomalies. However, feeding vitamin A for prolonged periods at exceptionally high levels is unlikely to produce severe embryotoxic or teratogenic effects in pigs.

**CONTROL**

**Dietary requirement**

The minimum daily requirement in all species is 40 IU of vitamin A/kg BW, which is a guideline for maintenance requirements. In the formulation of practical diets for all species, the daily allowances of vitamin A are commonly increased by 50–100% of the daily minimum requirements. During pregnancy, lactation, or rapid growth the allowances are usually increased by 50–75% of the requirements. The supplementation of diets to groups of animals is governed also by their previous intake of the vitamin and its probable level in the diet being fed. The rate of supplementation can vary from 0 to 110 IU/kg BW/d (1 IU of vitamin A is equivalent in activity to 0.3 μg of retinol; 5–8 μg β-carotene has the same activity as 1 μg of retinol).

Nutrient studies have indicated that pre-ruminant Holstein calves being fed milk replacer should receive 11 000 IU of vitamin A/kg DM for optimum growth and to maintain adequate liver vitamin A stores.

The amounts of the vitamin to be added to the ration of each species to meet the requirements for all purposes should be obtained from published recommended nutrient requirements of domestic animals. Some examples of daily allowances of vitamin A for farm animals are set out in Table 30.11.

**Supplementation method**

The method of supplementation will vary depending on the class of livestock and the ease with which the vitamin can be given. In pigs, the vitamin is incorporated directly into the complete ration, usually through the protein supplement. In feedlot and dairy cattle receiving complete feeds, the addition of vitamin A to the diet is simple. In beef cattle, which may
be fed primarily on carotene-deficient roughage during pregnancy, it may not be possible to supplement the diet on a daily basis. However, it may be possible to provide a concentrated dietary source of vitamin A on a regular basis by feeding a protein supplement once weekly. The protein supplement will contain 10–15 times the daily allowance, which permits hepatic storage of the vitamin.

Parenteral injection

An alternative method to dietary supplementation is the IM injection of vitamin A at intervals of 50–60 days at the rate of 3000–6000 IU/kg BW. Under most conditions, hepatic storage is good and optimum plasma and hepatic levels of vitamin A are maintained for up to 50–60 days. In pregnant beef cattle the last injection should not be more than 40–50 days before parturition to insure adequate levels of vitamin A in the colostrum. Ideally, the last injection should be given 30 days before parturition but this may not be practical under some management conditions. However, the most economical method of supplementing vitamin A is, in most cases, through the feed and when possible should be used.

The use of injectable mixtures of vitamins A, D, and E is not always justifiable. The injection of a mixture of vitamins A, D, and E of feeder cattle in northern Australia prior to transport did not, contrary to anecdotal evidence, reduce weight loss associated with transportation.24 Cattle in Queensland and north-western Australia have very high concentrations of hepatic vitamin A and in fact, drought-stricken cattle in the terminal stages of malnutrition have also had high liver concentrations. The indiscriminate use of vitamin A preparations in cattle is a public health concern because some bovine livers may contain high levels of vitamin A which are potentially teratogenic for pregnant women.22

**Oral vitamin A**

The oral administration of a single bolus of vitamin A at a dose of 2.8 mg/kg BW to debilitated Sahelian cattle during the dry season was effective in raising the milk levels of vitamin A and was as effective as adding 10 g of the powder to the drinking water.2 Both the powder and bolus products provided high levels of vitamin A in milk within 3 days of treatment and according to herder testimonies, night-blind people consuming milk from cattle previously treated with either oral vitamin A preparation were no longer affected with night blindness.

**VITAMIN K DEFICIENCY**

A primary deficiency of vitamin K, is unlikely under natural conditions in domestic animals because of the high content of substances with vitamin K activity in most plants and the substantial synthesis of these substances by microbial activity in the alimentary canal. Sporadic cases may occur when impairment of the flow of bile reduces the digestion and absorption of this fat-soluble vitamin. Experimentally produced vitamin K deficiency in piglets is manifested by hypersensitivity, anemia, anorexia, weakness, and a marked increase in prothrombin time. The minimum daily requirement for newborn pigs is 5 μg/kg BW and the minimum curative injection dose is four times larger.

A hemorrhagic disease of recently weaned pigs from 6 to 15 weeks of age is considered to be associated with vitamin K deficiency.2 Affected pigs fail to grow, become pale, develop large subcutaneous hematomas and exhibit lameness and epistaxis.3 Excessive and fatal hemorrhage following routine castration may occur in pigs from 30 to 40 days of age, but not at 15–20 days of age.2 Subcutaneous massive hemorrhage is more common in pigs at 40–70 days of age. Prothrombin time and activated partial thromboplastin time are prolonged along with decreased levels of vitamin K-dependent factors II, VII, IX, and X.4 At necropsy, hemorrhages are extensive in the muscles of the hindlimbs, forelimbs, and axillary and mandibular region.

Vitamin K, or vitamin K₃, given at a dose of 3 mg/kg BW IM as a single dose will restore the blood coagulation defects to normal.5 Vitamin K₂ added to the feed at a rate of 25 mg/kg for 4 days was also effective. The cause of the vitamin K deficiency was considered to be related to the use of antibacterial drugs in the feed but this has not been substantiated.

The most important therapeutic use of vitamin K in domestic animals is in sweet clover poisoning where toxic quantities of coumarin severely depress the prothrombin levels of the blood and interfere with its clotting mechanism. Industrial poisons used in rodent control which contain anticoagulants of the coumarin type, e.g., warfarin, cause fatal hypoprothrombinaemia; vitamin K is an effective antidote. For warfarin-induced anticoagulation in the horse, the administration of 300–500 mg of vitamin K₁ SC every 4–6 h until the prothrombin time returns to baseline values is recommended.6

Diseases associated with deficiencies of water-soluble vitamins

Water-soluble vitamins, including vitamin C and the B complex, are of minor importance in ruminants (except for vitamin B12) because of their synthesis in the alimentary tract of these animals.

The dairy cow's requirements for the B-complex vitamins were established in the 1940–1950s. At that time, vitamin requirements were defined as the smallest dietary amount necessary to prevent clinical signs of deficiency. It was demonstrated that even when fed a vitamin-free diet, the synthesis of B-complex vitamins by the rumen microflora was sufficient to avoid deficiencies. Consequently, it was concluded that a dietary supply of B-complex vitamins was unnecessary in ruminants. However, there is now evidence that in high-producing dairy cows the requirements for vitamin, nicotinic acid, folic acid, and vitamin B12 are increased under certain circumstances and the amounts supplied by the diet and by ruminal synthesis are not always adequate to maximize health and productivity of dairy cows.1

Niacin requirements per feed unit are higher with high-energy feeds. Niacin increases the number of ruminal protozoa and in cows with clinical or subclinical ketosis, repeated doses of niacin lead to a rapid decrease of non-esterified fatty acids. Dietary supplementation of niacin at 6 mg/d, have improved milk production.

Biotin supplementation of 20 mg/head per day in early lactation can result in improved hoof horn health. After 5 months of biotin supplementation, there is an improvement in the quality and resistance of cow heel and sole horns but 10 months of supplementation is required before an improvement in quality of coronary horn is observed.

Folic acid is essential for cell division and growth for protein synthesis. Supplementation of folic acid may increase milk production but there is insufficient data available to make a recommendation.

Vitamin B12 requirements are usually met by ruminal microflora synthesis if the dietary supply cobalt is adequate. High concentrate diets can modify bacterial synthesis of the vitamin and metabolic utilization of propionate increases the demand for Vitamin B12.

Thiamin, nicotinic acid, riboflavin, pantothenic acid, pyridoxine, biotin, and folic acid are all synthesized by microbial activity. Nicotinic acid and vitamin C are synthesized by other means. The young calf or lamb, in the period before ruminal activity begins, is likely to receive inadequate supplies of these vitamins and deficiency states can be produced experimentally. In the pre-ruminant stage, colostrum and milk are good sources of the water-soluble vitamins, ewes' milk being much richer than cows' milk. The production of signs of deficiency of the B vitamins in horses by the feeding of deficient diets has raised some doubts as to the availability of the B vitamins synthesized in the large intestine in this species.

Vitamin C is synthesized by all species and is not an important dietary essential in any of the domestic animals. Synthesis occurs in tissues and, although blood levels fall after birth, in the newborn calf they begin to rise again at about 3 weeks of age. However, a dermatosis of young calves has been associated with low levels of ascorbic acid in their plasma and responds to a single injection of 3 g of ascorbic acid. A heavy dandruff, followed by a waxy crust, alopecia and dermatitis commences on the ears and spreads over the cheeks, down the crest of the neck and over the shoulders. Some deaths have been recorded, but spontaneous recovery is more usual.

There is some interest in the administration of high doses of ascorbic acid orally to horses to counteract the effects of stress and minimize the effects of infections. A single oral dose of 20 g of ascorbic acid does not result in any increase in plasma concentrations. However, daily administration of either 4.5 or 20 g results in significant increases in plasma concentrations.

THIAMIN DEFICIENCY (HYPOTHIAMINOSIS)

The disease caused by deficiency of thiamin in tissues is characterized chiefly by nervous signs.

ETIOLOGY
Thiamin deficiency may be primary, due to deficiency of the vitamin in the diet, or secondary, because of destruction of the vitamin in the diet by thiaminase. A primary deficiency is unlikely under natural conditions because most plants, especially seeds, yeast, and milk contain adequate amounts.

Thiamin is normally synthesized in adequate quantities in the rumen of cattle and sheep on a well-balanced roughage diet. The degree of synthesis is governed to some extent by the composition of the ration, a sufficiency of readily fermentable carbohydrate causing an increase of synthesis of most vitamins of the B complex and a high intake in the diet reducing synthesis. The etiology of polioencephalomalacia has been discussed in detail under that heading. Microbial synthesis of thiamin also occurs in the alimentary tract of monogastric animals and in young calves and lambs, but not in sufficient quantities to avoid the necessity for a dietary supply, so that deficiency states can be readily induced in these animals with experimental diets. Thiamin is relatively unstable and easily destroyed by cooking.

The coccidiostat amprolium is a thiamin antagonist and others are produced by certain plants, bacteria, fungi, and fish.

EPIDEMIOLOGY
One of the best examples of secondary thiamin deficiency is inclusion of excess raw fish in the diet of carnivores, resulting in destruction of thiamin because of the high content of thiaminase in the fish.

Two major occurrences of secondary thiamin deficiency are recorded. In horses, the ingestion of excessive quantities of bracken fern (Pteridium aquilinum) and horsetail (Equisetum arvense) causes nervous signs because of the high concentration of thiaminase in these plants. The disease has been induced in a pig fed bracken rhizomes and the possibility exists of it occurring under natural conditions. It has also been reported in horses fed large quantities of turnips (Beta vulgaris) without adequate grain. The second important occurrence of thiamin deficiency is in the etiology of polioencephalomalacia and is discussed under that heading.

A thiaminase-induced subclinical thiamin deficiency causing suboptimal growth rate of weaner lambs has been described. Higher levels of thiaminase activity were present in the feces and rumen contents of lambs with poor growth rate compared with normal lambs. Bacillus thiaminolyticus was isolated from the feces and ruminal fluids of affected lambs and suplementation of thiaminase-excreting lambs with...
IM injections of thiamine hydrochloride was associated with significantly improved growth rate.\(^1\)

Thiamin deficiency occurs in sheep being subjected to live export from Australia to the Middle East.\(^1\) Sheep that died or were clinically ill and euthanized had significantly lower hepatic and ruminal thiaminase concentrations than clinically healthy control sheep. A high proportion had thiamin concentrations comparable with those found in sheep that die with polioencephalomalacia. The evidence indicates that the thiamin deficiency is a primary one associated with deprivation of feed during transportation to the preembarkation feedlots. The low feed intake and failure of the ruminal microbes to adapt, thrive and synthesize a net surplus of thiamin during alterations in the ruminal environment are considered to be major contributing factors.

**PATHOGENESIS**

The only known function of thiamin is its activity as a coenzyme in the metabolism of fats, carbohydrates and proteins and a deficiency of the vitamin leads to the accumulation of endogenous pyruvates. Although the brain is known to depend primarily on carbohydrate as a source of energy, there is no obvious relationship between a deficiency of thiamin and the development of the nervous signs which characterize it. Polioencephalomalacia has been produced experimentally in pre-ruminant lambs on a thiamin-free diet. There are other prodromal indications of deficiency disease. For example, there is a decrease in erythrocyte precursors and in erythrocyte transketolase. Additional clinical signs also in the circulatory and alimentary systems, but their pathogenesis cannot be clearly related to the known functions of thiamin. Subclinical thiamin deficiency due to thiaminases in the alimentary tract is associated with low erythrocyte transketolase activities and elevated thiamin pyrophosphate effects, which may explain the poor growth rate.\(^1\)

**CLINICAL FINDINGS**

**Bracken fern** (*Pteridium aquilinum*) and horsetail (*Equisetum arvense*) poisoning in the horse

Incoordination and falling and bradycardia due to cardiac irregularity, are the cardinal clinical signs of bracken fern poisoning in the horse. These signs disappear after the parenteral administration of thiamin. Similar clinical effects occur with horse-tail. Swaying from side to side occurs first, followed by pronounced incoordination, including crossing of the forelegs and wide action of the hindlegs. When standing, the legs are placed well apart and crouching and arching of the back are evident. Muscle tremor develops and eventually the horse is unable to rise. Clonic convulsions and opisthotonos are the terminal stage. Appetite is good until late in the disease when somnolence prevents eating. Temperatures are normal and the heart rate slow until the terminal period when both rise to above normal levels. Some evidence has also been presented relating the occurrence of hemiplegia of the vocal cords in horses with a below normal thiamin status. Neither plant is palatable to horses and poisoning rarely occurs at pasture. The greatest danger is when the immature plants are cut and preserved in meadow hay.

**Experimental syndromes**

These syndromes have not been observed to occur naturally but are produced readily on experimental rations.

- **Pigs,** inappetence, emaciation, leg weakness and a fall in body temperature, respiratory rate, and heart rate occur. The electrocardiogram is abnormal and congestive heart failure follows. Death occurs in 5 weeks on a severely deficient diet. In calves, weakness, incoordination, convulsions, and retraction of the head occur and in some cases anorexia, severe scouring and dehydration.
- **Lambs** 1–3 days old placed on a thiamin-deficient diet show signs after 3 weeks. Somnolence, anorexia, and loss of condition occur first, followed by tetanic convulsions.
- **Horses** fed amprolium (400–800 mg/kg BW daily) developed clinical signs of thiamin deficiency after 37–58 days. Bradycardia with dropped heart beats, ataxia, muscle fasciculation and periodic hypothermia of hooves, ears, and muzzle were the common signs, with blindness, diarrhea, and loss of body weight occurring inconstantly.

**CLINICAL PATHOLOGY**

Blood pyruvic acid levels in horses are raised from normal levels of 2–3 mg/dL to 6–8 mg/dL. Blood thiamin levels are reduced from normal levels of 8–10 µg/mL to 2.5–30 µg/mL. Electrocardiograms show evidence of myocardial insufficiency. In pigs, blood pyruvic levels are elevated and there is a fall in blood transketolase activity. These changes occur very early in the disease. In sheep subjected to export, liver and rumen thiamin concentrations and erythrocyte transketolase activities, were all below levels found in clinically normal sheep.\(^2\)

**NECROPSY FINDINGS**

No macroscopic lesions occur in thiamin deficiency other than non-specific congestive heart failure in horses. The myocardial lesions are those of interstitial edema and lesions are also present in the liver and intestine.

In the experimental syndrome in pigs, there are no degenerative lesions in the nervous system, but there is multiple focal necrosis of the atrial myocardium accompanied by macroscopic flabbiness and dilatation without hypertrophy of the heart.

**DIFFERENTIAL DIAGNOSIS**

Diagnosis of secondary thiamin deficiency in horses must be based on the signs of paralysis and known access to bracken fern or horsetail. A similar syndrome may occur with poisoning by:

- Crotalaria spp.
- Perennial ryegrass
- Indigofera enneaphylla
- Ragwort (*Senecio jacobaea*).

It is accompanied by hepatic necrosis and fibrosis. The encephalomyelitides are usually accompanied by signs of cerebral involvement, by fever and failure to respond to thiamin therapy.

**TREATMENT**

In clinical cases the injection of a solution of the vitamin produces dramatic results (5 mg/kg BW given every 3h). The initial dose is usually given IV followed by IM injections for 2–4 days. An oral source of thiamin should be given daily for 10 days and any dietary abnormalities corrected.

**CONTROL**

The daily requirement of thiamin for monogastric animals is, in general, 30–60 µg/kg BW. The addition of yeast, cereals, grains, liver, and meat meal to the ration usually provides adequate thiamin.

**REFERENCES**

**RIBOFLAVIN DEFICIENCY**

(HYPORIBOFLAVINOSIS)

Although riboflavin is essential for cellular oxidative processes in all animals, the occurrence of deficiency under natural conditions is rare in domestic animals because actively growing green plants and animal protein are good sources and some synthesis by alimentary tract microflora occurs in all species. Synthesis by microbial activity is sufficient for the needs of ruminants but a dietary source is required in these animals in the pre-ruminant stage. Milk is a very good source. Daily requirements for pigs are 60–80 µg/kg BW and 2–3 g/t of feed provides adequate supplementation. The trend towards confinement feeding of pigs has increased the danger of naturally occurring cases in that species.

On experimental diets the following syndromes have been observed:
Pigs: slow growth, frequent scouring, rough skin, and matting of the hair coat with heavy, sebaceous exudate are characteristic. There is a peculiar crippling of the legs with inability to walk and marked ocular lesions, including conjunctivitis, swollen eyelids, and cataract. The incidence of stillbirths may be high.

Calves: anorexia, poor growth, scours, excessive salivation and lacrimation, and alopecia occur. Areas of hyperemia develop at the oral commissures, on the edges of the lips, and around the navel. There are no ocular lesions.

NICOTINIC ACID DEFICIENCY (HYPONIACINOSIS)

Nicotinic acid or niacin is essential for normal carbohydrate metabolism. Because of the high content in most natural animal feeds, deficiency states are rare in ordinary circumstances, except in pigs fed rations high in corn. Corn has both a low niacin content and a low content of tryptophan, a niacin precursor. A low protein intake exacerbates the effects of the deficiency, but a high protein intake is not fully protective.

In ruminants, synthesis within the animal provides an adequate source. Even in young calves, signs of deficiency do not occur and because rumen microfloral activity is not yet of any magnitude, extra-ruminal synthesis appears probable. The oral supplementation of niacin in the diet of periparturient dairy cows may result in an increase in serum inorganic phosphorus and a decrease in serum potassium, calcium, and sodium concentrations. Niacin has been used to study the effects of artificially induced ketonemia and hypoglycemia in cattle.

The daily requirements of niacin for mature pigs are 0.1–0.4 mg/kg BW, but growing pigs appear to require rather more (0.6–1 mg/kg BW) for optimum growth.

Experimentally induced nicotinic acid deficiency in pigs is characterized by anorexia, poor growth, apathy, dull coat and alopecia. Severe, fatal epileptic seizures occur in some animals. Anemia with poikilocytosis is characteristic of this deficiency in cows and calves.

PYRIDOXINE (VITAMIN B6) DEFICIENCY (HYPOPYRIDOXINOSIS)

A deficiency of pyridoxine in the diet is not known to occur under natural conditions. Experimental deficiency in pigs is characterized by periodic epileptiform convulsions and at necropsy by generalized hemosiderosis with a microcytic anemia, hyperplasia of the bone marrow, and fatty infiltration of the liver. The daily requirement of pyridoxine in the pig is of the order of 100 μg/kg BW or 1 mg/kg of solid food, although higher levels have been recommended on occasions. Certain strains of chickens have a high requirement for pyridoxine and the same may be true of pigs.

Experimentally induced deficiency in calves is characterized by anorexia, poor growth, apathy, dull coat and alopecia. Severe, fatal epileptiform seizures occur in some animals. Anemia with poikilocytosis is characteristic of this deficiency in cows and calves.

PANTOTHENIC ACID DEFICIENCY (HYPOPANTOTHENOSIS)

Pantothenic acid is a dietary essential in all species other than ruminants, which synthesize it in the rumen. Deficiency under natural conditions has been recorded mainly in pigs on rations based on corn.

In pigs, a decrease in weight gain due to anorexia and inefficient food utilization occurs first. Dermatitis develops with a dark brown exudate collecting about the mouth, lower jaw, excessive nasal mucus, anorexia or quadriplegia, accompanied by distinctive lesions in the gray matter of the cervical and lumbar enlargements of the ventral horn of the spinal cord. The lesions are malacic and occur in the intermediate zone of the gray matter. The identical lesions and clinical picture have been observed in naturally occurring disease.

The oral therapeutic dose rate of pantothenic acid in pigs is 100–200 mg, 10–20 g/tonne of feed supplies sufficient pantothenic acid for pigs of all ages. Niacin is low in price and should always be added to pig rations based on corn.

BIOTIN (VITAMIN H) DEFICIENCY (HYPOBIOTINOSIS)

Biotin or vitamin H, has several important biochemical functions. It is a cofactor in several enzyme systems involved in carboxylation and transcarboxylation reactions and consequently has a significant effect on carbohydrate metabolism, fatty acid synthesis, amino acid deamination, purine synthesis, and nucleic acid metabolism. Biotin is found in almost all plant and animal materials and, being required in very small quantities, is unlikely to be deficient in diets under natural conditions, especially as microbial synthesis occurs in the alimentary tract.

Cattle

Biotin is now considered a significant factor in lameness of cattle.1 Biotin is important for the differentiation of epidermal cells which are required for normal production of keratin and hoof horn tissue. Biotin also acts as a co-factor in carboxylase enzymes and is an important factor in both gluconeogenesis and fatty acid synthesis. Significant differences in the fatty acid profile of horn tissue of cattle with claw lesions have been observed. Biotin supplementation reduces clinical white line disease, reduces horn lesions, and improves horn quality by strengthening the intercellular cementing material between keratinocytes.2 Improved hoof integrity in intensively managed dairy cows has occurred following biotin supplementation.3 However, a long period of supplementation is required before the effect of the vitamin on hoof health care is expressed. In addition, there may be improved milk production, milk composition, and cow fertility with biotin supplementation.

Biotin is synthesized in the rumen and absolute biotin deficiency has not been recognized. However, ruminal synthesis of biotin may be compromised by acidic conditions in the rumen, which may increase the need for supplementation of biotin in the diet of high-producing dairy cows. In the dairy cow in the periparturient period and early lactation, the levels of biotin may decrease. A decrease in plasma biotin levels of dairy cows at 25 days in milk (DIM), returning to constant levels from 100 DIM until the end of lactation.4 Feeding supplemental biotin at 20 g/d during the last 16 days post partum and at 30 g/d from calving through to 70 days post partum elevated concentrations of plasma and milk com-
pared with cows unsupplemented with biotin. Supplemental biotin also elevated plasma glucose and lowered non-esterified fatty acids, which indicates that supplemental biotin is involved in hepatic gluconeogenesis. The triacylglycerol concentration in liver tended to decrease at a faster rate within 2 days after parturition.

The supplementation of Holstein cows in the Atherton Tablelands in Australia, with biotin at 20 mg/head per day resulted in improved locomotion scores compared to unsupplemented cows. In the wet summer period, the number of lame cows observed by the farmer, were significantly fewer during the rainy period for the biotin-supplemented herds and required fewer antibiotic treatments than unsupplemented herds. Most hoof lesions were most commonly observed in the outer claws of the hind limb.

In a randomized control field trial on five commercial dairy farms in Gloucestershire, south-west UK, the effect of parity and duration of supplementation with oral biotin at 20 mg/d on white line disease was studied over a period of 18 months. The incidence of white line disease increased with increasing parity independent of biotin supplementation from two cases per 100 cow-years in primiparous cows to 15.5 cases per 100 cow-years in all multiparous cows, but up to 47.7 cases per 100 cow years for cows in parities >5. Supplementation with biotin reduced white line disease lameness by 45% in multiparous cows down to 8.5 cases per 100 cow-years, whereas the effect of biotin supplementation in primiparous cows was not significant. A supplementation of length of at least 6 months was required to reduce the risk of white line lameness in multiparous cows. The overall incidence rate of lameness (per 100 cows per year) was 68.9 with a range of 31.6 to 111.5 per farm. The incidence rates of the four most frequently reported causes of lameness were sole ulcer, 13.8; white line separation, 12.7; digital dermatitis, 12.0; and interdigital necrobacillosis, 7.1 per 100 cows per year. The incidence of lameness was highly variable between farms. However, when the data from all farms were pooled, the risk of lameness caused by white line separation in cattle supplemented with biotin was approximately 50%. Approximately 130 days of biotin supplementation is required before a significant difference in white line lesion lameness occurs.

A controlled 14-month field trial evaluated the effect of biotin supplementation on hoof lesions, milk production and reproductive performance of dairy cows housed in the same free-stall facility with the same environment, base diet, and management. Supplemented cows received 20 mg/d by computer feeder. The feet of a select number of cows were trimmed three times at 6-month intervals and hoof health was evaluated. At the final hoof trimming, the incidence of sole hemorrhages was significantly higher in the control group (50%) compared with the supplemented group at 24%. No cases of lameness occurred. Milk production and fat yield increased in all parities and fertility was improved in first calf heifers.

It is possible that biotin improves the quality of claw horn, which encourages the replacement of defective horn, improves healing and makes it less likely for sole lesions to develop from laminitis in its early stages. The administration of biotin at 40 mg per day for 50 days to dairy cows with uncomplicated sole ulcers, resulted in significant improvement in histological horn quality of the newly formed epidermis covering the sole ulcer. Biotin supplementation at 20 mg/d did not affect the tensile strength of the white line.

Vertical fissures, or sandcracks, are vertical cracks of the hoof that may extend across the coronary band and continue to the bearing surface of the dorsal wall of the claw. Sandcracks are common in beef cattle in western Canada. One survey, 37.5% of beef cows were affected with one or more cracks. Supplementary dietary biotin at 10 mg/head per day significantly increased serum levels of biotin and increased claw hardness compared with unsupplemented cows. After 18 months, 15% of the biotin supplemented cows had vertical fissures compared with 35% in the unsupplemented cows.

Pigs

The principal source of biotin for the pig is the feed it receives and feeds vary greatly in their biotin content and in the biological availability of that biotin. Diets based on cereals with a low available biotin content may provide insufficient dietary biotin for the maintenance of hoof horn integrity in pigs. The biotin content in basal diets fed to pigs has varied from 29 to 15 μg/kg available biotin and supplementation of these diets has resulted in improvements in litter size. Continuous feeding of sulfonamides or antibiotics may induce a deficiency. An antitumn to biotin (avidin) occurs in egg white and biotin deficiency can be produced experimentally by feeding large quantities of uncooked egg white.

In pigs, experimental biotin deficiency is manifested by alopecia, dermatitis, and painful cracking of the soles and the walls of the hooves. Naturally occurring outbreaks of lameness in gilts and sows associated with lesions of the soles and the walls of the hooves, which responded to biotin supplementation, have now been well-described. The severe lameness and long course of convalescence have been responsible for a high rate of culling in breeding animals. In gilts fed a basal diet with a low level of biotin (32 μg available biotin/kg) from 25 kg live weight to 170 days of age, there were no significant differences in the number of lesions and claws affected compared with gilts fed a biotin-supplemented diet (350 μg available biotin/kg). However, between 170 days of age and the first weaning, the incidence of hoof lesions increased markedly. Over the next four litters, the incidence of lesions increased with the age of the sow. The predominant lesions in the foot were cracks, which occurred mainly in two associated regions: the heel/toe junction and the heel and the sidewall and adjacent white-line region of the toe. Supplementation of the diet of breeding sows with biotin at an early stage of development makes a significant contribution to the maintenance of horn integrity.

Affected animals become progressively lame after being on a biotin-deficient ration for several months. Arching of the back and a hunched stance with the hindlegs positioned forward occurs initially. This posture has been described as a ‘kangaroo’-sitting posture. The foot pads become softer and the hoof horn less resilient. The feet are painful and some sows will not stand for breeding. Deep fissures at the wall-sole junction may extend upwards beneath the wall horn and gaping cracks may separate the toe and heel volar surfaces. The foot pads initially show excessive wear, later longitudinal painful cracks develop. In well-developed cases, the foot pads appear enlarged, the cracks are obvious and covered by necrotic debris. The foot pads of the hindfeet are usually more severely affected that those of the forefeet and the lateral digit is more frequently affected. The dewclaws are also affected by cracks and the accumulation of necrotic tissue.

Skin lesions also develop in affected gilts and sows. There is gradual alopecia, particularly over the back, the base of the tail, and the hindquarters. The hairs are more brittle than normal and break easily. The alopecia is accompanied by a dryness of the skin.

As the lesions of the feet and skin develop there is a marked drop in the serum biotin concentrations, which is considered as a sensitive index of biotin deficiency. Adequate biotin status may be indicated by serum biotin levels (ng/L) >700; marginal, 600–700; inadequate,
400–600; and deficient below 400.12

Compression and hardness tests made on external hoof have also been used as an indirect measure of biotin adequacy in pigs.16 The tests indicate that significant improvements in the strength and hardness of pig hoof horn are produced by biotin. Supplementation of the diet with biotin does not affect either horn growth or wear rates.14 Biotin supplementation does affect the structure of the coronary epidermis; there is an increase in the density of the horn tubules in the stratum medium, the horny squames in the stratum medium are more tightly packed and the tubules are more clearly defined.17

Reproductive performance of sows is also influenced by their biotin status.18 Supplementation of the diet with biotin may increase litter size, increase the number of pigs weaned, decrease the mean interval in days from weaning to service and improve conception rate. Over a period of four parities, piglet production increased by 1.42 pigs/sow year.16

**Biotin requirements**

**Pigs**

The daily requirements of biotin for pigs have not been well-defined, but certain amounts have been associated with an absence of lameness and improved reproductive performance. Basic diets for gilts contain 35–50 μg/kg and the addition of 350–500 μg/kg is recommended. This provides a daily intake of 4.0–5.0 mg/sow per day. The response to dietary supplementation may take several months; therefore, supplementation should begin at weaning. The details of biotin studies in pigs, including experimental deficiency, the absorption and synthesis of biotin, biotin availability in feedstuffs, and the biotin requirements of the growing pig are available.19

Supplementation of a basal diet, calculated to contain 56 μg/kg available biotin with daily allowances of biotin at 1160 μg/sow per day in pregnancy and 2320 μg/sow per day in lactation, produced significant improvements in litter size in second and fourth parity sows. It is suggested that the requirement is in excess of 375 μg available biotin per kg of diet.18 In a swine herd with a lameness problem, the supplementation of the sow’s ration during pregnancy and lactation with daily intakes of biotin of 400 and 800 μg/sow per day, respectively and the rations of the weaners and growers to 150 and 250 was effective.

**Horses**

The dietary supplementation of horses with 10–30 mg biotin/d for 6–9 months is considered to be effective as an aid in the treatment of weak horn hoof in horses.20 The hoof horn quality of more than two-thirds of the Lipizzaner horses had moderate to severe changes; micro-cracks visible in the transition from the middle to the inner zone of the coronary horn; separation of the sole from the coronary horn in the region within the white zone. Biotin supplementation for 19 months improved horn quality.21 Continuous dietary supplementation with biotin at a daily dose of 20 mg is necessary to improve and maintain hoof horn quality in horses with less than optimum quality hoof.22

**REFERENCES**

**FOCAL ACID DEFICIENCY**

Folic acid (pteroylglutamic acid) is necessary for nucleic acid metabolism and its deficiency in humans leads to the development of pernicious anemia. A dietary source is necessary to all species and an adequate intake is provided by pasture. Although naturally occurring deficiencies have not been diagnosed positively in domestic animals, folic acid has numerous and complex interrelationships with other nutrients and the possibility of a deficiency playing a part in inferior animal performance should not be overlooked. The vitamin has a particular interest for equine nutritionists. Permanently stabled horses and some horses in training may require additional folic acid, preferably on a daily basis by the oral route.1 Folic acid deficiency can be induced in fetal foals and adult horses by administration of folate orally coincident with administration of inhibition of folate metabolism (pyrimethamine trimethoprim, sulfonamides).2

Folic acid at a dose of 400–600; and deficient below 400.12

Simmins PH, Brooks PH Vet Rec 1983; 112:415.

**VITAMIN B12 DEFICIENCY**

Vitamin B12 deficiency is unlikely to occur under natural conditions other than because of a primary dietary deficiency of cobalt, which is an important disease in many countries of the world. Although microbial synthesis of the vitamin occurs in the rumen in the presence of adequate cobalt and in the intestines of other herbivores such as the horse, it is probably a dietary essential in the pig and young calf. Animal protein is a good source. A deficiency syndrome has been produced in young calves on...
a synthetic ration. Signs include anorexia, cessation of growth, loss of condition, and muscular weakness. The daily requirement under these conditions is 20–40 μg of vitamin B₁₂. Sows vary in their ability to absorb the vitamin and those with poor absorption ability, or on deficient diets, show poor reproductive performance. For pigs, 10–50 mg/tonne of feed is considered to be adequate.

The vitamin is used empirically in racing dogs and horses to alleviate parasitic and dietetic anemias in these animals at a dose rate of 2 μg/kg BW. Cyanocobalamin zinc tannate provides effective tissue levels of vitamin B₁₂ for 2–4 weeks after one injection and normal and abnormal blood levels have been established for all species. It is also used as a feed additive for fattening pigs, usually in the form of fish or meat meal or as ‘animal protein factor’. It is essential as a supplement if the diet contains no animal protein and maximum results from the feeding of antibiotics to pigs are obtained only if the intake of vitamin B₁₂ is adequate.

Environmental pollutants and noise

Pollution from outside the farm

Deposition of contaminants in soil and water on plants can derive from a large number of sources including atmospheric pollution, residues from the petroleum and metalloferrous industries — both mining and smelting, persistent pesticides, and the application of sludge. Deposition in soil, but not on plants, does not preclude animal toxicity as soil can comprise a significant proportion of the dry matter (DM) intake of grazing ruminants. Pollutants may exert their effect through direct toxicity, immunosuppression15 or, in the case of some heavy metals, also by the competitive induction of trace element deficiencies.

Mine spills and smelter emissions have been associated with soil and water contamination with a number of different heavy metals. Water from mines is also potentially toxic to livestock that drink it.1 Pastures adjacent to major roads and animals grazing them, are also contaminated by heavy metals from vehicle emissions.2 Cattle will readily ingest petroleum products and the toxicology of oil field pollutants has been reviewed.3 Another important group of compounds is the polychlorinated biphenyls and the polybrominated biphenyls and the chlorinated hydrocarbons generally. These substances are extensively used in agriculture and industry. They have very long half-lives and although they are not in themselves dangerous, they cause a great deal of trouble if they get into the human food chain and become deposited in fatty tissues.

Pollution from farms

Pollution of the environment by animal feces and urine is now of great importance especially to intensive animal farmers located near population centers. There are increasing regulations governing livestock farming, effluent disposal, nitrogen and mineral cycles, odor emission and increasing regulatory actions, or private law suits, against farms that offend. This is not a subject for a text on veterinary medicine although efforts to minimize nitrogen, phosphorus, and potassium fecal outputs by dietary manipulation and water restriction7-9 have potential veterinary and welfare implications.

Slurry application to pastures and run off to streams and ground water introduces health problems such as salmonellosis, cryptosporidiosis, leptospirosis, and mycobacteriosis, under which headings the subject is discussed. Shallow wells near animal accommodation are also likely to contain high levels of nitrates derived from nitrogen filtering through surrounding earth. Such water is a potential source of nitrate poisoning especially in pigs.

One of the important pollutants for housed animals is ammonia from urine. When it is combined with dust, it can cause severe inflammation of the respiratory mucosae. Dust may be the carrier of pathogenic bacteria or viruses, or antigens which provoke a hypersensitivity reaction, e.g. interstitial pneumonia.30 Carbon monoxide and hydrogen sulfide from slurry pits can cause mortality in both animals and humans. The highest risk is during agitation of the slurry, when they are released. Sulfur dioxide is also an environmental contaminant capable of causing respiratory tract irritation in animals.

Noise

Animals are more susceptible to high-pitched noise than are humans and the elimination of such noises in working facilities improves the orderly handling of cattle and sheep.11 Pollution by noise,12 a matter of increasing importance for veterinarians who police codes of practice for animal welfare and for those who are called upon to act as expert witnesses in cases involving excessive noise and its effects on animals, is also an important subject.

The effects of a sonic bang from aircraft are shortlived and are due to fear reactions but include injury due to sudden flight, killing of young by mink and rabbits, suffocation in panic-stricken chickens and reduced egg production. Cattle are unaffected and the effect on livestock and wildlife of the noise produced by low flying aircraft appears minimal.13-15

RADIATION INJURY

Etiology
Ionizing radiation from radionuclides in environment or feed results in nuclear bombs or nuclear power plant accidents.

Epidemiology
Type, severity and extent of exposure will depend on atmospheric conditions and the radionuclides released.

Clinical Findings
Anorexia, depression, and severe diarrhea in acute sickness. Bone marrow depression with anemia and septicemia.

Clinical Pathology
Neutropenia and thrombocytopenia, bone marrow depression.

Necropsy Findings
Hemorrhagic and ulcerative lesions in the alimentary tract. Pneumonia, general septicemia.

Diagnostic Confirmation
Radiation exposure from nuclear disaster.

Animals exposed to radioactive material may suffer radiation injury. They may also serve as reservoirs for radioactive material which could be passed to humans in meat, milk, and other animal products. This hazard to humans is a problem of public health and is primarily addressed by establishing tolerance limits for contamination in animal products for human food and by changes in agronomic practices and policy. Reviews of measures taken following the Chernobyl accident are cited in the Review Literature at the end of this section. The following discussion is restricted to the effects of irradiation on the health of animals exposed to it.

ETIOLOGY
Radiation injury can be caused in a number of ways including nuclear bombs, contamination from nuclear power plant accidents and exposure to X-rays, but the effects on the tissues are the same, differences occurring only in depth of penetration and degree of injury caused. The radiation emitted by radionuclides has a similar biological effect to external irradiation by X-rays because both sources are ionizing – they remove electrons from their orbits causing atoms within animal tissue and produce pairs of charged ions, which are the instruments of the biological damage.

Atomic explosions can also injure through the effects of blast and heat.

EPIEMIOLOGY
Incidence and case fatality
There is considerable variation in the effects of an atomic explosion, or a nuclear power plant accident, depending on the distance from and the time after the blast, whether the explosion occurs in the air or on the ground surface and the types of radionuclides released. With nuclear explosions, animals within the range of immediate irradiation are more severely affected than those exposed only to the ‘fallout’ of radionuclides on pasture. However, grazing animals are exposed to very great risk because of this fallout. The area where direct radiation effects occur is significantly smaller than that where ‘intervention levels’ for radionuclides are exceeded.1

Risk factors
Animal
Radio sensitivity differs between animal species when death is defined as the end point. Horses are more resistant to whole body radiation than other animal species. Sheep appear the most susceptible and die earlier than cattle at equivalent exposure doses. Pigs are the least susceptible to low radiation. Age is also a risk factor and calves are more susceptible than adult cattle and are prone to develop respiratory and enteric disease, effects that are uncommon in adult cattle which commonly show hemorrhagic disease.2

Nature of radiation
Of the radioactive materials produced by an atomic explosion, a number of radionuclides, including iodine-131, barium-140, strontium-89 and strontium-90, cesium-134 and cesium-137, are likely to enter biological systems. Of these, radioactive iodine, barium, and strontium-89 are of less importance because of their short half-lives. On the other hand, strontium-90, cesium-134, and cesium-137 may occur in very large quantities, have long half-lives and are therefore of greatest biological significance. If sufficient of these radionuclides is ingested and tissue levels of them reach critical points, injury similar to that produced by external irradiation will occur. Cesium-134 and cesium-137 are of particular concern because of their biological mobility. They behave metabolically like potassium and are distributed widely through the body. Both are beta and gamma emitters and effectively will administer a dose of whole-body radiation to an animal ingesting pasture contaminated with them. Iodine-131 (131I) behaves like stable iodine and is concentrated in the thyroid gland.

Soil type can influence radionuclide intake by animals grazing contaminated pastures. Persisting concentrations of radium in plants are associated with acid soils with high organic and low clay content.3 In mineral soils, cesium is strongly bound to clay particles which limits its uptake by plants; clay minerals, such as bentonite, fed to ruminants will reduce the alimentary absorption of radium.4 Animal contamination is further influenced by differences in uptake of radionuclides by different pasture species and animal breed differences in grazing behavior.5,6

Zoonotic implications
Radionuclides are excreted in the milk of animals7,8 and are present in the meat9,10 posing a risk for humans consuming them. Radiodine transfer to the milk of sheep and goats is considerably greater than to that of cows.10 The half-life of radiodine is sufficiently short that contaminated milk could be diverted to stored dairy products, although this would not have public acceptance. The maximum permissible concentration of radioactive substances in meat is reached at much lower levels of pasture contamination than would be required to cause physical injury to the cattle or sheep; in most countries it is set at around 1000–2000 Becquerels (Bq) per kg fresh weight.

PATHOGENESIS
The acute radiation syndromes and from acute radiation usually occur within the first few days after exposure to whole body radiation to 30–60 days depending on the radiation dose. Based on the dose the major manifestations have been divided into three major presentations, CNS, gastrointestinal, and hemorrhagic, but there is considerable overlap in clinical signs at all but the high doses that result in the per-acute CNS syndrome.3

Doses greater than 80–100 Gray (Gy) induce rapid damage to blood vessels, changes in permeability and an increase in intracranial pressure with death in 2–5 days. Gastrointestinal disease results when the radiation dose ranges between 10 and 80 Gy and results from damage to the rapidly dividing undifferentiated cells in crypts of intestinal villi which are the progenitor cells to the differentiated enterocytes of the intestinal villi. Damage to bone marrow stem cells is the main cause of death at whole body doses between 2 and 10 Gy with death in large animals occurring 6–8 weeks after exposure. Clinical disease is slow in development after exposure as the effect of this damage is not evident until the death of existing circulating blood cells. The effects are the result of decreased granulocytes, platelets, and red cells and are manifest with increased susceptibility to infection, bleeding syndromes, and anemia.

Initially there is a lymphopenia followed by a depression of granulocyte and platelet counts. The leukopenia permits invasion by bacteria from the alimentary tract and bacteraemia and septicaemia develop 1–4 weeks after irradiation. The clotting mechanism and antibody production are impaired and facilitate the invasion. Progressive necrosis of the gut wall without inflammation is characteristic. Thrombocytopenic hemor-
rhage into the lymphatic system and other tissues lead to the development of a profound anemia.

The activity of germinative epithelium is also profoundly depressed; if the animal survives the early stages listed above, the hair commences to shed, the skin to ulcerate, and a gross reduction in fertility occurs. Degenerative changes in the lens of the eye, particularly cataract, may also occur. Long-term effects in animals are of less concern than in man because of the short life span of animals and any genetic damage can be removed by selective breeding. Very long-term effects of irradiation include a high rate of mutations and a high incidence of tumors, mostly of the hemopoietic system but also an increased risk for squamous cell carcinoma of the skin.

Thyroid damage by \(^{131}I\) does not appear a major risk for ruminants The thyroid gland of the sheep is more radiosensitive than that of the cow but very high and sustained doses of \(^{131}I\) are required to produce damage and clinical signs in thyroid-damaged ruminants are minimal.

**CLINICAL FINDINGS**

**Acute syndrome**

After immediate irradiation with high doses death occurs from damage to the CNS. At lesser doses damage to the alimentary tract occurs and, particularly in young animals, there is a resulting intense, refractory diarrhea. Death occurs in a few days due to dehydration and electrolyte imbalance. Local contact of radioactive materials to skin causes changes within a few hours. Observable lesions vary from depliation and slight desquamation to extensive necrosis depending upon the irradiation dose.

**Subacute syndrome**

Immediately after irradiation with median doses there is an initial phase of ‘radiation sickness’ characterized by anorexia, vomiting in pigs, and profound lethargy which lasts from several hours to several days.

The second phase is one of apparent normality lasting until 1–4 weeks after irradiation. This is followed by a third phase in which most deaths occur associated with damage to stem cells in bone marrow and secondary infections. Clinical signs vary with the nature of the infection and the age of the animal. Calves commonly develop respiratory and enteric disease with fever, weakness, and diarrhea developing to melena and dysentery, sometimes with tenesmus. Anorexia is complete but there is great thirst. Weakness, recumbency and hyperirritability are present. Respiration is rapid and panting and there is a profuse nasal discharge, sometimes blood-stained. In adult cattle severe anemia and septicemia occur.

In general, if the animal survives this period, there is a long period of convalescence which is accompanied by failure to make normal weight gains, alopecia, sterility, and lenticular defects. The sterility may be permanent, or normal fertility may be restored by the end of 8 months in pigs and 2 years in cattle. During the ensuing years, recovered animals may produce mutant offspring. Tumors, especially of the hemopoietic system and of areas of skin which suffer radiation injury are also likely to occur.

Experimental irradiation of pregnant animals causes fetal death and resorption, defects of individual organ and limb development, decreased survival of young born alive and depressed growth rate and fertility of surviving young, the type of abnormality depending upon the stage of pregnancy at which exposure is experienced.

**Chronic exposure**

Chronic exposure to gamma and mixed neutron-gamma radiation for several years produces lenticular opacities. At levels of irradiation which cause lesions in the human lens similar opacities occur in the lens of cattle, but not of pigs or burros.

**CLINICAL PATHOLOGY**

In cattle receiving median somatic doses, the total leukocyte count falls precipitously during the first few days after irradiation with the peak of fall at the 15th–25th post-irradiation (PI) day. In this species, the most sensitive leukocyte is the neutrophil, in contrast to the lymphocyte which is most seriously affected by irradiation in humans.

Platelet counts begin to decrease from a normal of 500 000/mm\(^3\) on the 7th PI day to 40 000/mm\(^3\) at about PI day 21. Erythrocyte counts and hematocrit levels also fall and prothrombin times increase in parallel to the other changes mentioned. The return to pre-irradiation levels requires about a year for granulocytes and platelets, but from 4 to 5 years for agranulocytes.

**NECROPSY FINDINGS**

Gastroenteritis, varying from hemorrhagic to ulcerative, is constant and ulceration of the pharyngeal mucosa and pulmonary edema occur commonly. Hemorrhages into tissues are also characteristic and include all degrees from petechiae and ecchymoses to hematomas and large extravasations. In experimentally produced irradiation sickness, a severe fibrinous pneumonia, pleuropneumonia, and pericarditis are common. Degeneration of many tissues, but especially bone marrow, intestinal mucosa, and lymphoid tissue is evident histologically. Evidence of secondary bacterial invasion is usually seen. Confirmation of the diagnosis usually requires documentation of exposure to radiation.

**Samples for confirmation of diagnosis**

- Histology: jejunum, lymph node, bone marrow.

**DIFFERENTIAL DIAGNOSIS**

The subacute syndrome closely resembles poisoning by bracken fern in cattle and by trichloroethylene-extracted soybean meal, but the diagnosis will usually depend upon a knowledge of exposure to irradiation.

**CONTROL**

The problems of veterinary civil defence in the event of thermonuclear warfare are too extensive to discuss here and the necessary information is provided by most governments. The use of clay minerals and iron-hexacyanoferrates in the feed can bind and restrict the uptake of radiocesium from the alimentary tract of ruminants but is impractical for widespread use. Long-term control of exposure rests with changes in agronomic practices.

**REVIEW LITERATURE**

**REFERENCES**

BRISKET DISEASE (MOUNTAIN SICKNESS)

**ETIOLOGY**
Alveolar hypoxia in cattle at high altitudes results in pulmonary hypertension and the resultant increase in pressure load on the right ventricle can lead to cor pulmonale and heart failure. Any additional factor such as myocardial dystrophy, anemia, pulmonary disease, or hypoproteinemia may exacerbate the primary condition. The additional effort required to obtain feed on sparse pasture at high altitudes may also be a predisposing cause.

**EPIDEMIOLOGY**
Brisket disease occurs sporadically in high mountainous areas in North America and South America. The disease also occurs in the highlands of Ethiopia and India. Cattle residing above 1500 m are predisposed and at altitudes above 2200 m an annual incidence of 0.5–2% is recorded.

**Risk factors**
Brisket disease can occur in all ages and breeds of cattle that are maintained at high altitudes for some months. The incidence is highest in calves, yearlings, in late pregnant cattle, and in cattle newly introduced to these altitudes. Cattle can adapt to high altitudes and the morbidity rate in indigenous cattle seldom exceeds 1%. In affected cattle, case fatality is high unless they are moved to lower altitudes. Susceptibility is inherited.

The ingestion of locoweed (*Oxytropis sericea*) intensifies the effect of high altitude on the development of congestive heart failure. The mechanism is unknown, but when groups of cattle at high altitude graze locoweed the annual incidence may approach 100% with high case fatality.

An unidentified plant is also believed to potentiate the disease in mountainous areas of Brazil.

The congestive heart failure that develops at altitude is peculiar to cattle although other animal species may show an effect from altitude. Horses which are moved up from 300 to 2400 m above sea level show standard increases in pulse and respiratory rates and hemoglobin and erythrocyte levels. Mules are much less susceptible and appear to be unaffected by altitudes as high as 3200 m. Goats, sheep, and donkeys are also reputed to be affected in that order of reducing susceptibility. Llamas and alpacas are adapted to hypoxia at high altitudes, in particular by an oxygen dissociation curve in their hemoglobin which increases oxygen uptake.

**PATHOGENESIS**
Acute alveolar hypoxia (lowered alveolar PO$_2$) is a potent cause of constriction of the precapillary pulmonary vessels and pulmonary hypertension in several species, but cattle are especially reactive and there is a genetic predisposition that determines the magnitude of the response. Prolonged hypoxia and persistent pulmonary vasoconstriction leads to medial muscular hypertrophy of the small pulmonary arteries and arterioles with a further increase in pulmonary vascular resistance and the development of cor pulmonale.

The disease can be produced experimentally in low-pressure chambers. The movement of cattle from an altitude of 1100 up to 3000 m has been shown to cause hypertrophy of the right ventricle, an increase in pulmonary arterial pressure from 27 mmHg (3.6 kPa) to 45 mmHg (6.0 kPa) to over 100 mmHg (13.3 kPa) and the development of right heart failure.

**NECROPSY FINDINGS**
Central pulmonary arterial pressures increase significantly immediately after cattle are moved to high altitudes, but the high pressures subside as adaptation develops. Pressures rise from a normal of 22–26 mmHg (2.9–3.5 kPa) up to 37–55 mmHg (4.9–7.3 kPa) depending on whether the calf is susceptible or resistant to the effects of altitude. Cattle accustomed to live at high altitudes have much less pulmonary hypertension than introduced cattle.

In clinical cases, there can be a significant reduction in the packed cell volume and in hemoglobin levels.
LIGHTNING STROKE AND ELECTROCUTION

SYNOPSIS

Etiology Exposure to high-voltage electric currents.
Epidemiology Single or multiple cases. Following a thunderstorm dead animals at pasture may be under trees or along fence lines. Posterior paralysis in housed pigs.
Clinical findings Bone fractures, temporary unconsciousness, or immediate death. In recovered animals residual nervous signs may persist. Posterior paralysis in pigs.
Necropsy findings Singe and burn marks with some cases. Fractures of long bones in some cases and of lumbar vertebrae in swine.
Diagnostic confirmation Difficult. History and environmental evidence of lightning or electric shock exposure and no postmortem lesions of other causes of disease.

ETIOLOGY

The three common causes are flashes of linear lightning during thunderstorms, broken overhead electrical transmission wires which usually carry very high voltages and faulty electrical wiring in cowsheds and barns.

In lightning stroke, trees, fences, barns, and pools of water may become electrified and it is not unusual for damp ground to act as a conductor for electricity passing along the roots of stricken trees. Animals electrocuted by standing on electrified earth are unlikely to show burn marks on the body. Oak trees are particularly prone to lightning stroke and because of their spreading foliage and extensive root system, are common mediators of electrocution deaths in pastured animals.

Electrical transmission wires are most dangerous when they fall into pools of water, as they are likely to do during the storms which bring the wires down. In such cases, the entire pool is electrified and animals passing through it may be killed instantly. Electrocution can also occur from this source without obvious evidence of line fault.

In accidents caused by faulty wiring, voltages of 110–220 V are sufficient to kill adult cattle provided they make good contact with the source and the ground. Water pumps and milking machines are the common sources of electricity which may electrify water pipes or the milk line. In this event, the animal may electrify water pumps and milking machines.

PATIENTS
due to electrocution in barns may occur at any time.

PATHOGENESIS

Tissue damage from electrical trauma is induced by the direct effects of the electric current and the development of heat and tissue ischemia. Exposure to high-voltage electrical currents causes severe nervous shock with complete unconsciousness and flaccid paralysis. In some instances, focal destruction of nervous tissue occurs and residual signs of damage to the nervous system persist after nervous shock disappears. Death when it occurs is usually due to paralysis of vital medullary centers. Ventricular fibrillation may also occur and contribute to the fatal outcome. Superficial burns may be evident at the site of contact with the current or along the path of flow from the point of contact to ground. The burn is produced by heat generated from the resistance of tissues to the passage of the electricity. Fractures are believed to be the result of sudden and profound muscular contraction.

CLINICAL FINDINGS

Varying degrees of shock occur. With high-voltage currents and good earth contacts such as wet concrete floors, water, and damp earth, the animal may fall dead without a struggle. Singeing and buming are likely to occur because of the severity of the shock. The burns may be localized to the muzzle or feet and be in the form of radial deposits of carbon with or without disruption of tissue, or they may appear as tree-like, branching patterns of singeing running down the trunk and limbs.

In less severe shocks, the animal falls unconscious, sudden collapse, or there may be some struggling, followed by a period of unconsciousness varying from several minutes to several hours. When consciousness is regained, or the animal is removed from the electric field, the animal may rise and be perfectly normal.
or show depression, blindness, ataxia, posterior paralysis, monoplegia, and cutaneous hyperesthesia. In some cases there may be more local signs including nystagmus and unilateral paralysis. Slighting of the skin at the sites of burns may occur after a few days. These signs may persist or disappear gradually over a period of 1–2 weeks. With electrocution in pigs caused either by lightning stroke or wiring faults, the major signs are related to spinal injury or to fracture of the ileum, ischium, and the transverse processes of the lumbar vertebrae with a large number of animals exhibiting apparent lameness and especially posterior paralysis.3,4 Vestibular disease is described as a sequela to lightning strike in horses.3

The actual occurrence of electric shock often is not observed and electrocution should always be considered in the differential diagnosis of spinal or pelvic fracture or injury in pigs.

With minor shocks, especially as they occur in barns on low-voltage domestic current, the animal may be knocked down or remain standing. Consciousness is not lost and the clinical picture is one of restlessness. The animal may kick violently at the stanchion or the dividing rail. The attacks may be intermittent and occur only when the cattle supply a good ground contact such as standing in the gutter, when they are drinking, or when they are wet. Dairy farmers are often unaffected in the same environment because their boots provide effective insulation.

CLINICAL PATHOLOGY
Laboratory examinations are of no value in diagnosis.

NECROPSY FINDINGS
If electrocution is suspected it is best to ensure that possible sources of electric power are shut off before proceeding with a postmortem examination.

Diagnostic lesions are often minimal1 but singe marks on or under the skin, or damage to the environment, or both, occur in about 90% of lightning deaths. Rigor mortis develops but passes off quickly.

In cattle, anthrax is often a consideration as the carcass decomposes rapidly and blood may exude from the external orifices. The pupils are usually dilated and the anus relaxed. All viscera are congested and the blood is dark and unclotted. Petechial hemorrhages may occur throughout the body, including the trachea, endocardium, meninges, and central nervous system. The superficial lymph nodes, particularly the prescapular and the interior cervical, are often hemorrhagic. Superficial singeing of the hair, burn marks on the feet or muzzle, and internal or subcutaneous extrava-

ations of blood in arboreal patterns also occur.

In some cases of electrocution there are longitudinal fractures of long bones and in incidents involving pigs, local hemorrhage and extensive fractures of the bones in the pelvic area are observed.3 Fractures of the lumbar vertebrae have also been described in electrocuted swine.

Theoretically, the passage of electric current through tissue may cause cell nuclei to elongate and assume orientations parallel to one another. Skin lesions can be examined histologically for this change and hyperconcentration of skeletal muscle fibers may also be observed.

Differential Diagnosis
Great care must be taken in accepting an owner’s suggestion that an animal has been killed or injured by lightning stroke. Insurance against loss by lightning is seldom covered by insurance. In order to minimize the possibility of conflict and potential future legal problems it is wise to have a representative of the insurance company present at the autopsy so that all may agree on the diagnosis.

To make the diagnosis, there should be a history of exposure and evidence of sudden injury or death. In the latter case, half-chewed food may still be present in the mouth. Burns on the skin, scorching of the grass and tearing of the bark on nearby trees are also accepted as contributory evidence. The possibility of electrocution caused by faulty wiring should be considered when sudden shocks or death occur in animals confined in stanchions. Differentials include:

- Other causes of sudden death
- Pigs. Other causes of posterior paresis/paralysis

TREATMENT
Central nervous system stimulants and artificial respiration should be provided for unconscious animals but in most instances the animals are dead or recovered before treatment can be instituted.

CONTROL
Precautions taken to avoid lightning stroke in animals are largely ineffective, but proper installation of all electric equipment in barns and milking parlors is essential to prevent losses. All motors should be earthed to a special iron spike or pipe driven at least 2.5 m into the ground, preferably in a damp spot and electrical machinery that has potential contact with animals should be shielded. Earthing to water pipes should not be permitted. Minimum amperage fuses should be used to provide protection in cases of short-circuiting.

REFERENCES

STRAY VOLTAGE

Synopsis
Etiology Electrical shock.
Epidemiology Risk with any electrified housing system but most recognized in dairy cattle and pig housing.
Clinical findings Behavioral changes in feeding or eating patterns, reluctance to move freely in some areas of buildings. Claims for increased disease incidence and decreased production not substantiated experimentally.
Diagnostic confirmation Demonstration of stray voltage with amelioration of the problem when this is corrected.

ETIOLOGY
Stray voltage can produce minor electrical shock and discomfort to animals. The term ‘stray voltage’ is used to denote an electrical voltage between two points that can result in a current flow through an animal when it contacts them. The voltages are usually low and are usually not detected by humans because of the insulation provided by clothing and footwear. Other terms that have been used for stray voltage include ‘free electricity’, ‘tingle voltage’, and ‘transient voltage’. The term ‘neutral to earth voltage’ or ‘neutral to ground voltage’ usually applies to the voltage measured between the service entrance neutral bus and a reference ground rod. ‘Cow contact voltage’ refers to voltage measured between a potential cow contact, such as a drinker and the ground.

The source and cause of the problem is complex. Stray voltage can be associated with the electrical distribution network and the farmstead wiring system and the contribution from both sources can be superimposed. Seven potential sources have been identified, five of which originate on the farm.1

EPIDEMIOLOGY
The potential presence of stray voltage has been recognized for many years but the possible relation to production and disease gained particular attention in the 1980s when different surveys indicated that over 50% of dairy farms had significant cow contact voltage and more current studies indicate a continuing problem.2,4 Deteriorating wiring, poor wire insulation, and older buildings are risk factors.
Heavy milking cows are believed more sensitive to electric shock, scratched, infected, and sore muzzles and hooves may increase sensitivity.

PATHOGENESIS
The reaction of the animal to stray voltage will depend upon the current flow, or shock, which is related directly to the voltage and inversely to the impedance to flow in the animal. The impedance decreases as body weight increases owing to increase of the surface of contact and the pressure exerted by the hoofs on the floor and, with pigs, current flow at the same voltage is higher through a gilt or sow than through a piglet.5,6 There are some differences in impedance between different pathways in animals (e.g. mouth to hooves or udder to hooves) but there can also be individual animal variation in sensitivity to stray voltage. In general, the problem will only be suspected if the stray voltage is high enough so that a significant proportion of the herd shows signs.

The reactivity of cows to different voltage levels has been studied and the lowest behavioral perception is observed at 1–2 V for the most sensitive cows and moderate behavioral responses at 1.5–3 V. With pigs, feeding and drinking behavior is affected at 5 V but not at 2 V, and resting time is disturbed at 8 V.10,11

CLINICAL FINDINGS
Behavioral changes
The behavioral responses exhibited by cows exposed to stray voltage depend upon the site at which the voltage occurs and the strength of the current flow.12 Stray voltage in the milking parlor results in a reluctance to enter the parlor, a reluctance to cross the floor grids, extreme nervousness while in the parlor and rapid exit or stampeding from the parlor. Where stray voltage occurs at drinkers cows may show reluctance to drink, with lapping of water rather than full drinking and crowding at the drinker to result in one cow being the ground while others drink.1,3 Cows that are experiencing current flow are restless, they may tremble and the back is arched and the head is elevated with the ears held back rigidly and there is frequent urination and defecation.

In pigs, restlessness, increased aggressiveness and changes in drinking and feeding patterns have been associated with stray voltage.10

Effects on production and disease
Field observations have indicated that stray voltage in the milking parlor at milking time can result in incomplete milk letdown, increased milking times, elevated somatic cell counts, an increased incidence of clinical mastitis, and poor production.3,4 However, controlled trials have found no effect of stray voltage on the incidence of disease nor an effect on production in dairy cattle12,14 or pigs.10,11,15

DIFFERENTIAL DIAGNOSIS
The presence of stray voltage should be suspected where animals exhibit behavioral abnormalities and for the present, it is probably wise to consider it as part of the differential of problems of production inefficiency.

Cow contact voltage can be measured with a sensitive voltmeter but the ground must be well established. The measurement of the neutral to earth voltage does not give a good prediction of cow contact voltage and is not recommended as the sole measure for the risk of stray voltage on the farm. In most instances a qualified electrician is required to correct the problem. The use of a commercially available tingle voltage filter has been recorded to significantly reduce stray levels.3

VOLCANIC ERUPTIONS
Active and potentially active volcanic chains exist in several countries in close proximity to significant livestock production areas. Major volcanic eruptions are rare but the experiences of the eruptions of Hecla in Iceland, Mount St Helens in the USA, the Lonquimay complex in the Southern Andes, and Ruapehu in New Zealand suggest that most are inconvenient to orderly livestock production, but have minimal effects on animal health.

Blast and gas damage
Volcanic eruption can result in devastation of land areas from the effects of lateral blast and pyroclastic, laval, and mud flows. Livestock losses which occur in this way can be total, but the affected areas are restricted to the immediate vicinity of the eruption. Toxic gases from the eruption may accumulate in close low-lying areas and result in mortality.

Ash hazards
Significantly greater land areas can be affected by tephra fallout consisting of ash and rock fragments from the volcanic eruption. The size of the sector affected by ash fallout will be determined by the strength and direction of winds at the altitude reached by the ash column at the time of the eruption, but several thousand square kilometers can receive ash fallout varying from a light dusting to falls several centimeters in depth.

The hazards to livestock during the fallout period appear minimal, although in areas where the ash fall is heavy, there is virtually total darkness. Animals, particularly sheep, may be excessively and some die of suffocation or misadventure including drowning.

The immediate effect of the fallout is to blanket pastures with ash and in heavy fallout areas, taller succulents may become lodged and unavailable for grazing. Livestock may be forced to graze more robust, but toxic, plant species if stored feeds are not provided and loss from plant poisoning was observed following the Mount St Helens eruption. Hypocalcemia, apparently resulting from food deprivation, was also observed in the immediate post-fallout period with Mount St Helens and was also recorded following the Mount Hecla eruption.1

Ash fallout may have a devastating effect on insect life and this may be followed soon afterwards by death from starvation of insectivorous avian species. This may be misinterpreted by the public as evidence for ash toxicity.

Toxic chemicals
Potential hazards to livestock health exist in the chemical composition of ash. In the fallout from Mount St Helens and from Ruapehu several potentially toxic heavy metals and trace elements were present, but none in a concentration sufficient to be a hazard to livestock health.2,3 During the air-borne stage, wind sorting of the dust into particles of varying size, shape, and density results in area variation in the composition of the fallout. Consequently, area variations in chemical analysis over the fallout area can occur. Analyses based on acid-leachable or water-soluble analysis are more relevant to immediate animal health than those reporting total content.

Mortality resulted from acute fluorine poisoning in association with high fluoride levels in ash and ash-contaminated grasses and water in the period immediately following the Mount Hecla and Lonquimay eruptions.4,5 It is therefore advisable to remove livestock from the eruption area.
ash-contaminated pastures until this hazard is determined. In most circumstances, this will necessitate removal to indoor housing and feeding of stored feed and well water if they are available.

Physical properties
The ash particulate count in air and the respiratory exposure to livestock is highest during the fallout period, but can remain high for long periods following the fallout when ground ash is disturbed by animal movement, winds, and normal farming practices. A significant proportion of this material is of small particulate size and is respirable. Chemical and/or physical irritation of the respiratory tract, with a significant increase in the prevalence of respiratory disease, might be expected in these circumstances. This did not occur following the Mount St Helens eruption, even in animals with known pre-existing respiratory disease, nor was it a reported problem following the eruption of Mount Hecla. Signs of irritation such as lacrimation were observed widely, but with no untoward sequelae.

Long-term effects
Volcanic ash is composed predominantly of pumiceous volcanic glass and crystalline mineral silicates such as feldspar. These materials have no innate pulmonary toxicity. Volcanic ash may also contain variable amounts of free crystalline silica such as quartz, cristobalite and tridymite which, if present in respirable sized particles for prolonged exposure periods, can induce pulmonary fibrosis.

Silicosis is primarily a human health concern, although spontaneous silicosis is recorded in livestock. While it is a concern with all eruptions, the long-term health history of animals and man following volcanic eruptions suggests this hazard is minimal.

In the vicinity of Mount St Helens there have been two appreciable effects on livestock health:

The first has been a marked increase in the incidence of hypomagnesemia in cattle in the semiarid channelled scab lands of central Washington. This has possibly resulted from the reflective nature of the ash layer on the soil reducing soil temperature increase during early grass growth and thus reducing magnesium uptake. Grass magnesium concentrations are low and potassium levels are high but there are no preruption values for comparison.

The second effect has been an increase in the severity of selenium deficiency. The association between selenium deficiency and recent volcanic origin soils is well recognized. Problems have been corrected by additional and more intensive selenium supplementation.

Animals may ingest considerable quantities of ash from grazing contaminated pastures or from hay subsequently prepared from these areas. There is little field evidence for disturbance of digestive function in livestock following the Mount St Helens or Ruapehu eruptions and feeding trials of ash to cattle and sheep have shown no clinical or postmortem evidence of untoward effects nor any depression of production except that associated with decreased feed palatability at high ash feed levels.

BUSHFIRE (GRASSFIRE) INJURY (THERMAL BURNS)

Synopsis
Etiology Thermal or smoke inhalation injury from fire.
Epidemiology Large numbers of livestock with thermal burns in bush and prairie fires. Smoke inhalation injury more common in horses rescued from barn fires.
Clinical findings Edema and thermal injury in skin. Upper respiratory signs in short term and lower respiratory disease in the longer term, with smoke inhalation.
Treatment Palliative local therapy, fluid therapy to prevent shock with superficial thermal injury. Maintenance of airway and lower respiratory function with smoke inhalation. The major dilemma with treatment is the conflict between the welfare of the animals and the responsibility to the owner.

ETIOLOGY
Heat, carbon monoxide, and toxic gases are the cause of injury and death in fires. Most fire victims have thermal burns. The treatment of burns is, by common consent a surgical subject, but there are aspects of bushfire or forest fire injury which warrant discussion in a textbook of large animal medicine. For example, when large numbers of animals are affected the most important questions to be decided are whether to treat them and what to treat them with and, if they are not to be treated, whether they are to be summarily destroyed or salvaged for meat. When large numbers of animals are burnt there is also a major moral conflict for the veterinarian between the welfare of the animals and the responsibility to the owner.

EPIDEMIOLOGY
Forest fires
Although no written information is readily available about forest fires in softwood forests it is assumed that few animals would survive the suffocating effects of intense heat and high smoke concentration. The intensity of the heat arises from the fact that the entire forest from leaves to trunks is burned.

In hardwood forests, such as eucalyptus forests in Australia, the heat is not so severe because the tops only are destroyed. Underbrush is burned but the tree trunks are only scorched and usually survive to regrow. Depending on the density of the forest and the amount of underbrush there may be many survivors as badly burned animals. The most severe burns are on the lower surfaces and undersurfaces of the body and are caused by burning of the litter on the forest floor.

Grass fires
The most serious situation is caused by a grass or prairie fire which, because of the short period of intense heat that is generated by the wind-driven fire, burns but does not necessarily kill animals. The fires can be extensive and involve large numbers of animals. Many animals will die of suffocation, especially sheep, but the majority survive in various states of burn injury.

Barn fires
Animals may die of carbon monoxide poisoning and asphyxiation, or be burned all over, but some may be rescued without burn but with the risk of smoke-induced respiratory injury (Chapter 10). Animals trapped, but subsequently rescued, in barn fires are more usually horses.

The problems for veterinarians created by large-scale burnings are several-fold:

- The first is that national disaster services are usually recruited to deal with the damage to property and welfare problems of humans. They are often poorly equipped to deal with animal problems yet assume authority over their fate in the temporary absence of the owners. The normal reaction of the average person is to judge that burn injuries are much more serious than in fact they are and to shoot burned animals out of hand.
- The second problem is that the facilities for penning and treating burned animals have usually been destroyed in the fire so that a general feeling of helplessness prevails,
especially if several hundred animals are affected

- **Insurance** also exerts an influence on the owner's decision on the course to be followed. Most livestock are protected by fire insurance and there will be no argument with a veterinarian's decision that burned animals should be destroyed for humane reasons. This is often done unnecessarily if the interests of insurers are to be protected

- **Salvage** for slaughter is often difficult to arrange at such short notice for such large numbers and public sentiment is against the practice. However, delayed salvage must be kept in mind for animals which will have impaired functions because of burns, e.g. ewes with teat injuries, rams with preputial injuries, bulls with scrotal injury.

**CLINICAL FINDINGS**

**Burn injury**

The parts most affected by burning are the face, especially the eyelids, conjunctivae and lips, the undersurface of the body especially udder, teats, and perineum and the coronets. **Badly damaged corneas take many weeks to heal but badly swollen lips and eyelids can be almost normal within 48 h. Marked edema is always a feature of skin burns in animals, but badly burned skin will be dry and ready to slough in a week.**

The teats of **dairy cows** may be damaged to the point where they will not be milkable again; wethers and rams may suffer urethral obstruction. In dairy cattle it is heifers that have the worst prognosis with respect to machine milkability.

Separation of the coronary band from the **hoof** is a common occurrence as a result of burning and there may be sufficientweeping at the separation to suggest that the hoof is about to slough, but they seldom do and hooves that appear quite loose do heal normally.

**TREATMENT**

**Decision criteria**

A major decision must be made at the outset whether to treat an affected animal or whether to destroy it on humane considerations. This decision is more easily made when an individual, rather than several hundred animals, is the consideration.

Recommended **criteria** for deciding the fate of sheep burnt by **pasture fire** depend on the presence of burns to the hooves and legs below the carpal and tarsal joints which cause local swelling and a dry leathery appearance of the skin. Such sheep are likely to be recumbent and immobile and to die. Burns which do not cause swelling of the lower limbs, or to other parts of the body are not likely to be fatal, nor to produce chronic ill-health, unless they affect a large part, more than 15–20%, of the body surface.

Animals which are unconscious or very distressed, cannot walk, or have severe difficulty in breathing are poor prospects for recovery and are best **euthanized** forthwith. It may be necessary to monitor sheep for 10 days after a fire before deciding what to do with them. It is necessary at all times to consider the need to avoid inflicting suffering on the animals, but to also consider the farmer's need to retrieve his assets. If the animals are insured against fire it is also highly desirable to keep the insurer advised of developments.

Animals which have been trapped in a **burning building** are likely to be burned all over and to have upper and lower respiratory damage from smoke inhalation. Bronchoscopy can aid in establishing the severity of injury.

**Skin burns**

Extensive skin burns are accompanied by fluid shifts, vascular leakage, protein loss, and the potential for hypovolemia. The initial therapy is with crystalloid and colloid fluids as discussed in the section on shock. Tetanus prophylaxis is appropriate. Topical antibiotics, silver sulfadiazine and aloe vera are topical therapies. Non-steroidal anti-inflammatory agents can decrease the inflammatory response and help in pain management. Glucocorticoids may potentiate burn sepsis. In horses, euthanasia is recommended if greater than 50% of the body surface is affected.

**Smoke inhalation**

Tracheostomy may be required to maintain the upper airway. Bronchodilators such as aminophylline or terbutaline sulfate are used to relieve reflex bronchoconstriction and humidified oxygen and local hydration by fluid nebulization to relieve hypoxemia. Corticosteroids are used to reduce airway inflammation in animals with minimal cutaneous burns.

**REFERENCES**

**REVIEW LITERATURE**

**REFERENCES**

**WETNESS**

Frequent exposure to wetting, sufficient to keep the skin permanently wet for long periods, predisposes to fleece rot in sheep and mycotic dermatitis in all species. In horses it leads to a superficial dermatitis along the dorsum, especially over the croup and is known as scal. Frequent immersion of the lower limbs of cattle on irrigated pasture causes dermatitis on the backs of the pasterns leading to mycotic dermatitis. Wetting also predisposes to hypothermia in the young.

Standing in cold water for a period of more than 3 days causes the immersed parts to become edematous and congested and slough their skin in the form of a cuff around the limb. Recovery is slow and incomplete.

**REFERENCES**

**DROWNING**

Near drowning has been defined as survival following asphyxia and aspiration of water while submerged. Cases are rare in large animals but there is increased potential with the increasing popularity of swimming as a method of exercising and training horses. Fresh water can inactivate pulmonary surfactant and lead to collapse of the alveolus with a loss of pulmonary compliance and the resultant ventilation-perfusion mismatch coupled with alveolar damage can lead to severe hypoxemia. The inhalation of water may also carry bacteria and the risk of a secondary bacterial aspiration pneumonia. Affected animals present with an elevated heart rate, tachypnea, and dyspnea. There is a decrease in normal air flow sounds on auscultation, which may occur in all areas of aspeltation or be more pronounced in one lung and rales or crackles may be heard in local areas. Consolidation may be detected with thoracic radiography. The mucous membranes may be congested, cyanotic, or muddy. Arterial blood gas analysis has shown a metabolic acidosis and hypoxemia.

Therapy has been based on experience with near drowning cases in humans; horses have been successfully treated by nasal insufflation of humidified oxygen, the correction of the base deficit with sodium bicarbonate and lactated Ringer's solutions administered intravenously, treatment with bronchodilators and non-steroidal anti-inflammatory drugs and the pulmonary infusion with a surfactant transplant from a recently euthanized horse. Antibacterials are given to cover the risk or the presence of a bacterial pneumonia and the cover should include the possibility of infection with anaerobic organisms. Respiratory distress can be more severe when the animals are recumbent and enforced standing may be
indicated. Near drowning requires immediate and aggressive therapy and the recovery can be prolonged.

COLD INJURY (FROSTBITE, CHILBLAINS)

ETIOLOGY AND EPIDEMIOLOGY
The injury occurs during cold weather in the winter or spring months and is most common in calves which are weak or in which the peripheral circulation of the limbs is impaired, usually because of diarrhea and dehydration. In a retrospective study of frostbite in calves, 80% of cases were associated with a concurrent disease such as pneumonia, diarrhea, omphalitis, septicemia and ocular disease. Hypothermia (<37.5°C) was present in about 50% of the calves. The disease in calves appears more common in beef breeds, possibly because of management risk factors.

In dairy herds with loose housing, access to outdoor exercise yards without adequate bedding can be a risk factor. There can be a high incidence of teat lesions in drylot-housed herds in temperature areas when freak cold weather fronts invade the region. Regional differences in teat chapping in winter are associated with regional differences in winter temperature.

PATHOGENESIS
Physiologically, body heat is lost from the skin surface by radiation and convection and by conduction and evaporation when the skin and hair coat are wet. Newborn calves are particularly susceptible to cold because of their inadequate insulation and high ratio of body surface area (through which heat is lost) to body volume (in which heat is generated). The core and trunk body temperature is preferentially conserved during cold stress at the expense of the peripheral tissues which are most susceptible to cold injury.

The peripheral tissues are also most susceptible because of their contact with the ambient temperature and wet environments. When cattle are in sternal recumbency, the uppermost pelvic limb is fully exposed and the distal aspect of the opposite limb from the hoof to above the fetlock joint is exposed to the environment. The distal extremities of the thoracic limbs are usually covered by the thorax. Thus, any situation which results in prolonged sternal recumbency will allow the distal extremities of the pelvic limbs to cool excessively and if there is impairment of circulation because of pre-existing dehydration, varying degrees of cold injury can occur. Field observations suggest that if a weak calf does not move from a sternal recumbent position for several hours, the cold injury can progress to the stage of severe irreversible frostbite before the clinical signs are recognized by the owner.

The teats of dairy cows are also exposed when standing and lying. Residual teat dip after milking predisposes to cold injury. Cold injuries of extremities vary from mild to severe. Exposure to cold results in vasoconstriction and coolness of the affected part. Most dry-cold injury is superficial and the skin may become gangrenous resulting in a hard shell or carapace over healthier tissue. Deeper cold injury causes inflammation, redness or cyanosis, local swelling and pain or loss of sensation.

CLINICAL FINDINGS
Frostbite of the feet of calves is not readily obvious even to the experienced observer. The normal hair covering and pigmentation of the skin often mask the early changes of frostbite. Commonly, cases are identified during the treatment with fluids of scurving, recumbent calves, when further clinical examination reveals that the hindfeet are cool and clammy.

In the early stages of frostbite of the distal parts of the limbs, the tissues are swollen, edematous and may have well demarcated limits. After several hours of warming indoors, the feet remain cool and close examination reveals some moistness and dark red to bluish coloration of the skin. There may be a line of demarcation between normal and affected tissue at about the level of the fetlock joints. If the injury is not severe, complete recovery may occur in a few days.

In more severe cases, within 24–48 h, necrosis and sloughing of the skin may occur and the hooves may become detached several days later. Pain on palpation of affected tissues, especially at the line of demarcation, is obvious.

When there is avascular necrosis of the affected part, the skin may be hard like a shell (known as a carapace) and moderate palpation will elicit pain.

Freezing of the ears results in loss of pliability of the ears, gangrene, and loss of the affected parts and curling of the affected skin adjacent to the affected parts. Some sloughing of affected parts will occur and after several days the ears appear shortened.

Freezing of the tail occurs most commonly at the distal end resulting in stiffness and loss of flexibility because of a carapace. Varying portions of the tail may be affected but usually 5–10 cm of the distal end is involved. The distal parts of the tail of adult cattle may freeze in very cold weather.

In adult cattle, freezing of the teats and base of the udder can occur in lactating cattle which have inadequate bedding and shelter from wind and snow. Affected teats are swollen and cold and the skin begins to vesiculate and peel. Freezing of the teats of cows may result in permanent injury, chronic thrilis and the possibility of mastitis with gangrene. Less severe lesions predispose to mastitis.

Freezing of the scrotum occurs in yearling bulls kept outdoors during the cold winter months but the lesions are not commonly recognized until the spring of the year.

NECROPSY FINDINGS
Necrosis of the skin of the affected area with severe diffuse hemorrhagic subcutaneous edema is typical of frostbite.

TREATMENT
Affected calves should be moved to a warm well-bedded dry environment and circulation should be improved by providing fluid therapy as necessary. In early cases, affected calves will recover in a few days and the swelling and pain will regress. Field observations suggest that superficial freezing of the skin between the fetlock and coronets will heal over a period of several weeks providing the lesion does not extend into the coronary bands and the laminae of the fetlock which commonly results in sloughing of the hoof.

In severe cases with extensive necrosis, the skin will begin to slough. Such open wounds should be treated with suitable antibiotic ointments and bandaged for...
several days. Calves with extensive freezing of the hindlimbs extending from the feet up to hock joints are incurable and should be euthanized.

There is no specific treatment for freezing of the ears and tails of calves or the teats of cows.

**CONTROL**

The prevention of cold injury in newborn calves requires daily surveillance of calves to ensure that any animal which is inactive for any reason is examined for evidence of illness and treated immediately and placed in a protected environment.

When an exceptional cold period is forecast for dairy cows at risk, teat dipping should be temporarily suspended during the cold period. Additional bedding should be provided for loose-housed cows and bedding with some manure can be piled in the center of drylot yards to provide composting heat upon which the cows can bed.

Suspicions of poisoning is aroused when illness occurs in a number of previously healthy animals, all affected at the same time and showing the same signs and necropsy findings, to the same degree of severity. These conditions, of course, may also apply to some infections, metabolic and nutritional deficiency diseases. It is only by acquaintance with the syndromes produced by the common poisons, particularly those likely to occur locally, that this primary differentiation can be made.

Poisonous plants often show a geographical limitation in distribution; particular industrial enterprises may create poison hazards in local areas; certain agricultural practices, including the spraying of orchards, the dipping or spraying of cattle for ectoparasites, and the use of prepared concentrate feed for pigs and cattle, may also lead to poisoning in groups of animals. So many chemical agents are used in agriculture today that a section of miscellaneous farm chemicals likely to be associated with the poisoning of animals has been included.

The appearance of clinical illness soon after feeding, after a change of ration, after medication or spraying, or after change to new pasture, is a common history in many outbreaks of disease associated with chemical agents. The report which accompanies material for toxicological analysis should include a full record of history, clinical signs and necropsy findings and particularly the results of a search of the environment for access to a poison. If the animal has been treated, the drugs that were used and the dates of administration should be given as they may create difficulties for the analyst. The poison or group of poisons suspected should be defined.

Specimens for analysis should include a sample of the suspected source material. Next most important is a specimen of alimentary tract contents, so that ingestion of the material can be proven, and a sample of tissue, usually liver, to prove that absorption of the poison has occurred. Kidney also provides a route for concentrating many toxicants for excretion and is an important specimen for chemical poisoning. Most toxic chemicals are ingested but percutaneous absorption and inhalation must be considered as possible portals of entry. One of the advantages of an examination of alimentary tract contents is that qualitative tests can be carried out and in many cases this determines whether or not further examination of tissues is necessary.

Additional specimens required other than liver and alimentary tract and contents, vary with the poison and the following list is suggested for the common chemicals:
- Arsenic - kidney, skin, and hair
- Lead - kidney, liver, bones, and whole blood
- Phosphorus - kidney and muscle
- Mercury - kidney, brain if organomercurials are suspected
- Copper - kidney, liver, and blood
- Sodium chloride - alimentary tract and contents, brain, and serum
- Fluorine - bones, teeth, and urine, contaminated forages
- Hydrocyanic acid - ingesta in a filled and airtight container, blood and muscle
- Nitrate and nitrite - ingesta (plus chloroformal or formalin) in an airtight, filled container, blood, ocular vitreous humor
- Strychnine - blood, kidney, and urine
- Insecticides - liver, kidney, brain, fat, ingesta.

Careful packing of specimens is necessary to avoid loss of some poisons by escape gas or conversion by bacterial fermentation, and to prevent contamination. No preservative should be added except in the case of suspected nitrite poisoning. If a preservative is necessary because of distance from the laboratory, packing in dry ice or ethyl alcohol (1 mL/kg of tissue) is advisable; in the latter instance a specimen of the alcohol should also be sent. Ingesta and tissues must be kept separate as diffusion is likely to occur between the two. Specimens should be packed in glass or plastic to prevent contamination by lead in soldered joints of cans. Metal tops on jars should also be separated from the tissues by a layer of plastic or other impervious material. A suitable amount of material should be submitted for analysis: 1 kg of ingesta, 1 kg of liver, 0.5 kg of kidney, and proportionate amounts of other viscera are suggested to cover all contingencies. Urine (200 mL or whatever is available) may allow quick analysis of some toxicants.
Both blood and serum are helpful for rapid testing of some toxicants and for characterizing a potential poisoning through complete blood count and clinical chemistry. Special action is needed when plant poisoning is suspected. First examine the premises for evidence that known toxic plants actually appear to have been eaten. It is possible to ascertain the identity of the plants eaten recently by a careful examination of the ruminal contents. The freshest, least macerated material is best and whole leaves preferred. Atlases of epidermal plant fragments are available to aid in identification of ingested plant species in agricultural animals. Laboratories with sophisticated equipment can now identify most plant toxins in ruminal contents by spectrometric analysis, leaving the veterinarian with the simpler task of deciding whether any of the plants which contain the toxin are present in the environment. At such times access to a computerized data bank of plants and their toxins is a great advantage.

Commonly, with plant poisonings, there are perplexing epidemiological features. For example, animals already grazing in the dangerous field are often unaffected and only those recently introduced may be poisoned. Some of the factors which affect susceptibility to plant poisonings are:

- Hungry, ravenous animals are more likely to be affected.
- Animals thirsty or recently moved to a new location may sample toxic plants.
- Curious, excited animals are likely to sample the plants they would not otherwise eat.
- Young animals are less discerning and are less easily put off.
- Plants that are different in texture, e.g., sprayed weeds, lopped foliage, often appear to be attractive.
- Pica due to mineral deficiency or some other association may encourage toxic plant consumption.
- Genetic selection of animals toward tolerance of a particular poison, e.g., fluoroacetate.

Poisoning is in most instances accidental, although it may occasionally be deliberate. Deliberate or criminal poisoning is often suspected but is rarely proved. If there is a strong suspicion of criminal poisoning, or if litigation appears possible in accidental poisoning, specimens should be collected in duplicate and placed in sealed containers in the presence of witnesses. A complete set of specimens should be available to both plaintiff and defending parties for independent analysis. Also, if litigation appears possible, the veterinarian should make detailed observations of the clinical, pathological, and epidemiological findings and record them in detail. The taking of photographs of affected animals and the environmental surroundings is also recommended for future reference and documentation if necessary.

### MINERAL TOLERANCE OF ANIMALS

One of the very important aspects of toxicology as it applies to agricultural animals is the determination of levels of dietary constituents which the animals will tolerate for a limited period without impairing their performance and without producing unsafe residues in products destined for the human food chain. There is a great deal of information on this subject and it has been collated and published. Table 32.1 is an adapted summary of the information.

### PRINCIPLES OF TREATMENT IN CASES OF POISONING

There are certain principles which apply to all cases of poisoning and they are listed briefly below. The three main principles are:

- Removal of the residual poison from the alimentary tract or skin
- Provision of chemical and physiological antidotes to the poison that has been absorbed
- Effective supportive care, nursing, and convalescent care.

In farm animals, gastric lavage and emetics are of little or no practical value and the removal of residual poison from the alimentary tract depends largely upon the use of adsorbents and purgatives. The only effective adsorbent is activated charcoal. The dose rate is 1–3 g/kg BW repeated as necessary. It adsorbs chlorinated hydrocarbons, organophosphorus compounds, mycotoxins and plant alkaloids, the common feed additives, antibacterial agents and bacterial toxins. It does not adsorb cyanide, heavy metals, halogens, nitrite, alcohols, caustics, sodium chloride, or chlorate. A purgative is necessary to remove the combined adsorbent and poison; it can be administered simultaneously with the adsorbent. The use of irritant purgatives is not advisable when the poison is an irritant and has already been associated with gastroenteritis, and non-absorbable oily purgatives (e.g., mineral oil) are preferable in these cases. Saline purgatives (sodium sulfate) are of value in the treatment of non-irritant poisons such as cyanogenic glucosides. Neutralization of residual poison in the alimentary tract includes use of oxidizing agents or tannic acid preparations for precipitating alkaloids; proteins, including milk and eggs, are effective chemical antidotes for poisons that coagulate proteins; lead is precipitated by the addition of sulfates to the alimentary tract contents.

Poison that has already been absorbed can in some instances be inactivated or its excretion facilitated by the provision of chemical antidotes. For instance, sodium nitrite and sodium thiosulfate are effective systemic antidotes to hydrocyanic acid, and calcium versenate is an effective antidote against lead.

Treatment of the effects of a poison includes provision of physiological antidotes, e.g. the injection of a calcium salt in cases of overdosing with magnesium salts. Ancillary or supportive treatment, including the provision of fluids in dehydration due to diarrhea, demulcents in gastroenteritis, sedatives in excitement, stimulants in cases of central nervous system depression, all treat the effects of poisoning.

It is essential when undertaking the treatment of animals for poisoning, especially those which are producing milk or which are destined to become meat in a short time, to take into account, the possible unsuitability of the product for human consumption because of the presence of the poison or the antidote. Carefully planned sampling in concert with regulatory authorities can avoid unwanted contamination of the human food supply.

Diseases associated with inorganic poisons

LEAD POISONING (PLUMBISM)

**Clinical pathology** Lead levels in blood, feces, liver, kidney, elevated porphyrins in blood

**Lesions** Encephalopathy, degeneration of liver and kidney, pale muscleature, brain laminar cortical necrosis, intranuclear renal inclusion bodies.

**Diagnostic confirmation** Toxic levels of lead in blood and tissues.

**Differential diagnosis list**

**Cattle:** See Table 32.3
- Polioencephalomalacia
- Hypovitaminosis-A
- Ophthalmia
- Hypomagnesemic tetany
- Nervous acetonemia
- Arsenic poisoning
- Clavelceps passpall toxicity
- Meningoencephalitis
- Radies

**Horses:** See Table 22.1.
- Laryngeal hemiplegia
- Viral encephalomyelitis/West Nile virus
- Radies
- Hepatoencephalopathy due to hepatotoxic plants
- Equine degenerative myeloneuropathy
- Protozoal encephalomyelitis
- Equine motor neuron disease
- Horsetail poisoning
- Chronic weight loss
- Chronic upper respiratory tract disease
- Botulism

**Sheep:**
- Enzootic ataxia
- Polyarthritis
- Muscular dystrophy

**Treatment** Calcium versenate and thiamine hydrochloride.

**Control** Prevent access of animals to sources of lead.

**ETIOLOGY**

Lead poisoning is associated with the accidental ingestion of sources of lead metal or compounds or the ingestion of feed, usually forage, containing lead usually from pollution of the environment.

**EPIDEMIOLOGY**

**Occurrence** Lead is one of the most common poisonings in farm animals, especially young cattle. Sheep and horses are also affected but not as commonly. Pigs are not often exposed to lead and appear to be more tolerant to it than other species.

**Cattle.** Data from diagnostic toxicology laboratories illustrate that lead poisoning is the most common toxicosis of cattle. The disease occurred most commonly in younger cattle, with 52% of the cases reported in animals 6 months of age or less. Approximately 60% of the cases occurred during the summer months from May to August, when the cattle have ready access to lead-containing materials such as crankcase oil and batteries that are being changed in agricultural machinery. In many countries the incidence of the disease is highest in cattle in the spring of the year a few days after the animals have been turned out to pasture. Lead poisoning occurs most commonly in young cattle soon after spring turnout when animals gain access to discarded waste materials including batteries, dump oil, oil paint containers, and bonfire ash where painted lumber has been burned. In Alberta, Canada, over a period of 22 years, lead poisoning was the most frequently diagnosed toxicosis of cattle, representing 0.68% of all bovine submissions to the provincial diagnostic laboratories. Young cattle, particularly, are curious and seemingly aim to find sources of lead.

Lead poisoning in cattle is usually due to the accidental ingestion of a toxic quantity of lead over a short period of time. The natural curiosity, licking habits, and lack of oral discrimination of cattle makes any available lead-containing material a potential source of poisoning. Cattle will readily drink crankcase oil, lick machinery grease, and chew batteries. Present-day machinery grease does not commonly contain lead. Compared to earlier times, used crankcase oil may not contain lead if leaded gasoline is banned in a country or region, or if diesel engines are used where lead additive is not utilized in the fuel. In ruminants there is a tendency for metallic lead particles to settle in the reticulum and poisoning results from the gradual conversion of lead particles to soluble lead acetate. Horses, on the other hand, are much more selective than cattle in their eating habits. They usually do not lick old paint cans, lead storage batteries, and peeling paint, nor do they seem to find the taste of used motor oil attractive. Several epidemics of lead poisoning in domestic animals have been recorded throughout the world where the source of the metal was contamination of pasture or crops by nearby industrial lead operation. Animals eating vegetation in these areas may accumulate amounts of lead sufficient to produce clinical signs of lead poisoning.

**Sheep** are usually affected by eating forage contaminated by environmental sources of lead.

**Horses.** Lead poisoning in horses occurs most commonly when they graze lead-contaminated pastures rather than by the accidental ingestion of a toxic amount of lead. Young horses are particularly more susceptible than older horses and cattle grazing on the same pasture. Some cases in horses have been due to ingestion of paint chips from a fence on pasture.
Buffalo. Lead poisoning in buffalos has been reported and provides interesting comparative data; they may have a higher tolerance to lead than cattle.

Morbidity and case fatality
Where groups of animals have access to the same source of lead, outbreaks occur and the morbidity rate ranges from 10 to 30%. The case fatality rate may reach 100% but early intensive therapy can be successful and reduce the figure to less than 50%. In one recorded outbreak, in which a discarded 24-volt battery was accidentally mixed and ground up into the feed of 80 heifers, 55 of the animals died or were destroyed on humane grounds.

Sources of lead
Cattle on pasture. Lead poisoning occurs most commonly in cattle at pasture, particularly if the pasture is poor and the animals are allowed to forage in unusual places, such as rubbish dumps. Phosphorus deficiency may also be a predisposing factor, in that affected animals will chew solid objects as a manifestation of osteophagia. However, cattle on lush pasture may also seek out foreign material to chew. Confined housing of calves with or without overcrowding is often followed by the appearance of pica which may be associated with boredom or mineral deficiency.

Lead paint and lead batteries. The common sources of lead are lead-bearing paints and metallic lead. Discarded lead batteries are one of the most common sources of lead poisoning in cattle. In Alberta, Canada, over a period of 22 years, discarded batteries or used crankcase oil accounted for more than 80% of cases for which the source of lead was determined: batteries, 39.5%; used crankcase oil, 31.6%. The batteries are commonly placed in garbage dumps on the farm and, in temperate climate countries, the batteries freeze during the winter months and break open, exposing the plates which are attractive and palatable for cattle to lick and chew.

Lead contaminated feed. The contamination of forage supplies with shotgun lead pellets used in hunting and shooting exercises, can serve as a source of lead for cattle grazing the pasture or consuming haylage or silage made from the contaminated field. Automobile batteries have been accidentally added to feed mixers where they are ground by powerful augers and mixed into the feed supply of cattle. Feed accidentally contaminated with lead affected some 15,000 cattle on 330 farms in the Netherlands within a 3-month period. Discarded lead-based paint cans are particularly dangerous but fences, boards, and the walls of pens, painted canvas and burlap are also common sources in calves. Painted silos may cause significant contamination of the ensilage. One outbreak of lead poisoning in cattle was associated with silage containing 1200 mg/kg DM lead which had become contaminated by ash and debris left after burning an old lead-containing electrical cable in the silo before it had been filled.

Industrial lead. Metallic lead in the form of lead shot, solder, or leaded windows has been associated with mortalities, although, experimentally, sheet lead is not toxic. Lead sheeting which has been exposed to the weather or subjected to acid corrosion appears to be more damaging, possibly because of the formation of a fine coating of a soluble lead salt. Lead poisoning can be a major hazard in the vicinity of oil fields, and engine sump oil may contain over 500 mg lead per 100 mL. Automotive and other mineral oils are very palatable to young beef calves. In one study, used crankcase oil was the most common source of lead poisoning in cattle, followed by paint, grease, and lead car batteries. As lead use becomes more restricted in many countries, grease and lead contaminated engine oil have become less common sources of lead. Less common but still potent sources of lead are linoleum, roofing felt, putty, automobile oil filters, and aluminum paint. Some of the latter paints contain large quantities of lead, others none at all. Only lead-free aluminum paint should be used on fixtures to which animals have access.

Lead parasiticide sprays, particularly those containing lead arsenate, was once associated with heavy losses in cattle grazing in recently sprayed orchards or vegetable crops. These are not commonly used now, except in some countries, but cattle may accidentally ingest old stores of the compound.

Environmental pollution with lead
Environmental pollution with lead is a common occurrence in cities and on their edges. For farm animals, significant pollution is more likely to occur near smelters or other industrial enterprises, or near major highways where pasture is contaminated by exhaust fumes of automobiles, only if leaded gasoline is still used in the region. Much of the poisoning is subclinical because of the low level of absorption, and any program intending to use domestic animals as monitors of pollution would need to be based on tissue lead levels.

Lead in pastures near highways. The lead levels in whole blood of sheep grazing near main highways in three areas of the Nile delta region of Egypt were 0.062, 0.067, and 0.083 mg/mL (ppm). Pasture adjacent to heavily used roads may carry as much as 390 mg/kg of lead, in contrast to 10 mg/kg on lightly used roads. The concentration of lead on pasture varies markedly with proximity to the traffic, falling rapidly the greater the distance, and with the time of the year. Pastures contaminated by smelters are recorded as carrying 325 mg/kg of lead (equivalent to a daily intake for an animal of 6.4 mg/kg BW). In some locations near lead smelters, lead poisoning is considered to be a predictable occurrence in horses which are allowed to graze on local pastures. As a result horses are either not raised in these areas or hay is imported from other areas. Although ingestion is the principal method of poisoning of animals, inhalation may also be a significant method of entry for cattle grazing close to smelters or highways.

Lead, cadmium, and zinc. Lead as an environmental contaminant is often combined with cadmium which has some effects similar to those of lead so that the effects may be somewhat additive. Experimental poisoning with both elements is associated with reduced weight gains in calves at dose levels up to 18 mg/kg BW of each, and clinical signs appear at levels above 18 mg/kg BW of each. Lead is also combined with chrome for industrial purposes. It is not toxic when combined with lead at lead intake levels of 100 mg/kg BW.

Environmental pollution in the vicinity of lead and zinc ore processing factories can result in varying degrees of poisoning with lead, zinc, and cadmium. These can be monitored by the analysis of blood, hair, and tissues obtained at necropsy.

Lead in human food chain. There is some concern that toxic levels of lead may occur in the human food chain. Canadian studies of the lead and mercury residues in kidney and liver of slaughtered animals have shown that all levels were below the official tolerance level of 2 mg/kg WW for lead and 0.5 mg/kg for mercury. Levels of lead in beef randomly selected from supermarkets in the US were for muscle 0.46, liver 0.50, and kidney 0.45 mg/kg (WW). The upper range of liver levels exceeded the 1 mg/kg WW guideline which may cause for concern about the source of the lead. Moderate exposure of people to meat, including liver and kidney, from animals exposed to lead poisoning is thought not to represent a human health hazard. The biological monitoring of cadmium and lead from contaminated sandy soil into sudan-sorghum hay consumed by pregnant dairy goats over a period of 98 days revealed that only miniscule amounts of soil cadmium and...
lead were retained in the selected animal tissues (liver and kidney) via the ingestion of the hay.23 It was concluded that if these animal tissues were used as food, no deleterious effect to human health would be induced.

**Lead in blood, milk, kidneys, and liver.** The relationship between lead concentrations in blood of cattle with lead poisoning and those in the milk is exponential.20 The lead level in milk is 0.2-0.3 mg/L, and increases sharply if the concentration of lead in whole blood resulting from the daily exposure to lead which does not produce any clinical evidence of disease.21 The background levels of blood lead which have been reported ranged from 3 to 50 μg/dL, but most were less than 10 μg/dL. A recent analysis of 266 blood samples from dairy cattle submitted to the diagnostic laboratory at the New York State College of Veterinary Medicine, for reasons other than heavy metal toxicity, indicated that 259 (97%) had levels lower than minimum detectable level of 2.5 μg/dL (0.025 ppm).22 Six had concentrations between 2.6 and 5.8 and one had 10 μg/dL. Blood lead concentrations in cows with lead poisoning ranged from 56.4 to 1390.0 μg/dL.

**Toxic levels of lead**

The toxic level of lead varies between species and the chemical composition of the compound containing lead may influence its toxicity. Lead acetate is very soluble and more toxic than insoluble lead oxide, or solid lead sheeting.

**Acute lethal single doses.** In calves, acute single lethal doses range from 400 to 600 mg/kg body weight (BW), in adult cattle 600-800 mg/kg and for goats 400 mg/kg. The acute dose for horses is less than for ruminants, one horse having survived 1000 mg/kg BW on two occasions 6 months apart. Pigs are also less susceptible but single lethal dose levels are not recorded. Buffalo calves given a single oral dose of 600 mg/kg BW of lead acetate died within 120 hours.23 Young animals, e.g. milk-fed calves, are more susceptible. A daily intake of 2.7 mg/kg BW of lead can be associated with the death of calves fed a milk diet in 20 days or less, while 5 mg/kg BW of lead is consistently associated with signs of poisoning or death within 7 days. The absorption rate of lead is rapid and tissue depositions are high in calves on a milk replacer diet and given lead. In toxicity studies, calves on a milk diet absorb lead much more quickly than calves fed a grain diet. The addition of lactose to a grain diet will also increase the absorption of lead.

**Daily dose levels likely to lead to chronic poisoning** are important because of the impact that contamination of the environment by industrial effluents has had. Daily dose levels likely to lead to chronic plumbism in cattle are 6-7 mg/kg BW (equivalent to 100-200 mg/kg DM of diet). This dose level must be close to the definitive point because dose levels of 100 mg/kg (in diet) may be without effect. A dose level of 15 mg/kg BW results in the loss of weight gain and normochromic anemia. In sheep, dose levels of more than 4.5 mg/kg BW are necessary to produce a toxic effect. Horses are more susceptible to the daily administration of lead, 100 mg/kg BW producing toxic effects in 28 days. A dose rate of 15-30 mg/kg BW of lead for up to 190 days is associated with toxicity and some deaths, and deaths are recorded on pastures carrying 100-300 mg/kg on foliage. Pigs appear to be more resistant, and daily doses of 33-66 mg/kg BW were required for periods of up to 14 weeks to produce fatal effects, a more serious end-point than for the other dose rates quoted.

**PATHOGENESIS**

Regardless of the chemical form of the ingested lead, only a small proportion is absorbed because of the formation in the alimentary tract of insoluble lead complexes which are excreted in the feces. For example, only 1-2% of lead ingested as lead acetate or carbonate is absorbed from the alimentary tract of sheep. Of the lead absorbed, some is excreted in the bile, milk, and urine and the blood levels of lead provide a reliable indication of the lead status of the animal. Urine levels may not be as reliable. Deposition in tissues occurs, particularly in the liver and renal cortex and medulla in acute poisoning and in the bones in chronic poisoning. The deposition of lead in the brain is not high compared to other tissues but deposited lead is gradually liberated from tissues into the bloodstream and excreted via the bile and urine. Consideration must be given to these aspects of lead metabolism when assessing the results of chemical analyses of tissues.

Although acute lead poisoning usually develops rapidly there may be a delay of several days after toxic material has been ingested before clinical signs appear.

**Toxic effects of lead**

The toxic effects of lead are manifested in three main ways:

- Lead encephalopathy
- Gastroenteritis
- Degeneration of peripheral nerves.

In general, acute nervous system involvement occurs following the ingestion of large doses in susceptible animals such as calves, alimentary tract irritation following moderate doses, and peripheral nerve lesions following long-term ingestion of small amounts of lead. The nervous signs of encephalopathy and the lesions of peripheral nerve degeneration are due to the degenerative changes of nervous system tissue. Lead localizes principally in the cytoplasm of capillary endothelial cells and these localizations are later associated with the development of edema. The basic lesion is likely to be vascular with a basic change in transport mechanisms between the blood and brain.24 Gastroenteritis is associated with the caustic action of lead salts on the alimentary mucosa. Ruminal atony occurs in cattle and sheep and initially is associated with scant feces, followed later in some cases by diarrhea due to gastroenteritis. The rumen protozoa in cattle with acute lead poisoning are commonly absent or inactive. Peripheral nerve degeneration occurs principally in horses.

The lesions, including degeneration of the liver and kidney, vary in their severity with the tissue levels of lead attained. Lead does not remain in tissues for long periods except in bone where it is deposited in an inert form, but from which it can be liberated at a later date in sufficient quantities to be associated with chronic lead poisoning. This is particularly likely to occur during periods of acidosis.

The blue 'lead-line' at the gum–tooth junction, which is seen in man and the
dog does not commonly occur in ruminants because of failure to form tartar but may be present in the horse. The 'lead-line' is a deposit of lead sulfide formed by the combination of lead with sulfide from the tartar.

Lead is transferred across the placental barrier and high liver levels occur in the lambs of ewes fed more than normal amounts of lead. Calves born from cows experimentally poisoned with lead have elevated levels of lead in bone, kidney, and liver. In a naturally occurring case of lead poisoning in a pregnant heifer, the blood and liver concentrations in the fetus were 0.425 ppm and 4.84 ppm, respectively, which was 72% and 84% of the same tissue lead concentrations of the dam.25 Hepatic lysosomes of the fetus contained metallic electron densities which may have been lead.

The pathogenesis of the osteoporosis in young lambs with chronic lead poisoning has not been explained, nor has the paresis and paralysis of lambs which occur in the same circumstances. The paralysis in the former condition is caused by compression of the spinal cord by collapsed lumbar vertebrae.

Anemia may occur in chronic lead poisoning. The erythrocytes are microcytic and hypochromic, and reticulocytosis and basophilic stippling may be observed. However, basophilic stippling is non-specific and probably does not correlate well with levels of lead exposure. The basophilic stippling of erythrocytes is usually an indication of bone marrow response to anemia, although it can occur, rarely, in chronic lead poisoning. It may be related to the effects of lead on pyrimidine nucleotidase activity. The anemia in chronic lead poisoning is associated with two basic defects: a shortened erythrocyte lifespan and impairment of heme synthesis. Lead is associated with an increased concentration of protoporphyrin by inhibiting heme synthetase, the enzyme which combines protoporphyrin and iron to form heme. The measurement of free erythrocyte protoporphyrin is considered to be a sensitive indicator of chronic lead poisoning in calves. Lead is also associated with an inhibition of the enzyme delta-aminolevulinic acid dehydratase (ALA-D), resulting in a failure of utilization of delta-aminolevulinic acid which is excreted in increased quantities in the urine.

CLINICAL FINDINGS

Cattle

Both acute and subacute poisoning occurs in cattle. The acute form is more common in calves and the subacute form in adults.

In the acute form there is usually a sudden onset of signs and a short course of 12–24 hours so that many animals, especially those that are pastured, are found dead without signs having been observed. Staggering, and muscle tremors particularly of the head and neck, with champing of the jaws (chewing gum fits) and frothing at the mouth are obvious. Snapping of the eyelids, rolling of the eyes and bellowing are common. Blindness and cervical, facial and auricular twitching are consistent in acute lead poisoning of cattle. The animal eventually falls and intermittent tonic–clonic convulsions occur and may continue until death. Pupillary dilatation, opisthotonos and muscle tremor are marked and persist between the convulsive episodes. There is hyperesthesia to touch and sound, and the heart and respiratory rates are increased. In some cases, particularly in adults, the animal remains standing, is blind, maniacal, charges into fences, attempts to climb or jump over walls, and head-presses strongly against walls or fences. Frenzy is common and some animals appear to attack humans but the gait is stiff and jerky and progress is impeded. Death usually occurs during a convulsion and is due to respiratory failure.

In the subacute form the animal remains alive for 3–4 days. There is dullness, total anorexia, blindness, and some abnormality of gait including incoordination and staggering, and sometimes circling. The circling is intermittent and not always in the same direction and usually occurs when the animal is confined in a small space like a box stall. Muscle tremor and hyperesthesia are common but not as pronounced as in the acute form. Grindng of the teeth is common, excessive salivation may occur, and mild abdominal pain may be seen occasionally. Alimentary tract dysfunction is one of the most common abnormalities. Ruminal atony is accompanied by constipation in the early stages. Later a febrile diarrhea occurs in most cases.

The animal presents a picture of extreme dullness, will not eat or drink, and stands immobile for very long periods. Death frequently occurs by misadventure, the animal walking blindly into a waterhole or being trapped in a fence or between trees. In other circumstances the animal becomes recumbent and dies quietly. In both the acute and subacute forms, the palpebral eye preservation reflex is absent or markedly diminished. This is a useful distinguishing feature from poliomyelomalacia in which this reflex is usually normal. Edema of the optic disc may be present but is not common.

Experimental lead poisoning in young milk-fed calves, initially is characterized by severe depression and hypoglossal paresis which interferes with sucking. Within the next 12–24 hours, the calves become unsteady, ataxic, and exhibit muscular tremors of the head and forelimbs and finally convulsions, opisthotonos; they die in respiratory failure during status epilepticus.

Sheep

Lead poisoning in sheep is usually manifested by a subacute syndrome similar to that seen in adult cattle. There is anorexia and scant feces followed by the passage of dark, foul-smelling feces. Weakness and ataxia follow, often with abdominal pain, but there is no excitement, tetany, or convulsions. Polyuria occurs when the intake of lead is small but with large amounts there is oliguria.

Although ruminants are relatively resistant to chronic lead intoxication, two syndromes of posterior paresis have been described in young lambs in old lead-mining areas and tissue levels of lead are abnormally high in both instances. In both syndromes there is impairment of the gait. Osteoporosis is present in one but in the other there is no suggestion of skeletal changes. In the osteoporotic disease the signs occur only in lambs 3–12 weeks of age and never in adults. There is stiffness of gait, lameness, and posterior paralysis. Affected lambs are unthrifty and the bones, including the frontal bones, are very fragile. The paralysis is caused by lesions of the vertebrae, usually affecting one or more of the lumbar bones, and resulting in compression of the spinal cord. In the other form, gait abnormalities occur in the same lamb age group and are manifested initially by incomplete flexion of the limb joints so that the feet drag while walking. In a later stage the fetlocks are flexed, the extensor muscles paralytic, and the lamb soon becomes recumbent. Recovery is common, although many lambs die of intercurrent disease.

Chronic ingestion of metallic lead by pregnant sheep can be associated with abortion and transitory infertility.26

Horses

Horses are not commonly affected by lead poisoning, although the chronic form occurred occasionally in the vicinity of lead mines and processing works.27 The clinical findings are extremely variable.2 A roughened hair coat, pharyngeal dys-function, and weight loss were the most common clinical findings in 10 case reports involving a total of 68 animals.5 Some horses died without any previous clinical illness but where clinical signs are apparent they were usually distinct and dramatic rather than subtle. Inspiratory dyspnea associated with paralysis of the recurrent laryngeal nerve is the most
common finding. This may be accompanied by pharyngeal paralysis in which recurrent choke and regurgitation of food and water through the nostrils occurs. Aspiration pneumonia may result after inhalation of ingesta through the paralyzed larynx. Paralysis of the lips occasionally accompanies the other signs. General muscle weakness and stiffness of the joints occur commonly and the hair coat is usually harsh and dry. When chronic poisoning with both lead and zinc occurs the signs in zinc poisoning predominate despite high lead levels in liver and kidney. In experimental chronic lead poisoning in horses, there is noisily breathing constantly, but no lesions in the pharynx or larynx. Muscle fasciculations over the triceps are prominent in some horses and recumbency and convulsions may occur. When large amounts of lead are ingested by horses a syndrome similar to that of the subacute form in cattle occurs. There is complete anorexia, severe nervous depression, partial paralysis of the limbs followed in most cases by complete paralysis and recumbency. Mild-to-severe abdominal pain and clonic convulsions may also occur. The response to experimental lead poisoning in the horse is highly variable. The dose-response effect is highly variable and unpredictable.

**Pigs**

Early signs include squealing as though in pain, mild diarrhea, grinding of the teeth, and salivation. The disease is usually a prolonged one and listlessness, anorexia, and loss of weight develop followed by muscle tremor, incoordination, partial or complete blindness, enlargement of the carpal joints, and disincination to stand on the front feet. Convulsive seizures occur in the terminal stages.

**Subclinical lead poisoning**

Because of the present concern about environmental pollution, the effects of the chronic low-level intake of lead have been examined and defined. In cattle, at intake levels below those which are associated with clinical signs, there are metabolic changes and changes in blood variables accompanied by a decreased rate of growth. One concern is that continuous low-level consumption by pregnant females will result in teratogenic effects in the newborn. Trials to detect this manifestation in ewes have shown no effect on their lambs.

**CLINICAL PATHOLOGY**

In the living animal which has ingested lead, the element can be detected in blood, feces, urine, and milk.

**Blood lead**
The estimation of blood levels is generally useful for determining the lead status of the animal and is used most frequently to support or refute a clinical diagnosis of lead poisoning. Bovine blood lead reference materials are available and have been certified for many years. Whole blood levels of lead in normal ruminants are usually below 0.05–0.25 ppm; poisoned animals usually have levels above 0.35 ppm and deaths begin at 1.0 ppm. Interestingly, buffalo may have blood levels above 1.0 ppm and still survive, which suggests that they have a higher tolerance level than cattle. However, when used alone, blood lead concentrations do not permit evaluation of length of exposure or amount of lead deposition in the body or the effects of lead on physiological systems. Blood lead concentrations also fluctuate markedly after administration of lead and consequently the clinical importance of blood lead concentrations is often questionable and a diagnosis based on this single determinant is equivocal. Blood lead concentration also has limited value for assessing the effectiveness of therapy for lead poisoning. Blood lead concentrations may change rapidly during chelation therapy, often decreasing by 50% or more within 24 hours after initiation of treatment despite certain body tissues still containing high concentrations of lead. Thus the evaluation of biochemical indicators such as ALA-D may be useful. The blood and liver levels of fetuses from pregnant cattle with lead poisoning may be higher than what are considered toxic levels in adults which suggests concentration in the fetus.

Representative values of lead for normal and poisoned animals are summarized in Table 32.2. The levels found in the liver and the kidneys are presented under necropsy findings.

**Milk lead**

Only limited information is available on the concentrations of lead which occur in cattle affected with field cases of lead poisoning. Lead levels of 0.13 mg/L of milk have occurred in natural cases with a half-life of 4.6 days. The regulatory limit for lead in bovine milk in the Netherlands is 0.05 mg/L milk. In acute lead poisoning in lactating buffalo pastured near smelters in India, the lead concentrations in milk were 1.13 ppm compared to 0.24 ppm in the milk from bufferes in unpolluted areas. The mean lead concentrations in the forage of poisoned animals were 706 ± 73.0 ppm, compared to the unpolluted area of 78 ± 12 ppm.

**Fecal lead**

Fecal levels of lead represent unabsorbed and excreted lead deriving from the bones, and are of limited value unless considered in conjunction with blood levels because ingested lead may have been in an insoluble form and harmless to the animal. When fecal levels are high it can be assumed that the lead has been ingested in the preceding 2–3 weeks but high blood levels may be maintained for months after ingestion. Thus high blood and low fecal levels indicate that the lead was taken in some weeks previously but high blood and high fecal levels suggest recent ingestion and significant absorption.

**Urinary lead, ALA-D**

Urine lead levels are variable, rarely high (0.2–0.3 mg/L), and although elevated urine levels are usually associated with high blood levels, this relationship does not necessarily hold.

Because of some of the limitations of blood lead, other indirect measurements of lead poisoning, such as the levels of delta-aminolevulinc acid dehydratase (Delta-ALA-D) in blood, are being used to supplement blood lead determinations. For example, the best method of detecting the presence of lead poisoning in its early stages, except in the horse, is the estimation of ALA-D in the blood. At dietary intakes as low as 15 mg/kg DM of lead in cattle there are detectably lowered levels of ALA-D. At the same time, the urinary levels of delta aminolevulinic acid (Delta-ALA) are increased. Delta-ALA-D is important in the synthesis of heme and is probably the most sensitive enzyme in the heme pathway. Inhibition of the enzyme results in a block in the utilization of delta-ALA, a subsequent decline in heme synthesis and a marked increase in the urinary excretion of delta-ALA. In cattle, sheep, and pigs affected with chronic lead poisoning, the plasma levels of delta-ALA-D are decreased and the urinary levels of delta-ALA are increased before clinical signs are detectable. In sheep, erythrocyte delta-ALA-D is recommended as the most sensitive diagnostic test available.
The disadvantages of the assay for blood delta-ALA-D include age-related variations particularly in calves; the methods used for analysis are not yet uniform and blood must be collected in polystyrene or polyethylene tubes rather than glass tubes and an anticoagulant other than EDTA must be used. The levels of delta-ALA-D increase in calves from birth to 10 weeks of age and age-matched controls should be evaluated simultaneously when conducting the test in calves of under 6 months of age. In cattle under 1 year of age, delta-ALA-D values of less than 200 nmol of porphobilinogen (PBG)/mL of RBC/hour should raise suspicion of their having ingested lead. In this same age range values below 100 nmol would confirm ingestion of lead. In cattle equal to or less than 2 years of age, values of delta-ALA-D of less than 100 nmol of PBG/mL of RBC/hour would indicate ingestion of lead. Severe inhibition of delta-ALA-D occurs rapidly in calves given 1 mg of lead/kg BW per day or 5 mg of lead/kg BW/d. Inhibition of delta-ALA-D will reach approximately 50% of pre-exposure levels when blood lead concentrations are above 0.5 mg/kg, and if the initial dose of lead increases blood lead concentration above 0.5 mg/kg the delta-ALA-D becomes maximally depressed and remains so with continued exposure. The delta-ALA-D is so sensitive to lead that it remains inhibited even after lead exposure has ceased. Following treatment with a chelating agent the blood lead levels will often decline giving a false indication of a positive treatment effect. If the delta-ALA-D levels do not decrease following therapy, it indicates that there is sufficient lead present to continue to depress the enzyme. In summary, the evaluation of delta-ALA-D and blood lead concentrations together can assist in resolving diagnostic situations in which the blood lead concentration is in the questionable range of 0.25-0.35 ppm.

**Environmental lead**

Because of the frequency with which lead appears in the environment as a pollutant, there is often concern for the validity of the normal values for establishment of a diagnosis. In the average city-polluted atmosphere it seems that lead intake will be significantly elevated. The lead content of hair of cattle and horses, and of the wool of sheep, is reported to be raised significantly in poisoned animals but hair is not routinely used in diagnosis of acute poisoning. However, the lead content of hair when cattle are exposed to long-term ingestion as a result of industrial contamination can reach as high as 88 mg/kg (in a clean environment comparable figures are of the order of 0.1 mg/kg). There is likely to be a seasonal variation in deposition and intake of lead. Hair is also a valuable source of information on environmental pollution with cadmium, copper, and zinc.

**Hematology**

In chronic lead poisoning, hematological examination may reveal a normocytic, normochromic anemia in some and, although basophilic stippling does not occur often enough to be diagnostic, it is recorded in some experimental poisonings. It is recorded as occurring in lead-exposed pigs and a horse. In some, poikilocytosis and anisocytosis were marked. The cerebrospinal fluid (CSF) is approximately normal with slightly elevated leukocyte numbers but no increase in protein or other biochemical components.

**NECROPSY FINDINGS**

In most acute cases there are no gross lesions at necropsy. In cases of longer standing there may be some degree of abomasitis and enteritis, diffuse congestion of the lungs and degeneration of the liver and kidney. Episceral hemorrhages are common. Congestion of meningeal and cerebral vessels may also be observed and hemorrhages may be present in the meninges. An increase in cerebrospinal fluid is often recorded but is of minor degree in most cases. In chronic cases gross lesions are recorded in cattle. These include cerebrocortical softening, cavitation and yellow discoloration with more severe lesions in the occipital lobes. Histological lesions were most severe at the tips of the gyri. Similar lesions were produced experimentally. Acid-fast inclusion bodies deep in the renal cortex have diagnostic significance. Examination of the contents of the reticulum in ruminants for particulate lead matter is essential. Fleshes of paint, lumps of red lead, or sheet lead usually accumulate in this site. Their absence is not remarkable especially if animals have licked fresh paint but their presence does give weight to the provisional diagnosis.

**Liver and kidney lead**

The submission of alimentary tract contents and tissues for analysis forms an important part of the diagnosis of lead poisoning but results must be interpreted with caution.

**Cattle**

25 mg/kg of lead WW (wet weight) in kidney cortex is diagnostic and is a more reliable tissue for assay than liver which may contain 10-20 mg/kg WW. The concentrations in kidney are always much higher than in liver. A diagnostic laboratory found mean levels in livers of poisoned cattle of 93.3 pg/g WW weight, and 437.7 pg/g in kidneys. Tissue lead levels in cattle from industrial areas are significantly higher (liver 0.23 mg/kg WW, kidney 0.42 mg/kg WW) than in cattle from clear air zones (liver and kidney less than 0.1 mg/kg WW). Tissues which have been fixed in formalin are useful when they are the only tissues available.

**Horses**

Levels of 4-7 mg WW of lead have been found in the livers of horses dying of chronic lead poisoning but 25-250 mg/kg are more likely, and 40 mg/kg WW may occur in the livers of affected pigs. Mean levels in livers of poisoned horses are 5.5 mg/g WW.

**Samples for confirmation of diagnosis**

- **Toxicology** – 50 g liver, kidney, and reticulum content (ASSAY (Pb))
- **Histology** – formalin-fixed cerebral cortex, kidney (LM).

**DIFFERENTIAL DIAGNOSIS**

In all cases, much importance must be attached to the possibility of access to lead and the environmental circumstances which may arouse suspicion of other poisonings or errors in management. Estimation of the lead content of blood and feces should be carried out at the earliest opportunity and tissues form necropsy specimens submitted for analysis.

**Cattle**

Lead poisoning in cattle must be differentiated from the common diseases of the nervous system of cattle and other diseases in which neurological signs occur. The differential diagnosis of brain dysfunction and lead poisoning in cattle is summarized in Table 32.3. The diseases which closely resemble bilateral blindness are as follows:

- **Rabies** characterized by normal eyesight, incoordination, gradual ascending paralysis, inability to swallow, bellowing and death in 4-7 days.
- **Polioencephalomalacia** characterized by sudden onset of blindness, normal palpebral reflexes to touch, head pressing, tremors of head and neck, nystagmus, normal ruminal contractions.
- **Hypovitaminosis-A** characterized by blindness, dilated and fixed pupils, optic disc edema, convulsions followed by recovery.
Ophthalmitis characterized by blindness due to lesions of the eyes but normal mentation.

Other diseases in which blindness is not characteristic but tremors, ataxia, convulsions, and bizarre behavior occur include: hypomagnesemic tetany, nervous actonemia, arsenic poisoning, Claviceps paspali toxicity, memingoencephalitis.

Horses
Lead poisoning in horses must be differentiated from diseases causing loss of body weight, muscle fasciculations, incoordination, roughened hair coat, laryngeal and pharyngeal dysfunction. The differential diagnoses of diseases of the nervous system of the horse are summarized in Table 22.1. The diseases most closely resembling lead poisoning in horses include:

- Laryngeal hemiplegia
- Viral encephalomyelitis, including West Nile virus
- Rabies
- Hepatonecephalopathy due to hepatotoxic plants
- Equine degenerative myeloencephalopathy
- Protozoal encephalomyelitis
- Equine motor neuron disease
- Horsetail poisoning
- Chronic weight loss
- Chronic upper respiratory tract disease
- Botulism
- Fumonis in toxicosis (equine leukoencephalomacia)

Sheep
The chronic forms of lead poisoning in lambs must be differentiated from other forms of posterior paralysis, particularly:

- Enzootic ataxia due to copper deficiency
- Polyarthritis due to bacterial infection
- Enzootic muscular dystrophy which may be associated with lameness and paresis but may be distinguished clinically by careful examination of the joints and skeletal muscles.

**TREATMENT**

Sedation and care
The case fatality rate of acute lead poisoning of cattle is high because of their high susceptibility and the nature of the material ingested. Sedation by IV injection of anesthetic doses of pentobarbital sodium in calves and chloral hydrate in adults temporarily relieves the convulsions.

Calcium versenate
Calcium versenate (calcium disodium ethylenediamine tetra-acetate, CaEDTA) has been used successfully in cases of lead poisoning produced experimentally in calves and in natural cases in cattle.

CaEDTA is available as a 6.6% solution for IV administration. The manufacturer’s recommendations are to use 1 mL/kg BW per day given in divided doses 2–3 times daily over a period of 3–5 days. Based on the treatment of experimentally induced lead poisoning in calves, the optimum conditions for lead mobilization in calves are provided by concentrations of about 135 µmol EDTA/mL, or higher, maintained for 10–12 hours. This is attained by the IV infusion of calcium EDTA at a dose of 110–220 mg/kg BW over 12 hours, which is approached by rapid IV injections of two doses of 110 mg/kg BW weight, 6 hours apart. This can be done daily for 3–5 days.

CaEDTA removes lead directly from bone-sensitive sites and not from parenchymatous organs because cell membranes form a barrier to the therapeutic removal of intracellular lead. The lead is removed from soft tissues by equilibration with bone. The process takes time and thus necessitates multiple treatment. Thus it is recommended that calcium versenate be given on alternate days to allow redistribution of lead from soft tissues to available bone sites. An increase in the heart and respiratory rates and the development of muscle tremors during injection indicates a toxic reaction but can be avoided by slow administration. Recovery may take 5–15 days and parenteral or stomach tube alimentation may be required. Blindness may persist for several days after general recovery and may continue indefinitely. Dramatic improvement has also been reported in cases of chronic lead poisoning in horses after the use of calcium versenate.

**Thiamin hydrochloride**
In combination with CaEDTA, thiamin is now being used for the treatment of lead poisoning. Thiamin hydrochloride reduced the deposition of lead in most tissues especially liver, kidney, and the central and peripheral nervous system of experimentally poisoned calves. However, the levels of erythrocyte delta-aminolevulinic acid dehydratase (ALA-D) activity were decreased by 70% from pretreatment levels which indicated that thiamin had no protective effect on the ability of lead to inhibit the enzyme.

Thiamin hydrochloride reduced the deposition of lead in most tissues especially liver, kidney, and the central and peripheral nervous system of experimentally poisoned calves. However, the levels of erythrocyte delta-aminolevulinic acid dehydratase (ALA-D) activity were decreased by 70% from pretreatment levels which indicated that thiamin had no protective effect on the ability of lead to inhibit the enzyme.

In experimental lead poisoning in mature dairy cows, the use of thiamin was not successful in reducing blood lead concentration, but treatment with disodium CaEDTA and thiamin was effective. The use of thiamin also induced a remission of clinical signs of lead poisoning in cattle. Thus thiamin increases the elimination of lead from the body and may be beneficial in chelation therapy.

In naturally occurring cases in cattle, the use of thiamine and CaEDTA increases urinary lead output nearly a thousand times the untreated urinary level.

The blood and urinary lead half-lives with CaEDTA and thiamine therapy were 208 and 1.38 days, respectively.

In experimental lead poisoning in calves, thiamin at 25 mg/kg BW SC BID cured 50% of affected calves. The same dose of thiamin combined with 110 mg/kg BW of calcium versenate IV BID cured 100% of affected calves which had been given lead acetate at 5 mg/kg BW orally until clinical signs occurred. CaEDTA chelates lead from blood and bone while thiamine chelates lead in soft tissues and restores lead-induced biochemical alterations.

In experimental lead poisoning in laboratory rats and mice, thiamin at a dose of 25 or 50 mg/kg BW along with CaEDTA at 50 mg/kg BW was more effective than the respective individual treatments alone. Thiamine alone decreased the blood, liver, and kidney concentrations of lead, and thiamin at 50 mg/kg BW reduced the tissue concentrations in tissues more effectively than 25 mg/kg BW.

In experimental lead poisoning in sheep, the use of thiamin at 75 mg/kg BW SC along with CaEDTA at 100 mg/kg BW IV, increased the excretion of lead via the bile and urine. Overall, thiamin, CaEDTA, and thiamin and CaEDTA increased lead excretion by 72%, 595%, and 842%, respectively, over basal levels.

It appears that thiamin can mobilize intracellular lead into blood and increase lead excretion via bile and urine.

**Rumenotomy**
Rumenotomy to remove the ingested lead has been used but may be unsatisfactory because of the difficulty of removing particulate material from the recesses of the reticular mucosa. However, it may be appropriate when a valuable animal is affected and it is known that the animal ingested a certain compound of lead which may be removable from the reticulum and rumen. Oral dosing with small amounts of magnesium sulfate has been used on the basis that soluble lead salts will be precipitated as the insoluble sulfate and excreted in the feces. However, the lead is often present in large quantities and in the form of particles which are only slowly dissolved.

**Public health aspects of lead in meat and milk**
A major concern with the treatment of lead poisoned animals, particularly food-producing animals, is the assurance that the edible tissues of recovered animals do not contain toxic levels of lead. The length of time required after successful treatment of cattle with typical clinical lead poisoning before such animals can be sent to slaughter or before the milk can be used safely is not known. It is suggested that treated animals should be appropriately identified and blood lead levels determined once or twice monthly for several months. When the blood lead levels have dropped to background levels for three consecutive samplings at least 2 weeks apart, the animals are assumed...

to be safe for slaughter. Undocumented field observations suggest that at least 6 months are necessary for background levels to be achieved. Recently, a study in dairy cattle determined a blood lead half-life that ranged from 48 to 2507 days. This was presumed due in part to exposure to molasses-urea-protein blocks. Toxic agent may be substituted imidazole formed by combination of soluble carbohydrates and ammonia. Usually occurs when high quality forage treated with ammonia concentrate of more than 3% dry matter by weight. Can occur in nursing cows fed ammoniated feedstuffs containing pyrrolizidine alkaloids Many cattle may be affected.

### REFERENCES
ARSENIC POISONING

Synopsis

Etiology Insecticidal dipping fluids, sprays; herbicides, wood preservatives, pharmaceuticals, feed additives. Inorganic compounds most toxic; organic arsenicals least.

Epidemiology Outbreaks due to accidental access to source, or due to use of excessive amounts as a dose rate or over time. Most cases result from ingestion but percutaneous absorption also possible.

Clinical signs Enteric form a highly fatal gastroenteritis with diarrhea, dehydration. Nervous form with incoordination and blindness; or a syndrome of incoordination, restlessness, squealing, convulsions.

Clinical pathology High levels of arsenic in feces, urine, milk for 5 days (organic arsenicals), 10 days (inorganic arsenic). Chronic cases best assayed in hair or skin.

Necropsy lesions Gastroenteritis in enteric form, no lesions in nervous form.

Diagnostic confirmation Higher than normal levels of arsenic in body fluids or tissues.

Treatment

Primary: 2,3-dimercaptopropanol (BAL) or sodium thiosulfate.

Supportive: fluids, electrolytes for dehydration.

ETIOLOGY

Arsenic compounds likely to be encountered by large animals are as follows:

**Inorganic compounds used as insecticidal dips or as herbicides**

- Oxide, e.g. arsenic trioxide
- Trivalent, e.g. sodium arsenite
- Pentavalent, e.g. sodium arsenate.

**Organic compounds**

Aliphatic organic arsenicals:

- Pharmaceuticals, e.g. cacodylic and phenylarsenyl acids
- Weedicides, e.g. monosodium, and disodium methanearsonates (MSMA & DSMNA).

Aromatic organic arsenicals, used as pharmaceuticals:

- Trivalent phenylarsonic arsenicals, e.g. thiacetarsamide and arsphencomplexamine
- Pentavalent phenylarsonic arsenicals, e.g. arsenic acid, roxarsone (4-hydroxy-3-nitrophenylarsonic acid), nitalnarsone (4-nitrophenoxyphenylarsonic acid).

Relative toxicities

Inorganic and aliphatic compound poisoning. The organic pharmaceuticals are the least toxic, while the insoluble oxides of medium toxicity and the trivalent inorganic compounds are associated with the most severe syndrome. Toxic oral doses may range from 1 to 25 mg/kg for the arsenite, 30–100 mg/kg for the arsenate, cacodylic acid 25 mg/kg daily for 8–10 days, and 10–25 mg/kg for 5–6 days for the methanearsonates.\(^1\)\(^2\)

Aromatic organic arsenicals are toxic when the recommended cumulative dose is exceed by 2–4 times the recommended dose, delivered by either exceeding the recommended percentage in the feed or feeding it for too long. Seven to 10 days feeding of Arsanilic acid at 500 mg/kg diet or 3-nitro, 4-hydroxyphenylarsenic acid at 250 mg/kg diet will be associated with toxicosis in swine; approximately twice these concentrations will result in poisoning of poultry.\(^1\)

EPIDEMIOLOGY

Occurrence

Arsenic is less commonly associated with the poisoning of livestock nowadays because of the displacement of arsenic from almost all phases of farming activity.

Source of toxin

Arsenic is indestructible and remains in the environment permanently so that the source may not be recorded in contemporary history.

Dips and sprays. Fluids used for dipping and spraying of animals to control ectoparasites are the commonest source. Animals may swallow the solution while in the dip or in the draining yards after dipping. Animals that are not allowed to drain completely and faulty disposal of drainage from yards and dips may contaminate the pasture. Opened containers of dipping solutions or powders may accidentally contaminate feed or be mistakenly applied as a skin dressing. Appreciable amounts of arsenic are absorbed through the skin after dipping in sodium arsenite. The absorption is increased if the animals are dipped when hot, if the fleece is long, or if they are crowded too tightly in draining yards or driven too soon after dipping. However, in most outbreaks of poisoning some ingestion appears to occur and supplements the cutaneous absorption. There is some danger in dipping rams at mating time when erythema of the skin of the thighs and scrotum is present. Dipping immediately after shearing and jetting at too high pressure or with excessively strong solutions may also be associated with increased absorption.

Herbicides include sodium or potassium arsenite, arsenic pentoxide, and monosodium or disodium acid methanearsonate sprays used to kill potato haulms prior to mechanical harvesting.

Insecticidal sprays used in orchards and pasture contaminated by calcium arsenate applied to kill Colorado beetle grubs are sources. In most instances poisoning occurs when animals accidentally gain access to recently sprayed areas, although drifting of wind blown spray may result in accidental contamination of pasture. Grass clippings from lawn areas treated with arsenical herbicides 6 months earlier may carry 15 000 mg/kg arsenic. With lead arsenate the major effects are usually ascribed to the effects of the lead but this does not always appear to be so.

Insect baits may contain Paris green (copper acetarsentate) mixed with bran and when these are laid over large areas of land in an attempt to control grasshopper plagues they constitute a major hazard to livestock.

Wood preservatives especially arsenic-copper-chromium are used to treat pine in wooden calf pens. The compound has a salty taste and is licked avidly. Ashes from burned treated pine posts are also palatable to cattle.

Some metal-bearing ore deposits including iron, arsenic pyrites in volcanic soils, gold and copper ores contain large quantities of arsenic which may be licked in situ, or carried off in the fumes from
arsenic is excreted rapidly. Time lag. Because arsenic does not precipitate protein it does not limit its own absorption, and there is a considerable time lag after ingestion before clinical signs appear; corrosive substances produce lesions and signs immediately.

Percutaneous absorption. Arsenic absorbed from the skin may be associated with local necrosis without systemic signs if the peripheral circulation is poor or the concentration of arsenic is excessively high, but if the cutaneous circulation is good, the arsenic is quickly carried away and is associated with a systemic disease without skin necrosis.

Chronic poisoning. The chronic toxicity of arsenic at low levels of intake is due to its accumulation in particular organs, especially the liver, kidney, alimentary tract wall, epidermis, spleen, and lung.

Nervous tissue lesions. The nervous signs associated with organic arsenicals are the result of inhibition of dehydrogenase enzyme systems (e.g., pyruvate and alpha-ketoglutarate systems), causing degenerative changes in peripheral nerves. These appear as demyelination and axonal degeneration in prolonged cases. Animals recumbent longer than 7 days are unlikely to recover and will remain paralyzed until death from other associated conditions. In poisoning with the arsanilic acid compounds the lesions are mostly in the optic nerves, causing blindness. In poisoning with the phenylarsionic acid group the nerves to the limbs appear to be affected most.  

CLINICAL FINDINGS

Ruminant gastroenteritis syndromes

Acute cases are the commonest syndromes in ruminants; the onset of signs of illness is delayed 20–50 hours from the intake of the poison, the length of time varying with the fullness of the forestomachs. Distress develops suddenly, commencing with severe abdominal pain, restlessness, groaning, an increased respiratory rate, salvation, grinding of the teeth, complete ruminal stasis, and vomiting, even in cattle. A fluid and fetid diarrhea develops later. The heart rate is greatly increased, the pulse small in amplitude; dehydration, and oliguria are marked.

Percutaneous cases show little except depression and prostration and die before signs of enteritis develop. A fluid sound in the abdomen can be elicited by shaking the animal. Death occurs 3–4 hours after commencement of the illness and is usually preceded by clonic convulsions and diarrhea.

Subacute cases give the same signs as acute cases but the course may extend over 2–7 days. Nervous signs of muscle tremor, incoordination, and clonic convulsions are followed by terminal coma.

Chronic cases. Commonly observed signs include low body weight, a dry, staring coat which is easily shed, loss of vigor and spirit, capricious appetite, bouts of indigestion, and capricious appetite. Bouts of indigestion, conjunctival and mucosal edema, eyelid edema and conjunctivitis. Buccal mucosal ulceration may extend to the muzzle. Milk yield is seriously reduced and abortions and stillbirths may occur. Local skin lesions include initial hyperemia followed by necrosis and sloughing leaving indolent lesions which are extremely slow to heal.

Horses

Signs include marked congestion of the mucosae and a very sudden onset of severe colic which passes off in a few hours in horses which survive. Severe diarrhea may be followed by a period of complete stasis of the alimentary tract with diarrhea recurring just before death.

Nervous syndromes in pigs and lambs

Chronic poisoning resulting from over-dosing with arsanilic acid is manifested by
incordination and blindness appearing about 7 days after the compound is first fed. Consciousness, body temperature, and appetite are unaffected. If feeding is continued the signs gradually worsen but disappear within a few days if the feed is changed. Some pigs remain permanently blind or paralyzed.

In chronic poisoning with roxarsone and nitarsone the emphasis is on restlessness, frequent urination, and defecation, incoordination due to loss of balance, frequent shrill ‘screaming’, tremor, and convulsions, all of which are stimulated by rousing the pig. If it is left alone in a recumbent position it may appear normal.

**CLINICAL PATHOLOGY**

Arsenic can be detected in the urine, feces, and milk for periods of up to about 10 days, beginning shortly after the toxic material is ingested. The rate of excretion is faster with organic compounds than with inorganic arsenic and urine levels may be back to normal in 5 days. The most satisfactory material for laboratory examination from a living animal is a large volume (about 1 L) of urine in which arsenic levels may be as high as 16 mg/kg. Levels in milk are low. Normal levels of up to 0.25 mg/kg in cows’ milk may be elevated to 0.34–0.47 mg/kg in cases of acute poisoning and to 0.8–1.5 mg/kg in the milk of normal cows which graze arsenic-contaminated pasture for long periods. Depositin in the hair occurs and the arsenic persists there until the hair is shed, making possible the detection of prior arsenic ingestion in the absence of arsenic from the blood and feces. The hair of animals not exposed to arsenic should contain less than 0.5 mg/kg, but that of normal, exposed animals may contain as much as 5–10 mg/kg. Estimations of amounts of arsenic present in suspected materials are mandatory, but delay in sampling of herbage after a contaminating incident may distort results because of leaching of soluble compounds.

**NECROPSY FINDINGS**

In acute and subacute cases of inorganic arsenic poisoning there are pronounced hyperemia and patchy submucosal hemorrhage in the stomach, duodenum, and cecum. Hemorrhage and multifocal ulceration of the cecum and large colon have been observed in horses. In ruminants the stomachs are unaffected but typical lesions are present in the abomasum. The gut contents are very fluid, and contain much mucus and shreds of mucosa. Profuse subendocardial hemorrhages are common and ulceration of the gallbladder mucosa is often observed in sheep. Macroscopic lesions may be minimal in cases which die after a very short course. Histologically, most of the hemorrhages can be attributed to the necrosis of capillaries, although damage to the walls of larger vessels may sometimes be found. Severe intravascular hemolysis has been observed in sheep. Degenerative changes are common in the liver and kidney of animals suffering from arsenic toxicosis and these changes become more pronounced if the disease course is prolonged. In some cases of chronic poisoning, loss of myelin may be observed in the peripheral nerves, with secondary neural degeneration in the central nervous system.

The liver is the best organ for assay of acute arsenic poisoning, while kidney may contain high levels in subacute or chronic poisoning. Levels of over 10–15 mg/kg wet matter of arsenic trioxide in the kidney or liver are considered to be diagnostic of arsenic poisoning. However, it is probable that many animals die of arsenic poisoning when their hepatic levels are much lower than this. Maximum concentrations of arsenic in tissues occur about 8 hours after ingestion and animals which survive for 2–3 days may have levels as low as 3 mg/kg. Conversely, normal animals which are dipped routinely in arsenical dips may have hepatic levels of the element as high as 8 mg/kg. Levels of 1–3 mg/kg are obtained in cattle dying from arsenic poisoning after percutaneous exposure and levels of over 10 mg/kg in cattle which ingest arsenic dip. The toxic dose in ingesta varies widely but averages about 36 mg/kg. Assay of the arsenic level in hair may be useful in chronically poisoned animals.

Animals poisoned with organic arsenicals show no significant gross pathological changes. Histologically, degeneration of the optic nerves, optic tracts, and peripheral nerves is apparent. The animals maintain tissue levels of arsenic for as long as exposure continues, although the levels fall rapidly during the first 7 days after feeding of the arsenic ceases, and normal levels are not reached until a further 7 days. Levels of about 6 mg/kg arsenic trioxide in liver and kidney on a fresh, wet-matter basis indicated poisonous levels of intake. Arsenic levels in brain, spinal cord, and peripheral nerves are retained longer after poisoning than are liver and kidney values. Because the stomach and intestinal wall appear to attain maximum concentrations of arsenic most rapidly after poisoning, the use of these tissues for quantitative assay has been recommended. Therefore a part of the upper alimentary tract including contents should accompany the liver and kidney samples submitted for analysis. However, animals that are no longer exposed to arsenic or are recovering after exposure stops will have relatively little arsenic retained after the initial acute episode.

**Samples for confirmation of diagnosis**

- **Toxicology:** 50 g liver, kidney; segment of stomach/intestine including content; sample of suspected poison (ASSAY(As))
- **Histology:**
  - inorganic As: formalin-fixed stomach, intestine, cecum, large colon, liver, kidney, peripheral nerve;
  - organic As: formalin-fixed optic nerve and tract, peripheral nerve (LM).

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation in all kinds of arsenic poisoning is by detection of toxic levels of arsenic in tissues and fluids of the patient.

**Acute inorganic arsenical poisoning** presents a clinical syndrome of gastroenteritis with minor signs of nervous system involvement, which is common in other diseases. Differential diagnosis list:

- **Lead poisoning:** the emphasis is on nervous system signs with gastroenteritis an inconstant accompaniment
- **Bovine malignant catarrh** develops in somewhat the same manner especially in the alimentary tract form but there are diagnostic lesions in the eyes and buccal mucosa
- **Mucosal disease** is also characterized by erosions in the buccal and nasal mucosa
- **Salmonellosis** is often confused with arsenic poisoning especially when the disease is seen in the later stages and the fever has subsided
- **Poisonous plants** which are associated with nervous signs and gastroenteritis include bracken, mustards, and a miscellaneous group in which specific toxins have not been identified

**Chronic inorganic arsenical poisoning** is associated with a syndrome of diarrhea and weight loss in areas around mining and smelting plants. It may be confused with:

- *inaniation*
- *internal parasitism especially ostertagiosis, trichostrongylosis and oesophagostomiiasis*

**Organic arsenical poisoning** is characterized by dramatic but mild nervous signs, but a normal appetite and no fever.

**Differential diagnosis list:**

- Organic mercury poisoning
- Salt poisoning
- Encephalitis
- Tri-ortho-cresyl phosphate or other industrial organophosphates that could contaminate swine feeds
- Selenium toxicosis (chronic) in swine with focal symmetrical poliomyelomalacia.
TREATMENT
In acute cases treatment is of little value because of the large amounts ingested and the delay between ingestion and the appearance of illness, but affected animals are unsuitable for human consumption so that treatment is not usually undertaken.

Primary treatment
Compounds containing sulfur are theoretically the best antidotes and of these BAL (2,3-dimercaptopropranol) is an efficient antidote for poisoning by organic arsenicals, but is often disappointing in cases of poisoning by inorganic salts, unless therapy is begun before clinical signs appear. Dosing at 4-hourly intervals is necessary and the oily injection is associated with some local pain. Although BAL has a general beneficial effect and is recommended as a treatment, the drug is quite toxic itself and in the doses required may be associated with deaths in sheep. It also is associated with a reaction at the injection site sometimes serious enough to warrant the animal’s destruction.

Sodium thiosulfate is a practicable and frequently used treatment. The compound is almost completely non-toxic and can be given in large amounts and without accurate measurement. Intravenous injection is desirable as an initial treatment using 15–30 g of the salt in 100–200 mL of water and this should be followed by oral dosing of 30–60 g at 6-hour intervals. Treatment should be continued until recovery occurs which may require 3–4 days.

A comparison of these treatments in experimentally poisoned cattle shows little benefit from sodium thiosulfate administration and most effect with a combination of BAL and thioctic acid. Dimercaptosuccinate is a water soluble analog of dimercaprol, is less toxic than BAL, is available in the USA and should be more effective than BAL. The antioxidants zinc, methionine, and cysteine, used with chelation therapy, have been reported to enhance excretion of arsenic in experimental poisoning. Their use may be helpful as adjuncts to recommended chelation therapy.

Supportive treatment
Attempts should be made to adsorb the residual arsenic in the gut by administering charcoal (1–4 g/kg BW per os), and then removed by the administration of an oil demulcent, or osmotic aperient like magnesium sulfate. Drastic purgatives should be avoided. Several products are used in an attempt to precipitate arsenic in the gut lumen. Ferric hydrate is most commonly used but has little apparent effect on the course of the disease.

Severe dehydration occurs and supportive treatment must include the provision of ample fluids preferably by parenteral injection. An adequate supply of drinking water containing electrolytes should be provided and the animals should be disturbed as little as possible and provided with shelter from the sun. Astringent preparations given by mouth may help to reduce the loss of body fluids. Recovering animals should receive a bland diet and high-quality protein.

Withdrawal time. After the treatment of pigs with arsenic acid the arsenic content of their livers may exceed 1 mg/kg, the statutory level of arsenic in food for human consumption. At least 10 days should be permitted between ceasing to feed the arsenilate and slaughter to avoid poisoning of humans.

Control
Arsenical preparations must be handled and stored with care and contamination of feed and pasture avoided. Therapeutic preparations containing arsenic should be labelled ‘Poison’ and strict instructions given on dosage, particularly the length of time for which administration should continue. Animals to be dipped in arsenical solutions should be allowed to cool off before dipping, to drain properly afterwards and to dry before being driven. They should be watered before dipping to prevent them drinking the dip. Much mortality has occurred when instructions for mixing dip solutions were not closely followed. Dipping solutions containing more arsenic than is safe usually occur when tanks which have lost water by evaporation are reconstituted by guesswork. The maximum safe concentration of arsenic trioxide in a dip for cattle is 0.20%.

REVIEW LITERATURE

REFERENCES

SELENIUM POISONING

| Source of toxin | Organic selenocompounds (selenocysteine, selenocystine) occurring in pasture plants
|                | Inorganic selenium compounds administered as feed supplements
|                | Pharmaceutical preparations administered orally, frequently combined with vitamin E for prophylaxis or by injection in treatment.

 Toxicology
Selenium poisoning is associated with the ingestion of organic or inorganic selenium compounds as follows:

- Organic selenocompounds (selenocysteine, selenocystine) occurring in pasture plants
- Inorganic selenium compounds administered as feed supplements
- Pharmaceutical preparations administered orally, frequently combined with vitamin E for prophylaxis or by injection in treatment.

Toxic doses. Discrepancies exist in the toxic doses quoted in the literature and the following information is subject to that limitation. Daily intakes of 0.25 mg/kg BW are toxic for sheep and cattle; feed containing 44 mg/kg selenium for horses and 11 mg/kg for pigs is associated with poisoning. The daily intake of a diet containing 2 mg/kg of selenium can be marginally toxic for sheep. Toxic single oral doses (as mg/kg BW) are 2.2 for horses and sheep, 9 for cattle, and 15 for pigs. An oral dose of 10–15 mg of selenium has been known to kill lambs. Recommended limits for selenium in feed are given under Control, and for injection in the section on treatment.

EPIDEMIOLOGY
Occurrence
- Pastoral. Selenium poisoning occurs in restricted areas in North America, Ireland, Israel, Canada, Australia, and South Africa where the soils are derived from particular rock formations containing a high content of selenium. No authoritative reason has been advanced to explain why the reported occurrence of the disease in these areas is much less now than it used to be.
- Dosing errors. Substantial losses due to selenium poisoning also occur because of misunderstanding about the dose rates of selenium compounds used therapeutically or prophylactically.

Source of toxin
Pastoral. The effective selenium is contained in the top 60–90 cm of the soil.
profile, selenium at lower levels than this not being within reach of most plants. Selenium poisoning may occur on soils containing as little selenium as 0.01 mg/kg, but some soils may contain as much as 1200 mg/kg. Most pasture plants seldom contain selenium in excess of 100 ppm, but a number of species, the so-called converter or indicator plants, take up the element in such large quantities that selenium levels may reach as high as 10 000 ppm. Included in this category are Acacia cana, Artemisia canescens, Aster spp., some of the Astragalus, Atriplex and Castilleja spp., Comandra pallida, Descurainia pinnata, Grindelia spp., Machaeranthus ramosa, Morinda reticulata, Neptunia amplexicaulis, Oenopsis, Penstemon and Sideranthus spp., Stanleya pinnata and Xylorhiza spp.

These plants tend to grow preferentially on selenium-rich soils and are thus 'indicator' plants. They are in general unpalatable because of a strong odor so that an acute syndrome is unlikely but heavy losses have been attributed in the past to two chronic forms of the disease known as blind stagers and alkali disease. Much of these data are now discounted and losses due to chronic selenosis in cattle in the western USA in recent years have been small.

Industrial deposition, e.g. fly ash from soft coal deposited in fields has been shown to be associated with increased selenium levels in tissues from sheep grazing there.

Dietary supplement is used in the prevention of known deficiency syndromes such as white muscle disease in lambs, as a non-specific growth stimulant, and as a prophylactic for a large number of other vague syndromes. It is not surprising that the careless use of selenium compounds has induced selenium poisoning on a wider scale.

Prophylactic. It is now common practice to combine a selenium compound with an anthelmintic drench or injection and, if the mixture is not thoroughly shaken, poisoning may occur. Concurrent administration of monensin and selenium also increases the toxicity of the selenium being fed. There are many case reports of unexpected illness and mortality in animals dosed with selenium preparations and it is apparent that not all of the factors affecting selenium toxicity are known. Identified factors include the cobalt and protein status of the animal, deficiencies of either causing increased susceptibility.

Risk factors

Environment factors. Selenium poisoning in animals grazing plants growing on seleniferous soils may be restricted to very distinct areas as small as individual fields. A low rainfall predisposes to selenium poisoning because soluble, available selenium compounds are not leached out of the topsoil and lack of competing forage may force animals to eat large quantities of indicator plants.

Toxin factors. Organic selenium compounds, especially those occurring naturally in plants, are generally considered to be much more toxic than inorganic compounds but this difference may not be apparent in ruminants because of alterations in ingested compounds produced by digestive processes in the rumen. Selenite is more toxic than selenate and both are more damaging than selenium dioxide.

Host factors. Cattle are more tolerant than sheep. Pigs are unlikely to be exposed but can develop the disease in the field.

PATHOGENESIS

Acute oral poisoning is associated with chemical erosion of alimentary tract mucosa. Poisoning with a single injection, e.g. in pigs, is associated with sudden death due to vasogenic circulatory failure, a vasculogenic shock. The mechanism forming the basis of chronic poisoning has not been identified. Selenium occurs in plants in analogs of the sulfur-containing amino acids, e.g. selenocysteine, and a possible mechanism of intoxication is by interference with enzyme systems which contain these amino acids. Selenium reduces the sulfur and protein content of sheep's liver and high protein diets have a protective effect against selenium poisoning. Selenium is deposited in greatest concentration in the liver, kidney, and hair. It has a marked dystrophic effect on skeletal musculature and is associated with a marked rise in SGOT levels after subcutaneous administration.

CLINICAL FINDINGS

The terms blind stagers and alkali disease, used previously in this section have been discontinued as misleading and being based on misunderstandings about the etiological agents involved.

Acute poisoning. In naturally occurring and experimental poisoning there is severe respiratory distress, restlessness, complete anorexia, salivation, watery diarrhea, fever, tachycardia, abnormal posture and gait, prostration, and death after a short illness. Mildly affected pigs show posterior ataxia, walking on tiptoe, difficulty in rising, sternal recumbency, tremor, and vomiting in some. Extreme cases assume a posture of lateral recumbency.

Chronic poisoning is manifested by dullness, emaciation, rough coat, lack of vitality, stiffness, and lameness. In cattle, horses, and mules the hair at the base of the tail and switch is lost and in pigs, goats, and horses there may be general alopecia. There are hoof abnormalities including swelling of the coronary band, and deformity or separation and sloughing of the hooves in all species. Lameness is severe. Congenital hoof deformities may occur in newborn animals. Hemorrhagic lesions on the proximal wall and soles of claws on all four feet may accompany these deformities. Chronic poisoning in pigs on rations containing 20–27 mg/kg is also associated with a syndrome of reduced feed intake, paraplegia and quadriplegia due to poliomyelomalacia. Pigs on marginal levels of intake of selenium (10 mg/kg) develop necrosis of the coronary band, low conception rates, and increased neonatal mortality.

CLINICAL PATHOLOGY

Selenium can be detected in the urine, milk, and hair of affected animals. Clinical illness is evident at blood levels of 3 mg/kg and at urine levels of more than 4 mg/kg of selenium. Normal serum levels of 140–190 ng/mL are elevated to the 1500 ng/mL level. Critical levels of selenium in hair include the following:

- Less than 5.0 mg/kg suggests that chronic selenosis is unlikely
- From 5.0 to 10.0 mg/kg suggests that borderline problems will occur
- More than 10 mg/kg is diagnostic of chronic selenosis.

A moderate anemia occurs in acute and chronic poisoning and a depression of hemoglobin levels to about 7 g/dL is one of the early indications of selenium poisoning.

NECROPSY FINDINGS

In confirmed cases of natural or experimentally produced acute selenium poisoning most of the macroscopic findings can be attributed to cardiovascular compromise. There is pulmonary edema and congestion, petechiation of the thoracic viscera, and congestion of the liver, kidneys, and gastrointestinal tract. In parenterally overdosed lambs and piglets there is usually hydrothorax, hydropericardium, and ascites. Histologic lesions may be minimal if the clinical course is brief. Changes which may be observed in animals surviving more than 24 hours include a serious effusion within pulmonary alveoli, mild hyaline or granular degeneration of skeletal muscle fibers, hydropic degeneration in renal tubular epithelial cells and pericapillary degeneration and necrosis of hepatocytes. Cardiac
myocytes may appear swollen and contain areas of cytoplasmic granularity and lysis.

The causal link between selenium intoxication and blind staggers is weak and the lesions described in accounts of this largely historical disease are in dispute. It is probable that this clinical entity is the result of other etiologic factors. In animals suffering from subacute to chronic selenium poisoning there is a skeletal and cardiac myopathy. Deformities of the feet and skin are usually apparent, as described under Clinical findings. Atrophy and dilatation of the heart and pulmonary edema, cirrhosis and atrophy of the liver, glomerulonephritis, mild gastroenteritis, and erosion of articular surfaces have also been recorded. Symmetrical polyomelomalacia has been identified in both natural and experimental settings in pigs fed excessive selenium. The areas primarily affected are the ventral horns of the cervical and lumbar enlargements, with lesser damage in brainstem nuclei. The microscopic appearance of affected spinal cord includes vacuolation of the neuropil and sometimes of the cytoplasm of neurons. Neuronal chromatolysis, axonal swelling, and endothelial cell swelling and proliferation are consistently present.

**Samples for confirmation of diagnosis**
- **Toxicology** – 50 g liver, kidney; 500 g of suspect feed (ASSAY (Se))
- **Histology** – formalin-fixed skeletal muscle, heart, liver, kidney, +/- spinal cord from cervical and lumbar enlargements (LM).

**Selenium levels in tissue.** In chronic selenium in sheep hepatic and renal levels of selenium are about 20–30 mg/kg and levels in wool are in the range of 0.6–2.3 mg/kg. In horses hair levels of more than 5 mg/kg are recorded.

**DIFFERENTIAL DIAGNOSIS**
The diagnosis of selenium poisoning rests largely on the recognition of the typical syndromes in animals in areas where the soil content of selenium is high, or when there has been administration of selenium as medication or as a feed additive. The clinical and necropsy lesions associated with the poisoning cover a wide range of signs and lesions and are not easily summarized. Diagnostic confirmation depends on an assay of toxic levels of selenium in body tissues or fluids.

**Differential diagnostic list: Acute poisoning**
- Anaphylaxis
- Septicemia
- Toxemia
- Acute arsenic toxicity.

**Chronic poisoning**
- Hypovitaminosis A.

**TREATMENT**
A number of substances have been tried in the treatment of selenium poisoning, including potassium iodide, ascorbic acid, and beet pectin but without apparent effect. BAL is contraindicated.

**CONTROL**
The manufacturers' advice on dose rates for pharmaceutical and feed additive preparations should be followed at all times. As a further guide to safe dose levels which avoid toxicity the following guidelines are provided:
- In general, the ratio between acute toxic and therapeutic doses is 50–100:1 and dosing accidents should not be common.
- **Sheep.** The subcutaneous injection of selenium as sodium selenite is associated with poisoning in sheep at doses of 0.8 mg/kg BW and doses of 1.6 mg/kg are lethal. A single injection of 5 mg of selenium may kill some lambs and the toxic level for single injections in lambs has been reported as 455 µg/kg BW.
- **Cattle.** Lethal doses by injections are 1.2 mg/kg BW.
- **Pigs.** Lethal doses are between 1 and 2 mg/kg BW.
- **Ponies.** Only relatively large doses, e.g. 6–8 mg/kg BW is associated with fatality.

Selenium in feeds should not exceed 0.6–2.3 mg/kg. In horses hair levels of selenium are about 20–30 mg/kg and levels in wool are in the range of 0.01–0.02% of arsanilic acid in the diet. Pig, pig-kidney protein diet also has a general protective effect. BAL is contraindicated.

**REFERENCES**

**PHOSPHORUS POISONING**
Phosphorus is rarely used as a rodent poison nowadays and this is the only likely source of phosphorus for animals. Toxic effects are increased when the phosphorus is finely divided and mixed with oils or fats which facilitate its absorption. Phosphorus used for military purposes is associated with extensive contamination of pasture.

Phosphorus has a local caustic action and on ingestion is associated with severe irritation of the alimentary mucosa with signs of gastroenteritis appearing within an hour or two. Some phosphorus may be absorbed and is associated with acute hepatic necrosis but signs do not appear for several days.

**CLINICAL FINDINGS**
These include severe diarrhea, acute abdominal pain, salivation, and intense thirst. Pigs vomit violently and the vomitus is luminous and has a garlic odor. The patient often dies of acute shock during this stage. Survivors show jaundice, weakness and anorexia, oliguria and hematura. Death may occur in coma or be accompanied by convulsions. Phosphorus can be detected in the vomitus and feces of affected animals.

**NECROPSY FINDINGS**
Macroscopically there is congestion and hemorrhage of the alimentary mucosa. The carcass is often jaundiced and the liver is swollen and pale. Histologically there is fatty degeneration of both the liver and kidney, sometimes accompanied by hepatic necrosis. The acute stages of phosphorus poisoning may appear similar to acute stages of inorganic arsenic, mercury, or selenium poisoning.

Samples for confirmation of diagnosis
- **Toxicology** – 50 g liver, kidney and a portion of alimentary tract with content (ASSAY (P))
- **Histology** – formalin-fixed liver, kidney (LM).
Diagnostic confirmation requires evidence of access to the poison and the detection of large amounts of it in the alimentary tract.

Treatment. An emetic or hydragogue purgative should be given immediately. Supportive treatment includes the administration of astringents to allay the gastroenteritis and parenteral electrolyte solutions to relieve the dehydration. Hypotension and shock as well as coagulopathy may occur and should be treated supportively as needed.

**MERCURY POISONING**

</tr>
<tr>
<td><strong>Control</strong></td>
<td>Care in the handling of agricultural and pharmaceutical mercurials.</td>
<td><strong>PATHOGENESIS</strong></td>
<td>Inorganic mercury compounds are associated with coagulation of the alimentary mucosa, leading to the rapid development of gastroenteritis. Animals that survive the alimentary tract disorder and absorb mercury may show signs of damage to peripheral capillaries especially those at the sites where mercury is excreted, in the kidney, colon, and mouth. Nephrosis, colitis, and stomatitis may result. Organic mercurials in small doses liberate their mercury slowly into tissues and are associated with degenerative changes in brain, segmental degeneration in peripheral nerves, and degeneration in kidney. Extensive subcutaneous hemorrhages and a bleeding tendency occur in some cases of phenylmercuric acetate poisoning.</td>
</tr>
</tbody>
</table>

**CLINICAL FINDINGS**

Acute mercurial poisoning occurs when large amounts of inorganic mercury are ingested, there is an acute gastroenteritis with vomiting of blood-stained material and severe diarrhea. Death occurs within a few hours due to shock and dehydration. In less acute cases the patient survives several days and the syndrome includes salivation, a fetid breath, anorexia, oliguria, tachycardia, hyperpnea and, in some cases, posterior paralysis and terminal convulsions.

Chronic mercurialism occurs when small amounts of inorganic mercury are ingested over long periods. The syndrome includes depression, anorexia, emaciation, a stiff, stilted gait which may progress to paresis, alopecia, scabby lesions around the anus and vulva, pruritus, petechiation and tenderness of the gums and shedding of the teeth, persistent diarrhea, weakness, incoordination, and convulsions.

**ETIOLOGY**

Mercuric chloride and mercury binioid are highly poisonous, the toxic dose for horses and cattle being about 8 g and for sheep 4 g. Organic mercury taken regularly in the diet at a level of 1 mg/kg is associated with chronic poisoning in pigs. A level of 6 mg/kg is associated with deaths in pigs within 5 days.

**EPIDEMIOLOGY**

Source of toxin

Mercury poisoning in farm animals occurred in the past almost exclusively as a result of accidental feeding of grain, pellets, or concentrate mixtures treated with organic mercurial antifungal agents.

**Importance**

Meat from animals poisoned by mercury is unsuitable for human consumption. Milk is probably safe as little mercury is excreted in it.

The toxicity of mercury compounds depends on their solubility and the susceptibility of the animals.

Because of the availability of fungicidal agents other than mercury it is possible to limit the use of mercuric agents by legislation to those excreted rapidly by animals, the phenylmercury compounds, and prohibiting those which are retained in animal tissues, the ethyl and methyl compounds. Worldwide use of mercurial fungicides has declined and poisoning is much less common than in the past. The commonest agents, when used, are dusts of 5.25% methoxyethymmercury silicate or methylmercury dicyandiamide. These and ethylmercury chloride are toxic when fed to pigs at the rate of 0.19–0.76 mg of mercury per kg BW per day for 60–90 days. Methylmercury dicyandiamide fed to pigs at the rate of 5–15 mg/kg is associated with illness, and 20 mg/kg is associated with some deaths with a delay of 3 weeks between dosing and illness.

Treated seed is usually not harmful if it comprises only 10% of the ration and must be fed in large amounts for long periods before clinical illness occurs. A single feeding even of large amounts of grain is thought to be incapable of causing mercury poisoning in ruminants but horses may be susceptible.

Accidental administration of medicines containing mercury, licking of skin dressings (e.g., mercuric oxide), and absorption from liberally applied skin dressings or combined with dimethyl sulfide may be associated with sporadic cases as occurs in horses after application of mercury containing ‘blisters’. Inorganic mercury salts contaminating lakes or other anaerobic ecological areas can be reduced and converted to methyl mercury and serve as a source of organic mercurial poisoning or food contamination through accumulation in fish or fish meal.2

**Risk factors**

The toxicity of mercury compounds depends on their solubility and the susceptibility of the animals. Cattle are highly susceptible, toxicosis occurring on an average daily intake of mercury, in organic mercury form, of 10 mg/kg per day, while toxic effects are only obtained in sheep with intakes of 17.4 mg/kg BW per day. In horses, feeding inorganic mercury at the rate of 0.4 mg/kg BW produces only mild signs of poisoning and feeding methylmercury chloride (10 g over 10 weeks) is associated with serious illness.

Clinical signs include incoordination, head pressing, muscle tremor with twitching of the eyelids, tetanus-like spasms on stimulation, excessive salivation, recum bency, and inability to eat or drink, followed by tonic-clonic convulsions with opisthotonos.
**CLINICAL PATHOLOGY**
Mercury can be detected at higher levels than normal in the blood, feces, and urine of affected animals and in the toxic source material. Nephrosis can be diagnosed by examination of blood and urine; the earliest and most accurate indicators are the urinary concentrations of alkaline phosphatase and gamma-glutamyl transpeptidase. Less than 0.2% of ingested mercury is excreted in cow’s milk.1

**NECROPSY FINDINGS**
In acute cases there is severe gastroenteritis with edema, hyperemia, and petechiation of the alimentary mucosa. The liver and kidneys are swollen and the lungs are congested and show multiple hemorrhages. There may be an accompanying catarhal stomatitis. A crusting focus of dermatitis may be identified if exposure was percutaneous.

Histologically the renal tubular epithelial cells are swollen and vacuolated, and proteinuria is evident. An ulcerative colitis may also be visible. In chronic mercury-associated with organic mercury compounds there are also degenerative changes in nerve cells in the cortex of cerebrum, brain stem, and spinal cord. The lesions include neuronal necrosis, neuronophagia, cortical vacuolation, and gliosis. Fibrinoid necrosis of leptomeningeal arterioles may be seen. Other common microscopic changes include degeneration of granular cells of the cerebellar cortex and of Purkinje cells of the myocardin.

Mercury reaches its greatest concentration in kidney and this tissue should be submitted for assay. Levels of 100 mg/kg may be present in the kidney of animals poisoned with inorganic mercury. With chronic organic mercurial poisoning in swine levels of mercury up to 2000 mg/kg may be present in the kidney.

**Samples for confirmation of diagnosis**
- **Toxicology** – 50 g kidney, brain – half fresh and half in formalin. 500 g of suspect feed (ASSAY (Hg)); muscle tissue for potential residues in food animal edible tissues.
- **Histology** – formalin-fixed kidney, heart, oral and/or skin lesions; half of midsagittally sectioned brain (LM).

**DIFFERENTIAL DIAGNOSIS**
Acute mercury poisoning is rare but should be suspected in animals which are exposed to inorganic mercury compounds and which show signs of gastroenteritis and nephritis. Diagnostic confirmation depends on a positive tissue assay for mercury.

**Differential diagnosis list**
When there are indications of gastropathy or nephrosis the syndrome resembles:
- Lead poisoning
- Arsenic poisoning.
- Pigs poisoned by organic mercury compounds and showing nervous signs of blindness and incoordination resemble:
  - Pigs poisoned by organic arsenicals.

**TREATMENT**
Primary. In acute cases large amounts of coagulable protein such as eggs should be given by mouth immediately, followed by mild purgatives to facilitate removal from the gut before digestion and absorption occur. In acute and chronic cases treatment with sodium thiosulfate as described in arsenic poisoning is recommended. BAL can be used but has the same limitations here as in arsenic poisoning, and delay in treatment of any sort is likely to be fatal. An injection of BAL (6.5 mg/kg BW) should be given every 4 hours. Dimercapto succinic acid (DMSA) at 10 mg/kg BW. t.i.d. is reported effective in hastening the elimination of mercury in urine.4

Supportive treatment includes astringents given orally to control the gastroenteritis and fluids given parenterally to correct the dehydration.

**CONTROL**
Seed grains dusted with mercury compounds should not be fed to animals.

**FLUORINE POISONING**

**ETIOLOGY**
Fluorine intoxication has been observed in most countries, usually in association with specific natural or industrial hazards. In Europe and Great Britain losses are greatest on summer grazing of pastures contaminated by industrial fumes, including dust from factories converting rock phosphate to superphosphate as well as effluent from aluminum smelters. Iceland and parts of the southern Andes mountains are extensively affected by contamination from volcanic ash. Drinking water from deep wells, industrial contamination of

**DIAGNOSTIC CONFIRMATION**
Assay of food, water, bones, teeth for fluorine content.

**TREATMENT**
**Primary:** aluminum salts orally, calcium salts parenterally but little chance of improvement.

**Supportive:** parenteral glucose solutions.

**Control**
Drinking water held in tanks, fluoride precipitated by aluminum salts; applicable only for small water volumes.

**EPIDEMIOLOGY**
Occurrence
Fluorine intoxication has been observed in most countries, usually in association with specific natural or industrial hazards. In Europe and Great Britain losses are greatest on summer grazing of pastures contaminated by industrial fumes, including dust from factories converting rock phosphate to superphosphate as well as effluent from aluminum smelters. Iceland and parts of the southern Andes mountains are extensively affected by contamination from volcanic ash. Drinking water from deep wells, industrial contamination of
The feeding of fluorine-bearing phosphatic supplements are the common associations in North America. Deep wells also are an important source in Australia and South America. In Africa, the important association is the feeding of phosphatic rock supplements.

**Sources**

Fluorine occurs naturally in rock, particularly in association with phosphate, and these rocks, the soils derived from them and surface water leaching through the soils, may contain toxic quantities of fluorine. In such areas the soil content of fluorine may be as high as 2000–4000 mg/kg even up to 12,000 mg/kg, and the levels in water up to 8.7 mg/kg; soil fluorine varies in its solubility from 10 to 20%. Levels of fluorine likely to be toxic to animals are not usually encountered in natural circumstances, interference by man being necessary in most instances to increase fluorine intake above the critical level.

Plants, with few exceptions, do not absorb appreciable quantities of fluorine. Two exceptions are *Camellia* spp., the decorative camellias, and *Thea chinensis* (tea) plant. Major outbreaks of intoxication occur as the result of the ingestion of pasture contaminated with fluorine, and drinking water and mineral supplements which contain excessive amounts of fluorine.

**Contamination from industrial factories** by smoke, vapor, or dust may produce pasture containing 20–50 mg/kg of fluorine. Factories producing aluminum by the electrolytic process, iron and steel with fluorine-containing fluxes, superphosphate, glazed bricks, copper, glass and enamels are likely to be potent sources and may be associated with toxic levels of contamination as far as 14 km downwind from the factory. Dust from factories manufacturing superphosphate from rock phosphate may contain as much as 3.3% fluorine. Industrial plants engaged in the calcining of ironstone have also been incriminated as sources of fluorine.

**Dust and gases from volcanic eruptions** may also be associated with acute fatal fluorine intoxication in the period immediately after the eruption, and contamination of pasture may be sufficient to be associated with subsequent chronic intoxication in animals eating the herbage, although the fluorine content of the contaminated materials decreases very rapidly if rain falls. Iceland is particularly afflicted with fluorine intoxication deriving from this source.

Top-dressing of pasture with phosphatic limestone is commonly associated with fluorosis. Most phosphatic limestones, particularly those from North Africa, are rich in fluorine (0.9–1.4%). Non-phosphatic limestones contain insignificant amounts.

**Supplementary feeding of phosphates.** The common occurrence of phosphorus deficiency in animals has led to the search for cheap phosphatic materials suitable for animal feeding. Rock phosphates are commonly used and many deposits contain dangerous amounts of fluorine (3–4%). The fluorine content of the mineral can be reduced but the cost encourages the use of marginally safe material.

**Water.** The major occurrence of water-borne fluorine intoxication is from water obtained from deep wells or artesian bores. The available data suggest that, although minor teeth lesions occur at 5 mg/kg of fluorine it is not until levels of 10 mg/kg are exceeded that excessive tooth wear occurs and the nutrition of the animal is impaired. More serious systemic effects do not occur until the water contains 30 mg/kg.

**Miscellaneous sources** of fluorine include the ingestion of superphosphate itself, but a supernatant liquid of a suspension of the fertilizer will contain no fluorine. Some wood preservatives may contain large quantities of fluoride which may be associated with acute poisoning in some circumstances.

**Risk Factors**

Host factors are age and species. Daily intakes of 0.5–1.7 mg/kg of fluorine as sodium fluoride produce dental lesions in growing animals without affecting general well-being. Intakes equal to twice these amounts are consumed by adult animals without ill-effect. In heifers a continuous intake of 1.5 mg/kg BW per day is sufficient to be associated with severe dental fluorosis without affecting growth rate or reproductive function.

However, extensive osteofluorosis and periods of severe lameness will occur. The fluorine content of the bones of newborn calves depends on the dam's intake of fluorine in the last 3–4 months of pregnancy and not on her own bone composition.

Most recorded occurrences of fluorosis are in cattle. Sheep are less susceptible than cattle. A continuous intake of 1 mg/kg BW is the maximum safe limit for ruminants, an intake of 2 mg/kg BW produces clinical signs. In pigs an intake of 1 mg/kg BW added fluorine for long periods has no deleterious effect.

**Importance**

Death losses are rare and restricted largely to acute poisoning, the major losses taking the form of unthriftiness associated with chronic fluorosis. Although it is possible for animal tissues to contain amounts of fluorine in excess of permissible amounts this is not usually so in chronic fluorosis.

The fluorine content of milk in these circumstances is below that permitted in fluoridated drinking water (1 mg/L).

**Pathogenesis**

Fluorine is a general tissue poison; its exact mode of action does not appear to have been closely examined.

Acute intoxication, due to the ingestion of large amounts of soluble inorganic fluorides, is characterized by the immediate development of gastrointestinal irritation due to the formation of hydrofluoric acid in the acid medium of the stomach. Nervous signs including tetany and hyperesthesia, and inhibition of blood clotting, may follow as a result of the fixation of serum calcium to form physiologically inactive calcium fluoride in the blood plasma. Death occurs quickly.

**Organic fluorides,** including sodium fluoracetate, also known as compound 1080, and fluoracetamide, are associated with sudden death by poisoning the enzyme aconitase, leading to the accumulation of diagnostically significant levels of citrate in tissues and permanent damage to myocardium.

**Metabolic effects** due to the ingestion of small amounts of inorganic fluorides over long periods are associated with an initial marked reduction in the activity of ruminal infusoria, a reduction in food intake, and a decreased production of fatty acids. The level of fluorine intake is critical and intakes of 150 mg/kg or less have no effect on food intake. At intakes of 150–200 mg/kg there is a depressing effect on milk production, and at 200 mg/kg the intake of grain is reduced.

**Detoxication by deposition** of fluorine occurs in association with phosphate in the teeth and bones. Deposition in bone
Dental fluorosis occurs throughout life but in teeth only in the formative stages. Fluorides inhibit the action of ameloblasts and odontoblasts during tooth formation, resulting in failure of the developing tooth to accept minerals. In bones, fluorides alter mineralization and remodeling of bone by replacing hydroxyapatite in the bone crystalline structure. The degree of deposition varies, being greatest on the periosteal surface of the long bones where exostoses commonly develop. Thus teeth lesions occur only if the intake is high before the teeth have erupted but bone lesions occur at any stage. When the tissue levels of fluoride are moderate, characteristic lesions due to hypoplasia of the enamel appear in the teeth. At higher levels the storage capacity of these organs is exceeded and blood and urine levels rise. General signs of toxicity thus appear in tissues at the same time as bone lesions develop. The bone lesions of osteomalacia, osteoporosis, and exostosis formation, with accompanying pathological fractures, are associated with excessive mobilization of calcium and phosphorus to compensate for their increased urinary excretion in conjunction with fluoride.

The other tissues particularly prone to fluoride intoxication and in which degenerative changes occur are bone marrow, kidney, liver, adrenal glands, heart muscle, and central nervous system. A severe anemia may rarely occur as a result of toxic depression of bone marrow activity, although this is not a constant or expected sign. The facility of storage in bone explains the long latent period which occurs in animals subjected to chronic intoxication.

There has been controversy about whether fluoride passes the placental barrier in significant amounts. Although the current view is that placental passage is infinitesimal in amount, cases of neonatal dental fluorosis have been identified in cattle.

Fluoride does not occur in significant quantities in the milk or colostrum of poisoned cows.

Detoxification by leaching of fluoride from bones and teeth occurs after a decrease in the intake of fluoride leads to lowering of blood levels and mobilization from deposits commences. This is of importance when interpreting urine and blood levels of the element.

**CLINICAL FINDINGS**

**Acute intoxication**

The syndrome includes dyspnea, complete anorexia, vomiting, and diarrhea in pigs, and ruminal stasis with constipation or diarrhea in ruminants. Vomiting acts as a protective mechanism and toxic doses in pigs may be eliminated in this way without the development of other signs. Nervous signs are characteristic and include muscle tremor and weakness, a startled expression, pupillary dilatation, hyperesthesia, and constant chewing. Tetany and collapse and death follow within a few hours.

**Chronic intoxication-fluorosis**

Because of the distinct clinical separation between animals with dental lesions and those which have, in addition, signs of lameness and general ill-health it is customary to refer to two forms of the disease: dental fluorosis and osteofluorosis. Lesions of the teeth and bones are characteristic and the signs are largely referable to these lesions. Teeth changes are the earliest and most diagnostic sign but may not produce clinical effects until other signs have developed. Consequently, they are often missed until other clinical findings suggest that the teeth be examined. Severe dental fluorosis results in excessive dental wear, inability to graze properly, difficulty in swallowing, and lopping of water due to tooth pain. Continued impaired dentition leads to reduced milk production and poor weight gain or actual weight loss. Reproductive function may be reduced due to locomotor dysfunction and poor nutrition as a result of reduced feed intake.

**Osteofluorosis**

Lameness most marked in the loins, hip joints, and hind limbs and unthriftiness in animals of any age are the signs usually observed first. The occurrence of hip lameness or fractures of the third phalanx on a herd scale in cattle is thought to be diagnostic of fluorosis. Pain is evinced on pressure over limb bones and particularly over the bulbs of the heels. The bones may be palpably and visibly enlarged. This is most readily observed in the mandible, sternum, metacarpal, and metatarsal bones and the phalanges. This overall thickness may be subsequently replaced by well-defined exostoses. The bones are subject to easy fracture. These well-defined lesions occur only in advanced cases and are often accompanied by extensive tooth lesions in young animals. In addition to the cases affected by generalized lameness there are cases which show a sudden onset of very severe lameness, usually in a forelimb, associated with transverse fracture of the third phalanx.

**Dental fluorosis**

Temporary teeth of animals poisoned while in utero and permanent teeth exposed to intoxication before eruption will be affected. The earliest and mildest sign is molting with the appearance of pigmented (very light yellow, green, brown, or black) spots or bands arranged horizontally across the teeth. Occasional vertical bands may be seen where pigment is deposited along enamel fissures. Molting and staining occur on incisors and cheek teeth and are not evident when the affected tooth erupts and in fact may not appear until some months later. The cheek teeth are usually worse affected than the incisors but are very difficult to examine clinically. If the period of exposure to intoxication has been limited only some of the teeth may be affected but the defects will always be bilateral.

Molting may not progress any further but if the intoxication has been sufficiently severe, defective calcification of the enamel leads to accelerated attrition or erosion of the teeth, usually in the same teeth as the molting. The molting areas become pits and the teeth are brittle and break and wear easily and unevenly. Patterns of accelerated attrition are dependent upon the chronological occurrence of the intoxication and the eruption time of the teeth. Uneven and rapid wear of the cheek teeth makes proper mastication impossible. Infection of the dental alveoli and shedding of teeth commonly follow. The painful condition of the teeth and the inability to prehend and masticate seriously reduce the food intake and are associated with poor growth in the young and unthriftiness and acetonemia in adults. Affected cattle may lap cold drinking water to avoid the discomfort occasioned by normal drinking. Eruption of the teeth may be abnormal, resulting in irregular alignment.

A standard for the classification of fluorosis has been proposed based on the degree of molting, pitting, and rate of wear of the teeth. The effects of dental molting, pitting, and excessive wear of incisors can be used to estimate the lifetime exposure periods of cattle at risk during dentition. The additional clinically apparent abnormalities include delayed eruption of permanent incisor teeth, necrosis of alveolar bone resulting in recession of bone and gingiva, oblique eruption of permanent teeth, hypoplasia of teeth, wide spaces between teeth, and rapid development of any dental lesions.

**Other effects**

Reproduction, milk yield, and wool growth are not usually considered to be adversely affected except indirectly by the reduced food intake. Severely lame animals may have lowered reproductive performance indirectly due to physical dysfunction that interferes with mating.

Additional signs including diarrhea and anestrus and other forms of infertility in cattle, diarrhea in sheep, and polydipsia and polyuria in pigs are recorded in the

Diseases associated with inorganic poisons
naturally occurring disease but cannot be considered as constant or pathognomonic.

**Housed animals.** In animals that are grazed for only part of the year on pasture contaminated by factory effluent during the summer, there may be considerable clinical improvement during the winter and an annual recrudescence of signs when the animals are outside.

**Horses** with chronic fluorosis have lameness, dental lesions including excessive molar abrasion, and hyperostotic lesions of the metatarsus, metacarpus, mandible, and ribs.

**CLINICAL PATHOLOGY**

Normal cattle have blood levels of up to 0.2 mg fluorine per mg/dL of blood and 2–6 mg/kg in urine. Cattle on fluorine intakes sufficient to cause intoxication may have blood levels of 0.6 mg/dL, and urine levels of 16–68 mg/kg, although blood levels are often normal. Such high levels may not be an indication of high intakes immediately preceding the examination, as heavy deposits in bones may be associated with abnormally high blood and urine fluorine levels for some months after the intake has been reduced to normal. Urine levels should be corrected to a specific gravity of 1.040. Serum calcium and phosphorus levels are usually normal and there is a significant correlation between the amount of fluoride fed and the concentration of alkaline phosphatase in the serum. The increase in phosphatase activity is probably related to the abnormal formation of bone. The increased SAP activity may be three to seven times the normal level.

**Radiographic changes** of bones containing more than 4000 mg/kg of fluorine include increased density or abnormal porosity, periosteal feathering, and thickening, increased trabeculation, thickening of the compact bone, and narrowing of the marrow cavity. Spon­taneous rib fractures show incomplete union. Good data are available for fluorine concentrations in rib bones, and estimates of fluorine content in biopsy samples of ribs have been used in the clinicopathological study of the disease. Samples of tail bone and the spongiosa of the tuber coxae have also been used for these purposes.

**Organic fluorides** are difficult to assay in excretions and tissues, and even in contaminated feed sources. In affected animals indirect measurement based on tissue concentrations of citrate may be necessary. An additional suggested procedure is the administration of an aqueous extract of suspected poisoned tissues or feed material to guinea-pigs and the measurement of tissue levels of citrate in them.

**NECROPSY FINDINGS**

Severe gastroenteritis is present in acute poisoning. In chronic fluorosis the bones have a chalky, white appearance, are brittle and have either local or disseminated exostoses, particularly along the diaphyses. Intra-articular structures are not primarily affected, although there may be some spurring and bridging of the joints. Histologically there is defective and irregular calcification of newly formed trabecular bone and active periosteal bone formation. Hypoplasia of the enamel and dentine are consistent physical and histological defects in the teeth of affected young animals. Young animals may also develop thickened growth plates and widened metaphyses that are grossly similar to rachitic changes. Degenerative changes in kidney, liver, heart muscle, adrenal glands, and central nervous system have been reported in severe cases. Degeneration of the bone marrow and consequent aplastic anemia also occur.

Chemical examination of necropsy specimens is valuable in the diagnosis as the fluorine content of bones from poisoned animals is greatly increased. Levels of up to 1200 mg/kg are observed in normal animals but may be increased up to 3000 mg/kg in animals exposed to fluorine and showing only mottling of the teeth. Animals showing severe clinical signs have levels greater than 4000 mg/kg of bone on a dry, fat-free basis and after prolonged heavy feeding levels may be as high as 1.04%. Care must be taken in selecting the bone samples because of the great variation in the concentration of fluorine which occurs between different bones. Good data are available for comparison between metacarpal, metatarsal, rib, pelvic, and mandibular bones and antlers of deer. Mandibles usually show the greatest concentrations and in the long bones the distal and proximal quarters are more sensitive indicators than the center half.

Soft tissues are unreliable as a criterion for fluorosis because of their low levels of fluorine. In bone and teeth, ash levels of 0.01–0.15% fluorine are found in normal animals. Levels up to 1.5% fluorine indicate excessive intake but are not usually accompanied by anatomical changes. Where clinical signs of intoxication appear there is usually up to 2% fluorine in bone ash and 1% in teeth ash.

**Samples for confirmation of diagnosis**

- **Toxicology** – mandible/metatarsal; rib, vertebrae for evidence of osteofluorosis. Urine from affected animals for evidence of recent exposure (ASSAY (F))
- **Histology** – formalin-fixed metacarpal/metatarsal/mandible (LM).

**Diagnostic confirmation** depends on fluorine assay of food and water, of blood and urine of affected animals, and bones and teeth at necropsy.

**DIFFERENTIAL DIAGNOSIS**

**Diseases causing lameness and stiff gait at herd level:**
- Nutritional deficiency of phosphorus
- Nutritional deficiency of vitamin D
- Osteodystrophia fibrosa in horses
- Chronic selenium poisoning
- Enzootic calcinosis
- White muscle disease
- Ephemeral fever in cattle.

**TREATMENT**

Primary treatment, apart from removing the animals from the source of fluorine, is largely impractical. Acute cases require gastrointestinal sedatives.

**Supportive treatment** to neutralize residual fluorine in the alimentary tract and calcium salts intravenously is recommended. Aluminum salts act as neutralizers of the hydrofluoric acid produced in the stomach and because of their insolubility they are safe even in large quantities (30 g of aluminum sulfate daily for prevention, more for treatment). The calcium salts given intravenously should be given to effect, using the disappearance of tetany and hyperesthesia as a guide. This treatment will probably have to be repeated. The parenteral administration of glucose solutions is recommended because of the interference by fluorine with glucose metabolism. Irrespective of treatment used, no improvement in dental or osseous lesions can be anticipated but there may be amelioration of the other clinical signs.

**CONTROL**

**Fluorine content of feed**

Phosphatic feed supplements should contain not more than 0.2% fluorine for milking or breeding cattle or 0.3% for slaughter cattle, and should not comprise more than 2% of the grain ration if the fluorine content is of this order. In spite of this recommendation the feeding of rock phosphate containing 1–1.5% fluorine to cattle for long periods is maintained in some areas without major deleterious effects on health. Some deposits of rock phosphate have much higher contents of fluorine than others and commercial
defluorination makes these toxic deposits safe for animal feeding.

Bone meal in some areas may contain excessive quantities of fluorine and should be checked for its fluorine content. Access to superphosphate made from rock phosphate with high fluorine content should be avoided. Water from deep wells and artesian bores should be assayed for fluorine content before use.

Nutritional management
Where fluorine levels are marginal careful husbandry, including the watering of young, growing stock on fluorine-free supplies, and permitting only adults to be watered on the dangerous supplies, and rotating the animals between safe and dangerous waters at 3-month intervals may make it possible to utilize land areas otherwise unsuitable for stock raising. In some areas dairy herds may have to be maintained by the purchase of replacements rather than by the rearing of young stock. In areas where long-term ingestion of fluorine is likely to occur the aim should be to provide a diet of less than 50 mg/kg of the total diet of dairy cows. Adequate calcium and defluorinated phosphorus intakes should be insured as these reduce bone storage of fluorine.

Detoxication
Aluminum salts are the principal substances used to detoxicate food and water. They are relatively ineffective, reducing the accumulation of fluorine in bone by only 20–30%, and are thus referred to as ‘alleviators’. The sulfate and phosphate have been used but all the salts are unpalatable and can only be administered daily to animals being hand-fed relatively large amounts of concentrates. It is presumed that highly insoluble aluminum fluoride is formed in the alimentary canal.

Extensive field trials of aluminum as an alleviator have not justified its use as a practicable control measure in average circumstances. Best results are obtained by improvement in nutrition of the animals and better grassland management. If effective control measures are introduced it will be some years before the affected teeth have erupted and become visible and affected animals culled.

Slaked lime. The fluorine content of drinking water can be reduced from 10 to 0.95 mg/kg by adding freshly slaked lime to the water; 500–1000 mg/kg should be added and the water must be allowed to settle for 6 days. The method requires the use of large storage tanks.

Legislation to control fluoride emission from factories is now general but the usual limitation of not more than 1 μg/m³ does not completely avoid danger and serious losses can still occur at these emission levels. Prevailing tolerances for pasture contamination also appear to be incompletely protective.

REFERENCES

ALUMINUM POISONING
Aluminum is one of the potentially toxic elements introduced into the diets of animals by the deposition of soluble salts in acid rain, or by powder particles in factory effluent. Absorption by plants may also be a factor. Overt effects are rare but at high levels of intake, the aluminum suppresses the absorption of phosphorus and may be associated with the patient being in negative phosphorus balance. Retarded growth and hypophosphatemia have been produced experimentally in pigs.

REFERENCE

MOLYBDENUM POISONING

ETIOLOGY
Ingestion of toxic amounts of molybdenum.

Epidemiology
Enzootic in areas where soil, especially peat soils, contain high levels of molybdenum. Epizootics when molybdenum used in excessive amounts as an agricultural chemical.

Clinical signs
Signs of secondary hypocuprosis (weight loss, hair coat depigmentation, anemia) plus persistent, debilitating diarrhea.

Clinical pathology
High blood levels of molybdenum, low levels of copper.

Necropsy lesions
No significant lesions.

Diagnostic confirmation
High levels of molybdenum in feed and blood.

Treatment
Primary: copper salts orally.
Supportive: none necessary.
Control: Dietary supplementation with copper.

ETIOLOGY
A daily intake of 120–250 mg of molybdenum has proved to be toxic for cattle, although the toxic dose varies widely with the intake of sulfate, copper, and possibly other factors.

EPIDEMIOLOGY
Occurrence
The major occurrence of molybdenum poisoning is on pasture growing on molybdenum-rich soils, usually derived from particular geological formations, e.g. the ‘teat’ pastures of Somerset (UK), the USA, and Canada, marine black shales in the UK and pastures containing excess molybdenum intake with or without a marginal deficiency of copper in New Zealand, Canada, Ireland, and Australia.

Source
Toxic intakes
Soil molybdenum levels in problem areas vary between 10 and 100 mg/kg. Illness may occur on pasture containing 3–10 mg/kg. Although levels of less than 3 mg/kg are usually considered to be safe, signs of toxicity may occur at levels as low as 1 mg/kg if the sulfate intake is high and the copper status low; the trigger level of molybdenum at which the interference with the metabolism of copper may occur is 24 mg/kg dry matter in the diet.

Forage containing 10 mg/kg must be considered dangerous at all times and, on pasture affected by aerial contamination levels of 10–200 mg/kg may be encountered. Such intakes can be provided by:

- Industrial fallout of 5–40 ng/m³ of air or 2 mg/m² per month on pasture
- Contamination of pasture by motor oil containing molybdenum as an additive
- Aerial contamination by fumes from aluminum and steel alloy factories and oil refineries using molybdenum is associated with secondary copper deficiency
- The use of molybdenum in fertilizer mixtures to increase nitrogen fixation by legumes may lead to excessive amounts of molybdenum in soils.

Drinking water may not be as toxic as the same amount in fresh forages. For calves, the minimum toxic concentration in drinking water is between 10 and 50 mg/kg when dietary copper and sulfur intake in the diet is normal.

Risk factors
Sheep and cattle are clinically affected in field outbreaks of the disease and signs are most marked in young growing animals. Cattle are much more susceptible than sheep. Horses also appear to be susceptible.

The concentration of molybdenum in forage varies with the season, being highest in the spring and autumn and with the plant species, legumes, particularly teleclover, taking up molybdenum in much greater quantities than grasses.
Importance
The disease is not highly fatal but severe stunting and loss of production does occur.

PATHOGENESIS
Copper metabolism. An extended discussion of the role of molybdenum in copper metabolism is provided in the section on secondary deficiency. Excess molybdenum intake is associated with an increased formation of thiomolybdates, important enzyme inhibitors which interfere with the hepatic storage of copper and produce a state of copper deficiency. This situation is exacerbated by a high intake of sulfur or a low intake of copper. The syndrome of molybdenum intoxication resembles that of copper deficiency and treatment and prevention by the administration of copper is effective.

Molybdenum poisoning. Some of the signs of molybdenum poisoning, particularly diarrhea, are not characteristic of copper deficiency, and may represent a specific toxic effect of molybdenum. An identified specific toxic effect is that of causing the development of exostoses and hemorrhages about the long bones, and separation of the great trochanters of the femur in some sheep fed molybdenum experimentally. The lesions appear to be due to defects in connective tissue at muscle insertion points, and to defects in the epiphysial growth plates.

Experimental feeding of molybdenum, and its intravenous injection, produce a syndrome identical with that seen in the naturally occurring disease in cattle but liver and plasma levels of copper may not be depressed as is usual in naturally occurring cases. Experimental feeding of a large dose, up to 40 g, of molybdenum may be associated with only transient diarrhea. Most of the molybdenum is rapidly absorbed and excreted, 90% in the first week.

CLINICAL FINDINGS IN CATTLE
• Persistent scouring commences within 8–10 days of the animals having access to affected pasture
• Emaciation and a dry, staring coat develop and there is profound depression of milk production
• Depigmentation of black hair causes a red or gray tinge to appear. This may be particularly noticeable around the eyes, giving a bespectacled appearance. Intense craving for copper supplement has been noted
• Young cattle (3 months to 2 years) also show abnormalities of locomotion including marked stiffness of the legs and back, difficulty in rising, and great reluctance to move. The gait is suggestive of laminitis but the feet appear normal. The lameness may be due to the periosteal lesions described above. The appetite remains good
• Rare cases in horses show diarrhea and impaction colic and a high mortality rate.

CLINICAL PATHOLOGY
Blood copper levels are reduced from the normal of 1.0 µg/mL to 0.25 µg/mL. Seasonal variations occur depending on the intake of molybdenum.

Blood Molybdenum levels in normal animals are of the order of 0.05 mg/kg and rise to about 0.10 mg/kg when excess molybdenum is ingested. Levels as high as 0.70 and 1.4 mg/kg have been recorded in cattle and horses grazing on pasture contaminated by smelter fumes. On very large intakes of molybdenum cattle which are clinically normal may have molybdenum levels of 1000 mg/kg in feces, 45 mg/kg in urine, 10 mg/kg in blood, and 1 mg/kg in milk.

Necropsy findings
There are no gross or histological findings which characterize the disease, enteritis being conspicuously absent. The carcass is emaciated and dehydrated and there may be anemia if there is an accompanying copper deficiency. Tissue copper levels will be below normal.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation. The most effective method is to treat affected animals orally with copper sulfate (2 g daily or 1.5 g for adult sheep). The diarrhea ceases in 2–3 days and improvement in the other signs is rapid. The persistence of the diarrhea without other clinical signs, particularly in young cattle and sheep, may suggest:
• Internal parasitism, e.g. trichostrongylosis, ostertagiases; examination of feces for worm eggs is necessary for differentiation
• Johne's disease which affects only adults; usually only one animal in a herd shows clinical signs at any one time
• Acute enteritides including salmonellosis, winter dysentery and virus diarrhea, acute diseases accompanied by other diagnostic signs.

PRIMARY TREATMENT AND CONTROL
Molybdenum toxicity can be treated by the administration of copper, and controlled by increasing the copper content of the diet by 5 mg/kg. But the administration of copper to large numbers of animals presents a number of problems. For long-term control, the recommended ratio of Cu:Mo is 4:1 to 10:1, and a Sulfur:Mo ratio of <100:1 is considered safe vs. copper accumulation.

REFERENCES

PRIMARY COPPER POISONING
• Primary copper poisoning is associated with the intake of excessive amounts of copper
• Secondary copper poisoning, which occurs on low intakes of copper, is dealt with on p. 1823.
In both acute and chronic cases the mortality rate approximates 100%.

**Acute or chronic oral poisoning**
- Accidental administration of large quantities of soluble copper salts, e.g. as parasiticide drench
- Contamination of plants with fungicidal sprays
- Contamination of drinking water during snail eradication
- Grazing pasture too soon after it has been top-dressed with:
  - a copper salt to correct a mineral deficiency in the soil
  - poultry manure or dried chicken waste where the birds have been fed on a copper-rich diet
  - similarly with pig manure, dried pig wastes or pig slurry when the pigs have been fed on a copper-enriched ration as a growth supplement
- Grazing pasture growing on soils rich in copper
- Grazing pasture contaminated by smelter fumes or by drippings from overhead power cables made of copper but corroded by the constituents of an industrially polluted area
- Feeding of seed grain which has been treated with antifungal agents containing copper
- Feeding mineral or salt licks or mixtures containing excessive amounts of copper
- Salt or mineral mixtures containing copper ingested accidentally by salt-hungry livestock
- Copper-enriched concentrate rations fed as growth supplements to poultry or pigs in excessive quantities or fed to ruminants. Pigs can survive rations providing up to 250 mg/kg; these levels are toxic for ruminants in which 20 mg/kg is maximum copper content. For sheep, continued ingestion of cattle diets that contain elevated copper and limited molybdenum results in copper accumulation.
- Miscellaneous other sources of copper causing poisoning are palm oil cake, treated pine lumber containing arsenic, copper, and chromism.

**Acute parenteral poisoning**
Prophylactic injections of copper salts, especially the more soluble, aqueous preparations, are very toxic if recommended dose rates are exceeded. This procedure is being increasingly used to prevent copper deficiency in grazing ruminants where other cheaper methods are not applicable. The paste preparations, usually copper glycinate, appear to be non-toxic but the soluble preparations, e.g. copper edetate, when given at recommended doses, can be associated with heavy mortalities in sheep and calves. Copper as the diethylamine oxquinoline sulfonate has also been associated with deaths in sheep after injection of recommended dose rates. The absorption is fast and the blood levels high with these toxic compounds but not with copper methionate which has a good safety record. Deaths commence 24 hours after injection and continue for up to 7 days. Postmortem findings include hepatic centrilobular necrosis, nephrosis, pleural and peritoneal effusions.

**Toxic doses**
There is a great deal of published anecdotal evidence about the amount of copper in specific feeds fed to specific species which was associated with illness or deaths but almost no evidence of MD50s or similar levels for the several animal species. The following toxic dose rates are provided as a rough guide:

- **Single doses** of 20–110 mg of copper per kg BW produce acute copper poisoning in sheep and young calves
- The status of goats generally is uncertain
- In cattle a dose rate of 220–880 mg/kg BW is necessary to cause death

**Chronic poisoning** occurs in sheep and calves with daily intakes of 3.5 mg of copper/kg BW, 25 ppm being the maximum tolerated concentration in the feed. Even lower concentrations (15 ppm) may poison sheep if adequate molybdenum and sulfate are not present in the diet.

None of these data on toxic intakes come with information on competing and contributory dietary factors such as sulfate, molybdenum, and zinc and these are critical in determining the toxic effects of the copper intake.

**Risk factors**
Environmental factors
Both acute and chronic copper poisoning occurs under field conditions. Acute poisoning usually occurs because of the accidental administration of large quantities of soluble copper salts, but chronic poisoning occurs principally as a result of ingesting feed containing or contaminated by copper derived from the soil or by its application to the diet as an agricultural chemical or feed supplement.
The toxicity of the copper ingested in this way is governed not only by the absolute amount of copper but also by the interaction of a number of factors including the amount of molybdenum and sulfate present in the diet and the presence or absence of specific plants and the level of protein in the diet. In fact either copper deficiency or copper poisoning can occur on soils with apparently normal copper levels, the syndrome depending on the particular conditioning factors present. High molybdenum and sulfate levels in the rumen lead to the microbiological synthesis of non-absorbable thiomolybdates, and a high sulfate diet also leads to lower retention of copper in tissues.

There is also a competitive relationship between copper and zinc in the internal metabolism of ruminants, a high level of zinc in the diet reducing the intake of copper.

**Host factors**

**Species susceptibility.** Horses are the least susceptible with a tolerance to levels of 800 ppm in the diet. Cattle will usually tolerate 100 ppm and swine 250 ppm, but lethal hemolysis has occurred in cattle fed a low copper level mineral supplement (38 mg/kg BW for lactating cows) for 2 years. Goats are not featured in the literature on this subject and sheep criteria are recommended as guides.

Sheep are the most susceptible species, tolerating as little as 25 mg/kg BW; they are peculiar in the way in which copper is handled metabolically. Increased absorption is not easily achieved but abnormally high excretion is more difficult still, so that there is the general tendency for copper to accumulate.

**Breed susceptibility.** Sheep, e.g. the Texel and the Finnish Landrace, are more resistant while others, e.g. the Ronaldsay and the Orkney, are much more susceptible. The Angora goat appears to be most susceptible and Nubian goats appear to be more resistant than sheep. Angus cattle are much more susceptible than Charolais.

**Importance**
Many deaths due to copper poisoning are followed by deaths from general debility in sheep in poor condition. Dairy cows, especially those lactating at the time, fail to produce well, and special care is needed to bring them back to full production.

**PATHOGENESIS**
Soluble copper salts in high concentrations are protein coagulants. The ingestion of large quantities is associated with intense irritation of the alimentary mucosa and profound shock. Severe intravascular hemolysis occurs if the animal survives long enough. When excessive amounts of copper are injected the response is rapid and animals begin to die the next day and with a peak of mortality about the third day after dosing. Early deaths appear to be due to severe hepatic insufficiency and later deaths to renal failure due to tubular necrosis. There appear to be no renal lesions in sheep affected...
with chronic copper poisoning, unless a hemolytic crisis occurs, in which case there is a hemoglobinuric nephrosis.

The frequent ingestion of small amounts produces no ill-effects while copper accumulates in the liver. When maximum hepatic levels are reached after periods of exposure often as long as 6 months, the copper is released into the bloodstream and the animal dies of acute intravascular hemolysis. Thus there is really no such thing as ‘chronic’ copper intoxication; syndromes so called are fatal as acute hemolytic crises. One of the dangers of cumulative copper poisoning is that the animal shows normal health until the hemolytic crisis, when it becomes acutely ill and dies very quickly. Death is ascribed to acute anemia and hemoglobinuric nephrosis.

Two other abnormalities have been observed during and after the hemolytic crisis. One is the occurrence of methemoglobinemia, the other is the presence of degenerative lesions in the white matter of the brain. The accumulated copper can lead to the occurrence of a hemolytic crisis after ingestion of copper has ceased, and recurrent attacks can therefore occur in sheep that survive the attack. There are a number of explanations for the development of hemolysis. One is that the erythrocytes in affected sheep become immunogenic as a result of the copper accumulation. It is suggested that this immunogenicity leads to the development of an autoantibody and the final result of an autoimmune hemolytic anemia. Alternatively, copper may act as an oxidant on the red cell membrane, leading to membrane damage and acute hemolysis as a result of oxidant injury. This is consistent with the formation of methemoglobin, a result of oxidant effects during the acute hemolytic crisis.

The liberation of the hepatic copper is incompletely understood, but the favored hypothesis is that the accumulation of copper ions in the liver cells is associated with the accumulation of electron-dense lysozymes in the hepatocytes and their eventual necrosis. Various stresses including a fall in plane of nutrition, traveling, and lactation, are considered to precipitate the liberation. Complex mechanisms relating to disorders of cell membranes, a marked change in hemoglobin composition, including the development of methemoglobinemia and an increase in the oxidative status of the sheep, are described as occurring during the critical stages. During the prehemolytic stage of several weeks before the crisis there is hepatic necrosis and an elevation of levels of liver-specific enzymes. A much more serious necrosis of liver occurs at the time of the hemolytic crisis.

Sheep on a selenium-deficient diet and with low blood levels of glutathione peroxidase are more susceptible to chronic copper poisoning. Some sheep are also conditioned by inheritance to have low blood glutathione levels in spite of a normal dietary intake of selenium. They also have low glutathione peroxidase blood levels and may be more susceptible for this reason.

There is also a difference between breeds in their capacity to reduce copper absorption in response to the administration of zinc, Texels being much more responsive than Friesians and North Ronaldsdales are also known to be highly susceptible. These sheep normally subsist on seaweed which has a very low content of copper and molybdenum. When the sheep are fed on terrestrial herbage containing normal levels of copper and molybdenum and high levels of zinc they develop copper poisoning.

**CLINICAL FINDINGS**

**Acute intoxication**

Severe gastroenteritis occurs accompanied by abdominal pain and severe diarrhea and vomiting in some species. The feces and vomitus contain much mucus and have a characteristic green to blue color. Vomiting occurs in the pig and dog and intense thirst is apparent. Severe shock with a fall in body temperature and an increase in heart rate is followed by collapse and death usually within 24 hours. If the animal survives for a longer period, dysentery and jaundice become apparent.

Acute poisoning associated with the injection of copper salts is manifested only by anorexia, depression, and dehydration. In calves that survive the illness for 3 days or more massive ascites, hydrothorax, hydropericardium, hemoglobinuria and massive hemorrhages, dyspnea, head pressing, aimless wandering, circling, and ataxia occur. Lambs similarly poisoned and with similar postmortem lesions die within 24 hours of injection.

**Chronic intoxication**

In ruminants anorexia, thirst, hemoglobinuria, pallor, and jaundice appear suddenly. There is no disturbance of alimentary tract function. Depression is profound and the animal usually dies 24-48 hours after the appearance of signs. In pigs signs of illness are uncommon, most pigs being found dead without premonitory signs, although dullness, anorexia, poor weight gain, melena, weakness, pallor, hyperesthesia, and muscle tremor may be observed occasionally.

**CLINICAL PATHOLOGY**

Levels of copper in the blood and liver are markedly increased in chronic copper poisoning. In acute intoxications several days are required after ingestion before these levels rise appreciably. Fecal examination may show large amounts (8000-10 000 mg/kg) of copper. Liver biopsy is a satisfactory diagnostic technique and serves as a most important purpose in the detection of chronic copper poisoning as blood levels do not rise appreciably until the hemolytic crisis occurs just before death. Because of the greater concentration of copper in the caudate lobe as compared to other parts of the liver, an autopsy specimen is to be preferred.

Blood levels of copper during the hemolytic crisis are usually of the order of 78-114 μmol/L (4.9-7.2 μg/mL), compared with about 15.7 μmol/L (1 ppm) in normal animals. Normal liver levels of less than 5.5 mmol/kg dry matter (349 ppm) rise to above 15.7 mmol/kg (997 ppm) in the latter stages of chronic copper poisoning in sheep, to 95 mmol/kg in pigs, and to 30 mmol/kg in calves. In sheep, liver values greater than 7.85 mmol/kg and kidney values of greater than 1.25-1.57 mmol/kg dry matter are diagnostic. After a massive single dose it is important to include kidney among specimens submitted for copper assay, because levels may be high (more than 25 mg/kg dry matter) while liver copper levels have not yet risen. When comparing normal and toxic values it should be remembered whether results are expressed as dry weight basis or wet weight basis. Assuming approximately 20% dry matter in tissue, a wet weight value of 1.5 ppm copper is actually 7.5 ppm on a dry weight basis, comparable to the toxic range reported for blood above. Thus, a commonly observed toxic value of 200 ppm copper in liver (wet weight basis) would be reported as 1000 ppm copper on a dry weight basis.

The packed cell volume of the blood decreases sharply, from 40 down to 10% in 48 hours, during an acute hemolytic episode. Methemoglobinemia may be present and the urine should be checked for hemoglobin.

Serum enzyme activity is greatly increased just before the hemolytic episode, and there is a significant reduction in the rate of bromosulfalein clearance during this period in sheep and in calves poisoned experimentally. In sheep the aspartate aminotransferase (AST) levels may rise as high as 880 SF units per mL up to 6 weeks before obvious clinical signs appear, and the test is considered as a suitable monitor of copper poisoning in this species. Plasma aspartate aminotransferase and sorbitol dehydrogenase levels in blood are elevated at 60 days after the copper feeding begins, but diethyl succinate carboxylesterase levels rise within 7 days and are therefore
the better indicator. The hepatic enzymes GGT and AST were determined in one experimental study to be the best enzymes to assess copper load in sheep during the pre-hemolytic phase. GGT increases were evident 28 days before the hemolytic crisis and AST concentrations increased from 14 days prior to onset of acute copper toxicity.6

NECROPSY FINDINGS

Acute copper poisoning via oral exposure is uncommon in ruminants but gross changes include severe gastroenteritis with erosion and ulceration particularly in the abomasum. Macroscopic changes in calves poisoned by injected solutions of copper salts include hepateomegaly with an enhanced zonal pattern and massive fluid accumulations in body cavities. Characteristic microscopic findings in such acute copper toxicoses include extensive periportal hepatic necrosis and a variable amount of renal tubular nephrosis.

In chronic copper poisoning, jaundice and hemoglobinuria are usual but not constant findings. The liver is swollen, yellow and may contain hemorrhagic foci. The spleen is enlarged with a soft pulp and the kidneys are swollen and have a dark gunmetal color. The hemolytic crisis typical of ovine copper toxicosis results in massive acute hepato-cellular necrosis, which masks most of the chronic hepatic damage. These changes include hepato-cellular vacuolation and degeneration, increased single cell necrosis of hepatocytes, a variable amount of perilobular fibrosis, and proliferation of cholangiolar cells. These chronic lesions are more easily identified in cattle suffering from copper poisoning. Granular casts are often present in the renal tubules, especially in affected sheep. Hemosiderin deposits are increased in the liver and spleen.

Details of the critical copper levels of tissues are provided in the clinical pathology discussion. Although the lesions described above do occur in some outbreaks of the disease in pigs, they are not as pronounced as in ruminants and they are often accompanied by pulmonary edema and by severe hemorrhage from ulcers in the pars esophagea or large intestine.

Samples for confirmation of diagnosis
- Toxicology – 5 mL blood; 50 g liver, kidney; 100 g stomach content; 500 g suspect feed (ASSAY Cu)
- Histology – formalin-fixed liver, kidney, abomasum, spleen (LM).

TREATMENT

Primary treatment. For chronic copper poisoning daily oral treatment of lambs with 100 mg ammonium molybdate and 1 g anhydrous sodium sulfate significantly reduces the copper content of tissues and appearance to prevent deaths in lambs known to have toxic amounts of copper. The mode of action is by increasing the fecal excretion of copper. Under experimental conditions injection intravenously or subcutaneously has an ameliorating effect on copper poisoning by reducing the capacity of circulating copper to enter erythrocytes and cause their lysis. Injection of ammonium tetrathiomolybdate (three to six times intravenously at 2–3-day intervals at a dose rate of 27 mg/kg BW) is also effective. So too is the daily intravenous injections of sodium calcium edetate (70 mg/kg BW) for 2 days to calves. Different countries may have particular restrictions on the form of molybdenum approved for use, so locally available approved therapy should be determined and be a part of the veterinary pharmacy before acute hemolytic crises are encountered.

Supportive treatment should include blood transfusion. In acute cases gastrointestinal sedatives and symptomatic treatment for shock are recommended.

CONTROL

When chronic intoxication is occurring or appears probable the provision of additional molybdenum in the diet as described under the control of phytopogenous chronic copper poisoning should be effective as a preventive measure. Ferrous sulfide is effective but difficulty is usually encountered in getting the animals to eat it. In pigs and sheep the administration of iron and zinc reduces the risk of copper poisoning on diets supplemented by this element and a diet high in calcium encourages the development of copper poisoning, probably by creating a secondary zinc deficiency. A lick which contains dicalcium phosphate, sulfur, and zinc sulfate has been used to advantage as a prophylactic.7

REFERENCES

SECONDARY COPPER POISONING ('TOXEMIC JAUNDICE' COMPLEX)

Copper poisoning is a complex problem because of the many factors that influence the intake, metabolism, and excretion of the element. Consequently secondary copper poisoning ('toxemic jaundice') can occur on intakes of copper which are, in other dietary circumstances, non-toxic. The common syndromes include the following:

- Phytogenous chronic copper poisoning is a condition in which relatively small amounts of copper are ingested but excessive retention occurs because of the presence of specific plants which have no apparent association with liver damage.
- Hepatogenous chronic copper poisoning results from excessive retention of copper from the ingestion of specific plants which are associated with liver damage.
Phytopathogenic chronic copper poisoning

This occurs in sheep grazing pasture containing normal amounts of copper. Although the copper intake may be low, liver copper levels are high and a hemorrhagic crisis typical of chronic copper poisoning occurs. The prominent association is the contamination of the pasture by subterranean clover (Trifolium subterraneum) which may contain lower than normal quantities of copper (15–20 mg/kg). British breeds of sheep and their crosses with Merinos are most susceptible.

Control of the disease is by encouragement of grass growth in the pastures. Outbreaks can also be avoided if sheep are prevented from grazing lush, clover-dominant pastures in the autumn. Avoidance of stress, particularly malnutrition, is also important. The daily administration of molybdenum in the feed (7 mg/kg molybdenum) has been shown to greatly reduce the uptake of copper by lambs on diets of high copper content and this has been used as a practical preventive measure. Molybdenized superphosphate (70 g/ha), and molybdenized licks or mineral mixtures (86 kg salt, 63 kg finely ground gypsum, 0.45 kg sodium molybdate) are suitable alternatives. When an outbreak occurs, the administration of ammonium molybdate (50–100 mg/head per day) together with sodium sulfate (0.3–1.0 g/head per day) will stop further deaths in sheep within 3 days. Solutions of the above salts may be sprayed onto hay and sheep within 24 hours.

ETIOLOGY

Feed and water containing excessive quantities of salt are unpalatable to animals but excessive quantities of salt are sometimes ingested, especially in saline drinking waters. Specific details about the degree of salinity of drinking water that is compatible with health in animals are difficult to provide, because of the variation in the kinds of salts which occur in natural saline waters.

Toxic doses quoted for acute sodium chloride poisoning are for pigs, horses, and cattle 2.2 g/kg BW and for sheep 6 g/kg. The toxicity of salt is significantly influenced by the age and body weight of the subject. For example, dose rates which will kill pigs of 6.5–10 kg BW have little effect on pigs of 16–20 kg.

It is probable that the pathophysiological disturbance described here is one of water intoxication rather than salt poisoning in the absolute sense. High salt intakes are extensively used in sheep to restrict food intake during drought periods and in the control of urolithiasis in feeder wethers but salt poisoning does not occur if there is free access to water. Rations containing up to 13% of sodium chloride have been fed to ewes for long periods without apparent ill-effects, although diets containing 10–20% and water containing 1.5–2% sodium chloride do reduce food consumption. This may be of value when attempting to reduce feed intake but can be a disadvantage when sheep are watered on saline artesian water.

EPIDEMIOLOGY

Occurrence

Salt poisoning will occur wherever bore water is used for livestock drinking. It is reported principally from Australia, North America, and South Africa.

Sources of toxin

- Saline drinking water, especially after a change from fresh water, and especially if the animals are thirsty
- Water accumulating in salt troughs during drought periods
- Animals previously deprived of salt may eat excessive amounts if suddenly allowed access to unlimited quantities

SODIUM CHLORIDE POISONING

Etiology Ingestion of excessive amounts of sodium chloride OR normal intake but limited water intake.

Epidemiology Source of salt includes:
- Artesian bore water used as drinking water
- Water accumulating in pasture containers of salt mixture or lick
- Animals allowed access to salt after previous deprivation
- Excess salt in prepared feeds.

Clinical signs

Very large doses: vomiting, diarrhea, dehydration.

Average doses in cattle: opisthotonos, Nystagmus, blindness, convulsions, death.

Continuous intake in pigs: blindness, deafness, aimless wandering, head pressing, regularly periodic convulsions.

Continuous intake in ruminants: bawling, restlessless, anorexia.

Clinical pathology High blood levels of sodium and chloride. High salt content in water, feed. Eosinopenia only in pigs.

Necropsy lesions

Very large doses: gastroenteritis.

Average doses: eosinophilic meningitis in pigs; polioencephalomalacia in cattle.

High tissue levels of sodium and chloride.

Diagnostic confirmation Elevated sodium and chloride content of tissues. Cerebrospinal fluid sodium exceeds serum sodium. Elevated aqueous or vitreous humor sodium.

Treatment

Primary: remove source of salt, restrict water intake and allow acclimation to water slowly.

Supportive: gastroenteric sedatives and fluid/electrolyte replacement for gastroenteritis form; sedative and cerebral decompressant in convulsive form.

Control Limit intake of salt-rich water, whey, concentrate mixes; insure adequate drinking water supply at all times.
In animals kept in barns and small yards when prepared feeds contain too much salt, or salt is provided only intermittently, when trough space is limited and animals tend to gorge on swill or concentrate

- Swill fed to pigs may contain excessive amounts of salt when it contains dough residues from bakeries, brine from butchers' shops, salt whey from cheese factories, or salted fish waste

- Excessive sodium sulfate given to pigs as treatment for gut edema if the water intake is restricted

- Environmental pollution by oil wells. Cattle are attracted to oil residues of their salty flavor and may ingest toxic amounts

- Temporary restriction of the water supply to pigs of 8–12 weeks of age, lambs and calves fed prepared feeds containing the standard recommendation of 2% salt. Poisoning occurs when the animals are again allowed access to unlimited water. Similarly pigs brought into new pens where drinking water is supplied in automatic drinking cups may not be accustomed to their use and fail to drink for several days until they learn to operate the cups. Feeder lambs and calves may also be deprived of water when their troughs are frozen over.

Risk factors
Host factors
Sheep, beef cattle, and dairy cattle appear to be less susceptible than dairy cows in milk, which are in turn less susceptible than horses. Heavy milking cows, especially those in the early stages of lactation, are highly susceptible to salt poisoning because of their unstable fluid and electrolyte status.

Toxin factors
Saline waters often contain a mixture of salts and those containing high levels of magnesium or fluorine may be quite toxic. Water containing 0.2–0.5% magnesium chloride may be associated with reduced appetite and occasional diarrhea in sheep, especially if the sodium chloride content is also high, but water containing similar quantities of sodium sulfate does not have any harmful effect.

Variation between bore waters includes differences in the relative proportions of the acid radicals, particularly sulfates, carbonates, and chlorides.

Environment factors
Environmental temperatures have an effect on toxicity, signs occurring in the summer on water containing levels of salt which appear to be non-toxic in the winter. Australian recommendations are that the maximum concentration for sodium chloride or total salts in drinking water should not exceed 1.3% for sheep, 1% for cattle, and 0.9% for horses. South African and Canadian recommended levels are much lower but there does not appear to be any proof that such low levels of total and individual salts are necessary.

Importance
Many animals may be clinically affected and the mortality rate may be high where animals are kept under range conditions and have to depend on saline water supplies for drinking purposes. In animals kept under intensive conditions salt poisoning occurs only sporadically but most affected animals die and heavy losses may occur in groups of pigs.

PATHOGENESIS
Acute poisoning
When excessive amounts of salt are ingested gastroenteritis occurs because of the irritating effects of the high concentrations of salt. Dehydration results and is exacerbated by the increased osmotic pressure of the alimentary tract contents. Some salt is absorbed and may be associated with the involvement of the central nervous system as in chronic poisoning.

Chronic poisoning
Where the defect is one of decreased water but normal salt intake, there is an accumulation of sodium ions in tissues, including the brain, over a period of several days. An initial high sodium accumulation may inhibit anaerobic glycolysis, preventing active transport of sodium out of the cerebrospinal compartment. When water is made available in unlimited quantities, it migrates to the tissues to restore normal salt-water equilibrium. This is associated with acute cerebral edema and the appearance of signs referable to a sudden rise in intracranial pressure. The response is the same in all species but in pigs there is, in addition, an accumulation of eosinophils in nervous tissue and the meninges. The sodium ion is the one that accumulates in the tissues, identical syndromes being produced by the feeding of sodium propionate or sodium sulfate. It has also been observed that the feeding of soluble substances such as urea, which are excreted unchanged by the kidney, may be associated with anemia and an increase in the sodium ion concentration in brain tissue and the development of encephalomalacia.

This form of salt poisoning is chronic only in the sense that the sodium ion accumulates gradually. The clinical syndrome is acute in much the same way as the syndrome is acute in chronic copper poisoning. There is an apparent relationship between this form of salt poisoning and polioencephalomalacia in all species. Many outbreaks of this latter disease occur in circumstances which suggest chronic salt poisoning. Sheep become adapted to a continuous high salt intake (up to 1.3% sodium chloride in the drinking water) by significant changes in numbers of microflora in the rumen but this is not usually accompanied by any change in total metabolic activity. The same level of intake in sheep is associated with some mortality, chronic diarrhea and reduction in fertility, weight gain and wool growth.

CLINICAL FINDINGS
Acute salt poisoning in cattle
With very large doses the clinical signs are vomiting, diarrhea with mucus in the feces, abdominal pain, and anorexia. The more common syndrome, accompanying the dose of salt usually encountered, includes opisthotonos, nystagmus, tremor, blindness, paralyses, and knuckling at the fetlocks. There may be a nasal discharge and polyuria occurs constantly. A period of recumbency with convulsions follows and affected animals die within 24 hours of first becoming ill. Sheep show similar signs. In swine the signs include weakness and prostration, muscle tremor, clonic convulsions, coma and death after a course of about 48 hours.

Chronic salt poisoning
In pigs this is ushered in by the appearance of constipation, thirst and pruritus 2–4 days after exposure. A characteristic nervous syndrome follows within 12–24 hours. Initially there is apparent blindness and deafness, the pig remaining oblivious to normal stimuli and wandering about aimlessly, bumping into objects and pressing with the head. There may be circling or pivoting on one front leg. Recovery may occur at this stage or epileptiform convulsions begin, recurring at remarkably constant time intervals, usually 7 minutes, accompanied by tremor of the snout and neck. Clonic contractions of the neck muscles may be associated with jerky opisthotonos until the head is almost vertical causing the pig to walk backwards and assume a sitting posture. This may be followed by a clonic convulsion in lateral recumbency, with jaw clamping, salivation, and dyspnea. Death may occur due to respiratory failure or the pig relaxes into a state of coma for a few moments, revives and wanders about aimlessly until the next episode occurs. The pulse and temperature are normal and the convulsive pigs when both may be elevated. The course is variable and death may occur in a few hours or not for 3–4 days after the first appearance of illness.

Subacute poisoning
This syndrome in cattle and sheep on saline drinking water includes depression of...
appetite, thirst, constant bawling, especially in calves, loss of body weight, dehydratation, hypothermia, weakness, and occasional diarrhea. Incoordination, collapse, and tetanic convulsions with frothing from the mouth and nose may occur if the animals are forced to exercise. Acetonemia may be a complication in lactating cows.

**Eosinophilic dermatitis** has been observed at meat inspection in pigs transported in trucks salted to prevent slipping. The condition can be reproduced experimentally by rubbing salt in the skin.

**Subclinical salt poisoning** Lower levels of intake can suppress food intake and growth without overt clinical signs. This occurs in heifers drinking water containing 1.75% sodium chloride; the animals only maintain weight at a salt level of 1.5% and show suboptimal weight gains when the water contains 1.25% sodium chloride. Drinking water containing 0.25% salt significantly reduces the milk yield of high-producing dairy cows.

**CLINICAL PATHOLOGY**

In pigs serum sodium levels are elevated appreciably above normal levels (135–145 mmol/L), to about 170–210 mmol/L during the severe stage of chronic sodium salt poisoning.1 Also polydipsia is recorded at blood serum levels of sodium chloride of 900 mg/dL, typical signs of salt poisoning at 1300 mg/dL, and death when levels exceed 1500 mg/dL. An eosinopenia is also evident during this stage and a return to normal levels usually indicates recovery. In cattle the same changes occur but there is no eosinopenia. Samples of feed and drinking water should be collected for salt assay.

**NECROPSY FINDINGS**

In acute salt poisoning of cattle there is marked congestion of the mucosa of the omasum and abomasum. The feces are fluid and dark. Animals that have survived for several days show hydropericardium and edema of the skeletal muscles. The blood appears to be thinner than normal. Gastroenteritis may be evident in some pigs poisoned with large doses of salt but in chronic poisoning there are no gross lesions. Histologically the neurologic lesions of acute poisoning are restricted to expansion of perivascular spaces in the brain. In contrast, the microscopic changes in chronic salt poisoning in pigs are quite diagnostic. The expansion of perivascular spaces typical of acute cerebral edema is accompanied by meningitis featuring large numbers of eosinophils, which extend along Virchow–Robin spaces into the brain tissue. In pigs that survive there may be residual polioencephalomalacia, especially of the cerebral cortex. Chemical estimation of the amount of sodium and chloride in tissues, especially brain, may be of diagnostic value. Levels exceeding 150 mg/kg of sodium in the brain and liver, and of chlorides in excess of 180 mg in the brain, 70 mg in muscle and 250 mg/kg in the liver are considered to indicate salt poisoning. Brain sodium concentrations from 2230 to 4250 μg/g tissue have been recorded in water deprivation/salt intoxication of cattle.2 Aqueous humor sodium values in these circumstances have ranged from 172 to 218 meq/L.

**Samples for confirmation of diagnosis**

- **Toxicology** – 50 g liver, skeletal muscle, brain, serum, cerebrospinal fluid, aqueous, or vitreous humor, feed, water (ASSAY (Na)(Cl))
- **Histology** – formalin-fixed half of sagittally-sectioned brain (LM).

### TREATMENT

**Primary treatment** of both acute and chronic salt poisoning is the immediate removal of the toxic feed or water. Serum sodium levels should not be reduced by more than 0.5 mEq/hour if possible, serum sodium should be measured and a formula used to calculate the free water deficit as follows:

\[
\text{Free water deficit (L)} = 0.6 \times \text{body weight (kg)} \times (\text{current serum sodium concentration/reference range serum sodium concentration}) - 1
\]

Initially access to fresh water should be restricted to small amounts at frequent intervals; unlimited access may be associated with a sudden increase in the number of animals affected. In advanced cases animals may be unable to drink and water may have to be administered by stomach tube.

**Supportive treatment** includes alimentary tract sedatives when gastroenteritis is present and administration of isotonic fluids when dehydration has occurred. When there is evidence of cerebral edema it may be necessary to administer a sedative, and cerebral decompression may be attempted by the use of diuretics or hypertonic solutions injected parenterally.

**CONTROL**

Drinking water for all classes of livestock should not contain more than 0.5% sodium chloride or total salts, although sheep and beef cattle can survive on water containing as much as 1.7% sodium chloride or total salts. Waters containing a high concentration of fluoride or magnesium are particularly dangerous to livestock. Both salt and water should be freely available at all times. Diets fed to pigs should not contain more than 1% salt. The way in which whey is fed to pigs – with minimum water intake – makes prevention difficult unless the whey can be kept free of salt at the cheese factory.

### REFERENCE

### ZINC POISONING

#### Synopsis

**Etiology** Soluble zinc salts in drinking water.

**Epidemiology** Rare occurrence due to contamination of water from galvanized vessels, or industrial pollution.
Zinc poisoning in livestock is a rare occurrence and poorly documented. Zinc is associated with constipation in cattle and efficiency when zinc is fed at the rate of 0.1% of diet. Toxic doses are not well defined but are likely to be associated with poisoning when zinc is fed at the rate of 1 g/kg BW. At 1.5–2.0 g/kg BW there is reduced feed consumption in both species and deprived appetite in cattle.

**ETIOLOGY**

Toxic doses are not well defined but drinking water containing 6–8 mg/kg of zinc is associated with constipation in cattle and 200 g of zinc as lactate fed over a period of 2 months as a 0.1% solution is associated with arthritis in pigs. The maximum amount tolerated by pigs is 0.1% zinc (as zinc carbonate) in the diet. Experimental zinc poisoning in sheep and cattle is associated with reduced weight gains and feed efficiency when zinc is fed at the rate of 1 g/kg BW. At 1.5–1.7 g/kg BW there is reduced feed consumption in both species and depraved appetite in cattle.

**EPIDEMIOLOGY**

Occurrence

Zinc poisoning in livestock is a rare occurrence and poorly documented.

**Source of toxin**

Zinc released from galvanized surfaces when:

- subjected to electrolysis when galvanized and copper pipes are joined
- galvanized bins flake zinc when used for storage of pig swill
- an outbreak of poisoning has occurred in pigs fed buttermilk from a dairy factory. The buttermilk was piped to the pig pens each day through a long galvanized iron pipe. The buttermilk lay in pools in the pipe after each batch was run through; souring occurred and the lactic acid produced was associated with the formation of zinc lactate which was passed to the pigs in the next batch of buttermilk. The concentration of zinc in the milk (0.066%) was slightly higher than the minimum toxic strength (0.05%).

The addition of zinc to pig rations as a preventive against parakeratosis is unlikely to be associated with poisoning because of the unpalatability of rations containing excessive amounts of zinc obtained orally is absorbed primarily from the proximal small intestine and approximately one-third of absorbed zinc is protein bound in the plasma. Phytic acid content of plant proteins interferes with absorption of zinc in monogastric diets. Other nutrients or elements that reduce zinc absorption include calcium, cadmium, and copper. Once absorbed, zinc accumulates rapidly in liver and pancreas with slower accumulation in muscle and bone. Excretion is primarily in feces contributed from bile and from secretion via intestinal mucosa and bile.

The pathogenesis of zinc poisoning has not been determined, but it is likely that the arthritic lesions observed will be due to faulty calcium absorption. This lesion in equines has also been suggested related to interactions of zinc and copper with interference in collagen metabolism. The development of anemia in some animals is poorly understood, but may be a result of interactions of zinc, copper, and calcium.

**CLINICAL FINDINGS**

**Acute poisoning**

Cattle. Large doses are associated with light green-colored diarrhea and drastic reduction in milk yield. Severe cases show additional signs including somnolence and paresis.

Pigs. Large doses are associated with decreased food intake, arthritis, hemorrhages in the axillae, gastritis, and enteritis. Death may occur within 21 days.

**Chronic poisoning**

Dairy cattle show chronic constipation and a fall in milk yield.

Pigs fed buttermilk containing zinc show anorexia, lethargy, unthriftiness, rough coat, subcutaneous hematomas, stiffness, lameness, progressive weakness with enlargement of the joints, particularly the shoulder joint, and finally recumbency.

Horses. Chronic poisoning is associated with a non-specific, degenerative arthritis especially at the distal end of the tibia. The lesion is accompanied by an effusion into the joint capsule and the obvious enlargement of the hock joint. There may also be a generalized osteoporosis, lameness, and illthrift.

Experimental dosing with large quantities of soluble zinc salts is associated with diarrhea, dysentery, or subcutaneous edema, jaundice, posterior weakness and death. Zinc fed experimentally to foals is associated with pharyngeal and laryngeal paralysis, stiffness and lameness resulting from swelling of the epiphyses of long bones.

**PATHOGENESIS**

Zinc obtained orally is absorbed primarily from the proximal small intestine and approximately one-third of absorbed zinc is protein bound in the plasma. Phytic acid content of plant proteins interferes with absorption of zinc in monogastric diets. Other nutrients or elements that reduce zinc absorption include calcium, cadmium, and copper. Once absorbed, zinc accumulates rapidly in liver and pancreas with slower accumulation in muscle and bone. Excretion is primarily in feces contributed from bile and from secretion via intestinal mucosa and bile.

The pathogenesis of zinc poisoning has not been determined, but it is likely that the arthritic lesions observed will be due to faulty calcium absorption. This lesion in equines has also been suggested related to interactions of zinc and copper with interference in collagen metabolism. The development of anemia in some animals is poorly understood, but may be a result of interactions of zinc, copper, and calcium.
usual levels of about 140 μg/mL in normal cattle. Estimated as zinc protoporphyrin, the levels in poisoned donkeys and mules reach 900-1900 μg/mL. 1 Fecal levels of zinc are likely to be elevated from an average of 220 mg/kg in normal animals to 8740 mg/kg in affected ones.

**Necropsy Findings**

Severe, acute poisoning in sheep is associated with an abomasitis and duodenitis, in which the mucosa may appear green in color. In survivors a severe, fibrosing pancreatitis may develop. Acute poisoning in cattle has been accompanied by generalized pulmonary emphysema, a pale flabby myocardium, renal hemorrhages, and severe hepatic degeneration. Chronic poisoning in this species may result in lesions in many organs but the most consistent damage is in the pancreas. Atrophy of exocrine pancreatic acini with extensive interstitial fibrosis have also been described in piglets receiving a total parenteral nutrition diet. 8

In chronic zinc poisoning in pigs there is a non-specific, degenerative arthritis affecting particularly the head of the humerus, the articular cartilage being separated from the underlying osteoporotic bone. In foals, similar joint lesions and nephrosclerosis may be seen.

The hepatic zinc content in normal animals is high (30-150 mg/kg wet matter in calves) and may reach levels of 400-600 mg/kg wet matter after continued ingestion of zinc chromate paste without being accompanied by signs of zinc poisoning. In acute poisoning by zinc oxide in cattle, levels of 2000 mg/kg dry matter in liver and 300-700 mg/kg dry matter in kidney may be achieved; tissue copper levels in these animals may be reduced to 10-20 mg/kg. Tissue levels in calves dying of experimental zinc poisoning are much lower: 200-400 mg/kg. 8

**Samples for confirmation of diagnosis**

| Toxicology | 50 g liver, kidney; 500 g suspect feed or ingesta (ASSAY (Zn)) |
| Histology | Formalin-fixed pancreas (LM) |

**Tissue assay** The zinc content of liver in normal animals is high (30-150 mg/kg wet matter in calves) and may reach levels of 400-600 mg/kg wet matter after continued ingestion of zinc chromate paste without being accompanied by signs of zinc poisoning. In acute poisoning by zinc oxide in cattle levels of 2000 mg/kg dry matter in liver and 300-700 mg/kg dry matter in kidney may be achieved; tissue copper levels in these animals may be reduced to 10-20 mg/kg. Tissue levels in calves dying of experimental zinc poisoning are much lower: 200-400 mg/kg.

**Differential Diagnosis**

Diagnostic confirmation of zinc poisoning depends on identification of elevated levels of zinc in fluids or tissues. Differential diagnosis list Diseases with similar clinical profiles include, in pigs:

- Rickets limited in occurrence to young pigs
- Erysipelas

**Treatment**

**Primary**: Other than removal of the source of the zinc, none are recommended.

**Supportive treatment**: is limited to symptomatic treatment.

**Control**

Galvanized utensils and piping should be rinsed after each use in carrying milk. The addition of extra amounts of calcium to the diet of pigs is capable of preventing the toxic effects of zinc if the calcium supplementation is heavy and the zinc intake is not too high.

**Poisoning by Organic Iron Compounds**

Fatal poisoning in piglets and in horses and calves is associated with the injection of organic iron preparations as prophylaxis against juvenile anemia.
Piglets
Within 1 or 2 hours of injection sudden deaths occur, sometimes accompanied by vomiting and diarrhea. By necropsy examination there is severe myocardial degeneration of skeletal but not cardiac muscle. The progeny of vitamin E deficient sows are most susceptible, and the most toxic compounds are those which contain a high proportion of their iron in ionic, and therefore readily absorbable, form. In the state of deficiency of vitamin E the muscle cell membranes are damaged and extensive biochemical changes result, including a great increase in extracellular potassium levels causing cardiac arrest and sudden death.

Age resistance. Pigs at 2 days of age are much more susceptible to the toxic effects of these iron compounds than are 8-day-old pigs. A suggested reason for this age resistance is the older pigs' better renal functional ability to excrete iron. Another possible reason is the greater mobilization of calcium by older pigs in response to iron administration. This mobilization, or calciophilaxis, can be great enough to result in deposition of calcium in damaged tissues or to cause death. This effect appears to be precipitated by simultaneous or immediately preceding (within 24 hours) injection of vitamin D3 but the injection is not essential to it.

Much of the administered iron is taken up by the reticuloendothelial (monocyte-macrophage) system, and this blockage of the system by the iron preparation may remove the buffering action of the system against absorbed inorganic and bacterial toxins.

There is an additional possible damaging effect of iron injection in young pigs, the development of asymmetric hind-quarters. In this condition there is asymmetry but the muscles are normal in composition and appear to have asymmetric blood supplies.

Horses
Deaths have occurred in horses within a few minutes of intramuscular injection of iron compounds. Others have shown severe shock but recovered. Death when it occurs appears to be due to acute heart failure. Newborn foals also die soon after the oral administration of a 'digestive inoculant' which contains ferrous fumarate (16 mg/kg) or the iron compound alone. Naturally occurring cases1 and experimental cases point to acute hepatitis as the critical lesion, and the iron compound as the cause. Commencing 2 days after dosing the signs include depression, ataxia, recumbency, jaundice, and nystagmus. The mortality rate is 66% and the lesions are hepatitis and jaundice.

Cattle
Acute hepatitis and sudden deaths have occurred in 6–9-month-old bulls about 24 hours after injection of an organic iron preparation.2

IODINE POISONING
ETIOLOGY
Poisoning with inorganic iodine is not as common and is associated with illness in animals, because the toxic dose is so great. Doses of 10 mg/kg BW daily are usually required to produce fatal illness in calves. There is a special occurrence of goiter in foals when the foal and the dam are fed excessive amounts of iodine, when kelp is fed as a dietary supplement. Intakes of 35–40 mg iodide/day to a mare can be associated with the development of goiter in her foal. Toxicity has also occurred at much lower levels of intake (e.g. 160 mg/day per cow) and appears to be a practical risk when cows or calves are fed organic iodides such as ethylene diamine dihydroiodide constantly as a prophylactic against footrot.

CLINICAL FINDINGS
Inorganic iodine. In cattle and sheep signs include heavy dusting of the hair coat with large-sized dandruff scales, hair loss, dryness of the coat, lacrimation, hyperthermia, nasal discharge, hypersalivation, coughing due to bronchopneumonia, and anorexia. Exophthalmos occurs in some cases and severely affected animals may die of bronchopneumonia. In horses alopecia and heavy dandruff are characteristic.

Organic iodine. Toxic effects include a serious increased susceptibility to calf pneumonia and to abortion in pregnant cows.

CLINICAL PATHOLOGY/NECROPSY
Squamous metaplasia of tracheal and parotid duct epithelium is visible histologically, and serum vitamin A levels are reduced. Serum iodine levels are elevated above the normal level of 5–10 µg/100 mL up to 20–130 µg/mL.

REVIEW LITERATURE

CADMIUM POISONING
There is much interest in cadmium as an environmental pollutant and the likelihood of its entering the human food chain via animals used as food. The chances of cadmium accumulating in lean meat are not very great because the levels of ingestion required to produce significant levels are so high that they would be associated with observable clinical illness. However, kidney and liver do accumulate cadmium much more readily than other tissues. Naturally occurring cases of poisoning by cadmium salts are rare in animals, most cases result from accidental administrations of farm chemicals, e.g. a cadmium-containing fungicide.

Sewage and sewage sludge may have higher than desirable levels of cadmium but have not been shown to be associated with poisoning when used as pasture top-dressing or as feed. Conversely, cattle are seen to be effective screens or filters between the high content of cadmium in the diet and the human consumer of the meat.

Ruminants
Chronic poisoning in cattle is associated with inappetence, weakness, loss of weight, poor hoof keratinization, dry brittle horns, matting of the hair, keratosis, and peeling of the skin. At necropsy there is hyperkeratosis of forestomach epithelium and degenerative changes in most organs. In sheep, levels of 60 µg/g of feed for 137 days are needed to be associated with illness. Experimental poisoning of sheep is associated with anemia, nephropathy, and bone demineralization at a dose rate of 2.5 mg/kg body weight per day. Abortion, congenital defects, and stillbirths are also listed as toxic outcomes. The cutaneous lesions can be partly offset by the administration of zinc.

Pigs
In young pigs, levels in the feed of 50 mg/kg for 6 weeks reduce growth rate and are associated with an iron-responsive anemia.

CHROMIUM POISONING
Use of protein concentrates prepared from tannery waste as an animal feed is not recommended because of the material's high chromium content. Trivalent chromium salts given orally to pigs at the rate of 0.5–1.5 and at 3 mg/kg BW is associated with transient diarrhea. With the higher dosage there is also tremor, dyspnea, and anorexia.

VANADIUM POISONING
Experimental and natural poisoning of adult cattle and calves are recorded. Signs include diarrhea, sometimes dysentery, oliguria, difficulty in standing, and incoordination. Field cases are only likely to be encountered when industrial contamination of pasture occurs. Careful ploughing-in of the pasture, especially when the vanadium is contained in a fertilizer such as basic slag, reduces the toxic risk.1
BROMIDE POISONING
Accidental access to sodium bromide can result in a syndrome of somnolence, lateral recumbency, drooping of the ears, eyelids, and tail and dribbling of urine.

COBALT POISONING
Overdosing with cobalt compounds is associated with weight loss, rough hair coat, listlessness, anorexia, and muscular incoordination. Toxic effects appear in calves at dose rates of about 40-55 mg of elemental cobalt per 50 kg BW per day. Sheep are much less susceptible, ingesting 15 mg/kg BW of cobalt without apparent effect. Pigs tolerate up to 200 mg cobalt/kg of diet but intakes of 400 and 600 mg/kg are associated with growth depression, anorexia, stiffness of the legs, incoordination, and muscle tremors. Supplementation of the diet with methionine, or with additional iron, manganese, and zinc alleviate the toxic effects.

BORON POISONING
Because boron is now accepted as an essential plant food, it is being added to agricultural fertilizers and adding another toxic chemical to the list of farm hazards for animals. To improve the availability of the element a solubilized form of it is used, increasing its toxicity and its palatability. Signs include depression, weakness, tremor, ataxia, and short seizures of gait spasticity, dorsiflexion of the head, flutter of the periorbicular muscles, followed by stumbling backwards and sternal recumbency, then lateral recumbency and a quiet death. The case fatality rate is 100%. There are no gross lesions on necropsy examination.

Experimental dosing with the fertilizer in goats is associated with the above syndrome plus head-shaking, ear-flucking, star-gazing (staring), phantom dodging, oral champing, restless weight shifting from foot to foot, sawhorse stance, mild diarrhea, and frequent urination. The goats do not eat or drink but paw and nuzzle the food and water as though they are hungry but unable to prehend.1

REFERENCE

Diseases associated with farm chemicals
Poisoning of animals by agricultural chemicals has become a major area of study in farm-animal medicine. It is a problem area because of the multiplicity of the products used, their extraordinary potency, and the difficulty of determining their generic composition from their trade names. It is possible to arrive at a diagnosis by observing clinical signs and necropsy lesions if one of the more common compounds has been used, but in many other instances it is not possible to do so. It is necessary in the case of any suspected poisoning to inquire in great detail into the history of exposure of the affected animals to any noxious materials. Having identified possible exposure it is then necessary to identify exactly the compound used and then consult a suitable information source, usually the manufacturer, about toxicity problems.

Poisoning of animals has been the prime concern of veterinarians when dealing with agricultural chemicals, but there is now an additional involvement, the need to certify animals and their products as being free of residues of agricultural chemicals. Part of this responsibility is to adequately warn owners of the dangers when dispensing drugs which are regarded as contaminants in human food. The additional involvement for the veterinarian is to identify the source of violative residues when public health authorities advise that rules concerning food purity have been disregarded.

The subject has now become so large that it forms a complete new literature. It is not possible to review all the known toxic compounds in a few pages, and only the more common substances are dealt with here.

ETIOLOGY
Carbon tetrachloride is sometimes accidentally administered in excessive quantities but deaths more commonly occur when sheep are given standard doses or cattle are dosed by mouth, instead of by injection. Standard doses of 2 mL per sheep to kill adult Fasciola hepatica or 1 mL/10 kg BW to obtain efficiency against immature forms, have been widely used but in some circumstances these doses can be highly toxic. Doses as low as 0.5 mL/10 kg BW can be associated with liver damage in calves and clinical effects are apparent at 1 mL/10 kg BW in goats.

EPIDEMIOLOGY
Risk factors
Factors which increase the likelihood that carbon tetrachloride will be toxic in a particular dosing incident are:
- Lush pasture
- Concurrent administration of a hepatotoxic anthelmintic, or dieldrin or phenobarbital
- Damage to the liver by plant or chemical poisons
- Ingestion of oxalate-rich plants
- Cold stress in shorn sheep
- Lactating ewes are more susceptible than dry sheep
- Accidental administration of the dose directly into the respiratory tract or inhalation of vapor due to faulty placement of the dose.

PATHOGENESIS
Inhalation of carbon tetrachloride is associated with an immediate and acute depression of the central nervous system and peripheral and circulatory collapse. Diffuse pulmonary edema occurs and sheep that survive show hepatic and renal damage.

Ingestion of toxic doses may result in death within 24 hours due to anesthetic depression and severe pulmonary edema, or may occur 3-7 days later resulting from renal and hepatic insufficiency. Deaths are associated with almost complete liver and kidney failure.

CLINICAL FINDINGS
In gross overdosing or inhalation there is an immediate onset of staggering, falling, progressive narcosis, collapse, convulsions, and death due to respiratory failure. Animals that survive this stage or, as in the most common form of carbon tetrachloride poisoning in which animals absorb insufficient dose to produce narcosis, additional signs may be manifested in 3-4 days. These comprise anorexia, depression, muscle weakness, diarrhea, and jaundice. After a further 2-3 days affected sheep go down and mild-to-moderate clonic convulsions may occur, but death is always preceded by a period of coma. Survivors...
are emaciated and weak, and may develop photosensitization or shed their wool. They are very susceptible to environmental stresses, particularly inclement weather, and isolated deaths may occur for several months.

**CLINICAL PATHOLOGY**

In the first 3 days after dosing, liver dysfunction is suggested by a pronounced elevation of AST levels and renal dysfunction by an elevation of blood urea levels. After 4 days from dosing the AST levels return to normal but elevated blood urea levels remain. The BSP test is highly positive and gamma-glutamyltransferase levels are increased.

**NECROPSY FINDINGS**

Animals dying after inhalation of the drug show marked pulmonary, hepatic, and renal damage. Those dying of massive oral overdosing may show abomasitis and mottling accompanied by centrilobular necrosis and fatty degeneration, and renal lesions of extensive tubular necrosis and degeneration, are observed in animals which die after the ingestion of small doses.

**DIFFERENTIAL DIAGNOSIS**

The history of deaths during dosing or commencing in sheep 3-4 days after drenching with carbon tetrachloride usually suggests the diagnosis. Diagnostic confirmation depends on demonstration of lesions of acute hepatitis.

**Differential diagnosis list**

Diseases manifested by acute hepatitis include:
- Facial eczema which requires the presence of *Pithomyces chartarum*
- Lupinosis
- Poisoning by *Senecio, Crotalaria, or Heliotropium spp.*

**TREATMENT**

**Primary.** In inhalation poisoning, artificial respiration and respiratory center stimulants are indicated. For the hepatitis there is no specific treatment.

**Supportive treatment.** should include the parenteral administration of calcium solutions and the provision of readily digestible carbohydrate. In valuable and seriously affected animals, the latter are probably best provided by the repeated parenteral injection of glucose and protein hydrolysate solutions.

**CONTROL**

Alternative, less toxic flukicides are almost universally used now. Carbon tetrachloride should not be used if sheep are stressed by cold or lack of feed, or if they have been grazing hepatotoxic plants. It should never be given simultaneously with anthelmintics that damage the liver. Sheep should be drenched into the pharynx when standing naturally so that the dose can be swallowed immediately.

**Phenothiazine poisoning**

Exposure to phenothiazine and potential poisoning has occurred in the past from its extensive use as an anthelmintic. Today, one of the remaining common uses may be for control of small strongyles in horses. Keratitis, the noteworthy sign of poisoning, usually occurs in calves, rarely in pigs and goats, and usually after a heavy single dose of phenothiazine, but it can occur in a program of daily intake in a dietary premix. Phenothiazine is absorbed from the rumen as the sulfoxide, conjugated in the liver and excreted in the urine as leucophenothiazine and leucothionol. As urine is voided, further oxidation turns the metabolic products to a red-brown dye, phenothiazine and thionol which may be confused as hematuria or hemoglobinuria. Cattle are unable to detoxify all the sulfoxide and some escapes into the circulation and can enter the aqueous humor of the eye, causing photosensitization. Other photodynamic agents which cannot enter the eye may also be produced, and they, with the sulfoxide, are associated with photosensitization of light-colored parts of the body. Hyperlacrimation, with severe blepharospasm and photophobia commences 12-36 hours after treatment and is followed by the development of a white opacity on the lateral or dorsal aspects of the cornea, depending on which is exposed to sunlight. Most animals recover within a few days, particularly if kept inside or in a shaded paddock. If the animals continue to be exposed a severe conjunctivitis with keratitis may result.

**Tetrachlorethylene poisoning**

Tetrachlorethylene rarely produces incoordination which may be evident for 1 or 2 hours after dosing in cattle or sheep. Treatment is not usually necessary.

**Hexachlorethane poisoning**

Hexachlorethane is preferred to carbon tetrachloride for the treatment of fascioliasis in cattle but it is not completely without danger. Deaths are rare (1 in 20,000 cattle treated), and in sheep (1 in 40,000) but non-fatal illness is not uncommon. Susceptible groups may show narcosis, muscle tremor, and recumbency after administration of the standard dose (cattle: 15 g per 6 months of age up to a maximum of 60 g; sheep: 0.6 g/kg BW); such animals should be given half this dose on two occasions at 48-hour intervals.

**CLINICAL SIGNS**

In severe cases these take the form of ataxia, dullness, anorexia, dyspnea, ruminal tympany, and sometimes abdominal pain, diarrhea, and dysentery. The groups include:
- Emaciated animals
- Occasional idiosyncratic animals
- When the liver damage is associated with fluke, infestation is severe
- Animals on high protein diets, or grazing rape or kale
- Parturient or heavily lactating cows.

**Necropsy lesions** include acute abomasitis and enteritis, edema of the abomasal mucosa, and hepatic centrilobular necrosis.

**Treatment** with calcium borogluconate as in milk fever elicits a good response.

**Hexachlorophene**

At high dose rates (25-50 mg/kg BW) hexachlorophene is associated with atrophy of seminiferous epithelium of the testis of young adult rams. Repeated dosing is associated with periporal fatty changes in liver.

**Rafoxanide and closantel**

Rafoxanide and closantel, both highly regarded anthelmintics, and cixioxanide, a discredited drug, are all halogenated salicylanilides, and have approximately the same low level of toxicity. They are capable of causing temporary or permanent blindness if overdosed. In the latter case there is degeneration of optic nerve tracts and other optic pathways in the brain.

**Nicotine poisoning**

Nicotine poisoning seldom occurs in animals except in lambs and calves where nicotine sulfate is still incorporated in some vermifuges. Doses of 0.2-0.3 g nicotine sulfate have been toxic for lambs weighing 14-20 kg. Animals in poor condition are more susceptible than well-nourished animals. Animals are affected within a few minutes of dosing and show dyspnea with rapid shallow respirations, muscle tremor and weakness, recumbency, and clonic convulsions. Animals that survive the acute episode may show abdominal pain, salivation, and diarrhea. At necropsy there may be abomasitis and inflammation of the duodenum.

**Treatment** should include artificial respiration and the administration of respiratory center stimulants. Oral dosing with tannic acid preparations will precipitate the alkaloid and retard further absorption.

**Piperazine**

Piperazine compounds are relatively non-toxic but poisoning can occur in horses on normal or excessive doses. Signs follow a delay of 12-24 hours and include incoordination, pupillary dilatation, hyperesthesia, tremor, somnolence, and either sway while at rest or lateral recumbency. Recovery follows in 48-72 hours without treatment.
Thiabendazole (2-(4'-thiazolyl)-benzimidazole)

At an oral dose rate of 800 mg/kg BW in sheep transient signs of salivation, anorexia, and depression appear. There are similar signs at larger dose rates and death is likely at a dose rate of 1200 mg/kg BW. Toxic nephrosis is the cause of death and is reflected in the clinical and pathological findings of hypokalemia, hypoproteinemia, and uremia.

Levamisole

All commercial preparations of levamisole consist of the lev isomer. Its mechanism of action is similar to nicotine by causing prolonged depolarization and neuromuscular junction blockade. In pigs, concurrent treatment with levamisole and pyrantel tartrate resulted in enhanced toxicity of the levamisole. Following treatment at standard doses, some cattle and, more rarely, sheep show signs of lip-licking, increased salivation, head-shaking, skin tremors, and excitability. The excitability is more marked in calves; with higher doses the signs are more pronounced, defecation is frequent and hyperesthesia in the form of a continuous twitching of the skin may be seen. Double doses in goats produce mild depression and ptosis, while higher doses produce, in addition, head-shaking, twitching of facial muscles, grinding of teeth, salivation, tail-twitching, increased micturition, and straining. Accidental injection of pigs caused vomiting, salivation, ataxia, recumbency, and a high mortality within a few minutes of injection.

Parbendazole, cambendazole, and albendazole

Parbendazole and cambendazole are teratogens and are specifically contraindicated in pregnant animals especially during the first third of pregnancy and at dose rates higher than normal. The safety margin is small and their use at any dose level is not recommended in these females. Defects produced include rotational and flexing deformities of the limbs, overflexion of the carpal joints, abnormalities of posture and gait, vertebral fusion and asymmetric cranial ossification, cerebral hypoplasia and hydrocephalus. Albendazole at 4 times the standard dose also produces some abnormalities if given early in pregnancy.

Fenbendazole

A dose of fenbendazole and the flukeicide, bromsalans, to cattle either simultaneously or within a few days of each other may be accompanied by deaths. As fenbendazole and the other tertiary benzimidazoles, oxendazole, and albendazole, are extremely valuable in removing dormant Ostertagia ostertagi larvae, it is suggested that fasonal (bromsalans) should not be used where this is an important problem or that 2 weeks should elapse between treatments.

Ivermectin

The intravenous injection into horses of a cattle formulation of ivermectin, contrary to the recommended usage, may cause immediate collapse with coma and periodic nystagmus. Treatment intravenously with flumethasone and flunixin meglumine is effective. Intramuscular injection of the ivermectin is associated with ventral midline edema, due possibly to a reaction to dead microfilariae, edema of limbs and eyelids, fever, dyspnea, disorientation, colic, and sudden death. Transient swelling at the injection site is common.

Occasional outbreaks of severe neurological disorders occur in only Murray Grey cattle after the administration of normal dose rates. Signs include incoordination, knuckling of the fetlocks, a swaying gait, muscle fasciculations, ear droop, blindness, and drooling of saliva, all apparent within 24 hours of dosing. The tongue is paralyzed and protrudes in some. Exercise enhances the syndrome and the patients collapse. Some are dead within 24 hours, some survive for 3 weeks, but all die. There are no gross necropsy lesions but the concentration of ivermectin in the brain is 10 times normal. A genetic penetrability of the meninges is suspected.

Organophosphatic anthelmintics

These are dealt with in the next section on insecticides. Industrial organophosphates and organophosphatic defoliants are dealt with in the section on miscellaneous farm chemicals.

Sumicidin

Sumicidin (fenvalerate) is a synthetic pyrethroid anthelmintic capable of causing non-fatal restlessness, yawning, frothing at the mouth, dyspnea, ear and tail erection, pupillary dilation, ruminal tympany, regurgitation of ruminal contents, staggering, tremor, clonic convulsions and recumbency after a single oral dose. Single oral doses of >450 mg/kg are lethal. Repeated daily dosing (113 or 225 mg/kg BW) also causes death after 5–15 days.4

INSECTICIDES

CHLORINATED HYDROCARBONS

(ORGANOCHLORINES)

Synopsis

Etiology Poisoning by any of the group of insecticides including aldrin, hexachloride, chlordane, DDT, dieldrin, endrin, heptachlor, isodrin, lindane, methoxychlor, toxaphene.

Epidemiology Accidental or misinformed overdosing. Usage on animals now superceded by other less toxic compounds. Stored or leftover products may accidentally be accessed by animals. Importance now due to residues in animal products used in human food chain.

Clinical signs Excitement, tremor, intermittent convulsions, hyperthermia, death.

Clinical pathology Assay of compounds in animal tissues.

Necropsy lesions No consistent significant lesions; some animals show pale musculature.

Diagnostic confirmation Chemical assay of liver or brain for acute poisoning; fat or other animal tissue for chronic poisoning.

Treatment Primary nil. Supportive: by sedation, control of hyperthermia, removal of residual chemical; activated charcoal for oral detoxication.

Control Use alternative insecticides. Avoid mixed farming enterprises which include use of these insecticides for insect control in crops.

ETIOLOGY

This group of poisons includes DDT, benzene hexachloride (and its pure gamma isomer - lindane), aldrin, dieldrin, chlordane, toxaphene, methoxychlor, DDD, isodrin, endrin, and heptachlor.

General toxicity data for the more common compounds are given in Table 32.4. Methoxychlor is less toxic than DDT, and isodrin and endrin are more toxic than aldrin and dieldrin. Camphor (2-bornanone) is chemically similar to toxaphene and is associated with a similar syndrome when fed accidentally.

EPIDEMIOLOGY

Occurrence

Poisoning with these compounds has been recorded in all animal species. The chlorinated hydrocarbons have come under so much criticism as environmental contaminants that they are rarely used directly on animals nowadays, so that outbreaks of clinical illness associated with them are much less common than they were.

Source of toxin

Ingestion, inhalation, aspiration, and percutaneous absorption are all possible portals of entry so that contamination of feed and application of sprays and dips can all be associated with poisoning.
Organochlorides are closely regulated and banned in some countries but still widely used in agriculture, primarily on growing plants to control insect pests, and on stored seed grain to control fungi. If the plants or grain, even milled and by products, e.g. bran, are fed to animals they can be associated with problems of tissue residues; if they are fed in sufficient quantities they can be associated with clinical illness. Many outbreaks are associated with the application to animals of products intended for crops, e.g. endosulfan, and labelled specifically ‘Not For Animal Use’. These insecticides may also contaminate soil and persist there for many years. Rooting animals such as pigs are particularly susceptible to this source of poisoning. These compounds are also sometimes fed accidentally and in large amounts in lieu of feed additives, and are associated with acute poisoning. In feed plotted or shedded animals cases may continue for periods as long as a year because of repeated contamination from the environment. Insect baits, e.g. grasshopper baits containing toxaphene and chlordane, used on pasture and for leaf-eating insects on market gardens can be associated with poisoning in livestock, which may eat large quantities of them. These insecticides, especially heptachlor, are incorporated in the soil before the crop of potatoes or maize is sown to control soil pests. Subsequent graving of the field will cause contamination of the livestock for several years.

### Method of application
Dipping of animals is the most hazardous method of application because entry may occur through all portals. Spraying is safer, percutaneous absorption and inhalation being the only portals of entry. The small particle size of the compound and concentration of animals in confined spaces while spraying, increase the possibility of poisoning. Oily preparations are not used for animal treatment but are used inadvertently and are readily absorbed through the skin.

### Formulation used
Concentrations of insecticide in formulations used for spraying barns are much higher than those used for animals. Amongst spray preparations simple solutions are most dangerous followed by emulsions and least of all suspensions of wettable powder. Dusted is safest and is preferred to other methods. Preparations for use on plants are often unstable emulsions, which come out of suspension quickly when they reach the plant. If these preparations are used in animal dips the first few animals through the dip can be heavily contaminated and suffer acute, lethal toxic effects. Although the treatment of pastures to control their insect pests is usually safe to animals grazing, the treated pasture or hay made from it can cause contamination of animal products. This contamination can be avoided by incorporating the insecticide into superphosphate granules (‘prills’) instead of applying it as sprays or dusts. The use of chlorinated hydrocarbons to protect stored seeds provides a hazard to animals if they are fed on the treated seed.

### Risk factors
The compounds vary in their ability to pass the skin barrier. Benzene hexachloride, aldrin, dieldrin, and chlordane are readily absorbed. Species susceptibility to skin absorption also varies widely. Very young animals of any species are more susceptible than adults, and lactating and emaciated animals also show increased susceptibility.

When these compounds were first used in dips, skin and foot infections occurred frequently because of contamination of the dip in the absence of a bactericidal agent. Cases of otitis media have occurred for the same reason, but more rarely.

### Importance
All of these compounds are capable of causing death due to acute poisoning but these are increasingly rare. Because the compounds are soluble in fat and accumulate in body stores of it they are formidable threats to the meat industry. They are also excreted in significant amounts in milk and enter the human food chain at this point. They are contaminated still further in cream and butter. They also represent a threat to sucklings, but the degree of contamination in fetuses and sucking animals is much less than in their dams.

The principal importance of organochlorine poisoning is the contamination of animal tissues at levels which are not acceptable by modern health standards. These contaminations become the subject of veterinary investigations, and are susceptible to standard techniques of epidemiological examination.

### PATHOGENESIS
The mode of action of organochlorides is to induce repetitive discharge of motor and sensory neurons by interference with
axonal transmission of nerve impulses. After absorption, cyclodiene insecticides are activated by the mixed function oxidase (MFO) system and any prior chemical or environmental exposures that increase the MFO system may exacerbate the onset of poisoning. The diphenyl aliphatic (DDT) organochlorines affect sodium channels, prolonging sodium influx and inhibiting potassium efflux at the nerve membrane. The cycloidiene organochlorines competitively inhibit the binding of gamma amino butyric acid (GABA) at receptor sites, resulting in loss of GABA inhibition and resultant stimulation of the neuron. In all organochlorine poisonings recovery may occur, but with smaller animals paralysis follows and finally collapse and death ensue.

Most of the substances accumulate in the fat depots, where they are a potential source of environmental exposures that increase the compound into the bloodstream and the appearance of signs of toxicity.

**CLINICAL FINDINGS**
The speed of onset of illness after exposure varies from a few minutes to a few hours, depending on the portal of entry and the compound and its formulation, but it is never very long.

The toxic effects produced by the members of this group include complete anorexia, increased excitability and irritability followed by ataxia, muscle tremor, weakness and paralysis and terminal convulsions in severe cases. Salivation and teeth grinding occur in large animals and vomiting in pigs. Variations on this clinical syndrome which is common to all organochlorine intoxications include:

- DDT and methoxychlor chronic poisoning may be associated with moderate liver damage
- Benzene hexachloride, lindane, chlordane, toxaphene, dieldrin, endrin, aldrin, heptachlor are associated with an exaggerated syndrome including teeth grinding, champing of jaws, dyspnea, tetany, snapping of the eyelids, auricular spasms, opisthotonos, frequent micturition, frenzied movements, walking backwards, climbing walls, violent somersaults, and aimless jumping. Fever of 5–7% above normal may occur, possibly a result of seizure activity. Seizures may persist for 2 or 3 days if the animal does not die.

**CLINICAL PATHOLOGY**
Blood, hair, and ingesta can be assayed chemically for specific toxins. The removal of a biopsy from the fat pad near the cow’s tail offers a satisfactory means of providing samples for tissue analysis. Organochlorine residues in acutely poisoned animals may reach 4–7 ppm in brain or liver.

**NECROPSY FINDINGS**
At necropsy there are no specific major lesions in the nervous system but toxic hepatitis and tubular nephritis appear in some cases. For assay specimens of hair, if the portal is percutaneous, and of the ingesta, if oral intake is probable, are appropriate. Tissue levels need to be high to be good indicators of recent intoxication. If possible the specimens should be deep frozen and the suspected compound should be nominated as assay procedures are long and involved.

**DIFFERENTIAL DIAGNOSIS**
The predominantly nervous syndrome attracts attention to encephalitis, encephalomalacia and toxic and metabolic encephalomyelopathies in all species. Differential diagnosis depends on a positive assay on animal tissues.

Differential diagnosis list:
- Lead poisoning, confirmed by a positive assay for lead on tissue
- Rabies confirmed by histopathological examination
- Pseudobabesia of cattle in early stages with purpurs and the accompanying frenzy
- Polioencephalomalacia confirmed by histopathological examination
- Thromboembolic meningoencephalitis in cattle confirmed by the isolation of Histophilus somni
- Salt poisoning in pigs identifiable by the characteristic lesions of eosinophilic meningoencephalitis.

**TREATMENT**
There is no specific primary treatment.

Supportive treatment includes sedation with pentobarbital sodium; repeated doses until signs disappear are preferred, with intravenous injections of glucose and calcium and the administration of a non-oily purgative. Activated charcoal (2 g/kg) given early by stomach tube will bind pesticide in rumen and reduce further absorption. Residual chemical should be removed from the coat, and this may be facilitated by judicious washing with soap and copious water rinse.

Toxic residues. Treatment to reduce the contamination of tissues is unsuccessful, and in most cases the time required for the contamination to subside naturally is long, of the order of 3–6 months, but varying between specific compounds. For example, cows fed DDT prepartum have required an average of 189 days from parturition for the level in the milk fat to decline to 125 ppm. Contamination in other species and with other chlorinated hydrocarbon compounds also tends to be persistent. After the source of contamination is removed drenching of cows with up to 2 kg of activated charcoal followed by daily incorporation in their feed for 2 weeks, or small amounts of mineral oil by mouth at short intervals, have been recommended for this purpose. Neither of these procedures is really practical in the average farm operation. The common procedure for reducing the level of contamination in animals is to put them in a feedlot without any contact with pasture and feed them on energy intensive rations. Sheep decontaminate much more quickly than cattle and animals on a high plane of nutrition eliminate the toxins more quickly.

**CONTROL**
Mixed enterprise farms, especially vegetable cropping and cattle farming, are the main sources for contamination incidents. Avoidance of the use of the compounds is recommended.

**ORGANOPHOSPHORUS COMPOUNDS AND CARBAMATES (ORGANOPHOSPHATES)**
### Treatment
Acute disease: primary treatment is atropine in large doses to effect or atropine plus oxime, remove residual toxin from hair coat and prevent absorption from GI tract with activated charcoal and cathartics.

### Control
Avoid use in stressed, especially dehydrated, animals. Special constraints with Chlorpyrifos.

### ETIOLOGY
Organophosphorus compounds and carbamates act in essentially the same way therapeutically and toxicologically, but bonding of the compound to the esterase enzyme is irreversible in the organophosphorus compounds and spontaneously degradable with the carbamates, rendering the carbamates potentially less dangerous. A large number of compounds are included in the group and those used for the direct treatment of animals have been selected for their low toxicity. A vast amount of information is available on the relative toxicities of the many compounds but it is not possible to provide details here and the information does not lend itself to summarization.

### EPIDEMIOLOGY

#### Occurrence
All animal species are affected. OP compound and carbamate poisoning is a common poisoning encountered by veterinarians in animal agriculture but the losses are still very small.

#### Source of toxin
- Grazing in recently sprayed areas, particularly orchards where the most toxic compounds are frequently used
- Spray used on cereal crops and in orchards carried by wind onto pasture fields
- Hay or cubes made from plants sprayed with organophosphate compounds
- Inadvertent access to granular insecticides intended for crops
- Use of old insecticide containers as feeding utensils
- Contamination of water supplies
- Too high a concentration of the insecticide in a spray
- Application to animals of products containing oily bases and designed specifically for spraying on walls or plants

#### Risk factors
Host factors
These include susceptible groups such as:
- Young animals (but with some compounds adults are more so), stressed, water-deprived, and chilled animals. The increased susceptibility due to restriction of water intake is noted especially after oral treatment to control warble-fly infestations
- Pregnant females in that congenital defects occur in their offspring
- Brahman and Brahman-cross cattle appear to be more susceptible to some compounds than other cattle
- Dorset Down sheep may be especially susceptible
- Chlorpyrifos is more toxic for male animals with high blood levels of testosterone and is not recommended for use in bulls over 8 months of age.

#### Importance
The introduction of these compounds into animal therapeutics as treatments for poisoning, and as causes of pollution of the environment, is described under that heading. The most severe effects in this category are discussed under that heading. The susceptibility of sheep is determined by restriction of water intake is noted especially after oral treatment to control warble-fly infestations.

#### Toxic factors
These include:
- Formulation used, especially the solvent or vehicle used and droplet size
- Method of application, e.g. the toxicity of pour-ons is delayed by 24 hours compared to sprays
- Toxicity of some compounds appears to increase with storage.

### PATHOGENESIS
Organophosphorus compounds are highly toxic and are readily absorbed by ingestion, inhalation and by percutaneous absorption. Once absorbed, sulfur containing organophosphates (phosphorothioates and phosphorodithioates) are metabolized by MFOs and sulfur is exchanged for oxygen thus increasing toxicity. There are two forms of toxicity, cholinesterase inactivation and an organophosphorus-induced, delayed neurotoxicity.

#### Cholinesterase inactivation
The inactivation of cholinesterase by these organophosphorus compounds is associated with an increase in acetylcholine in tissues and increased activity of the parasympathetic nervous system and of the postganglionic cholinergic nerves of the sympathetic nervous system. The toxic effects thus reproduce the muscarinic and nicotinic responses of acetylcholine administration. Differences between the toxicities of compounds depend on the stability of this bonding between esterase and compound, and the toxicity of the substance formed by the bonding.

#### The muscarinic effects of acetylcholine
are the visceral responses of the respiratory system and include marked respiratory distress due to a decrease in dynamic lung compliance and arterial oxygen tension and an increase in total pulmonary resistance; there is bronchial constriction and increased mucous secretion by bronchiolar glands in the alimentary tract there is increased peristalsis and salivation. Effects in other systems include hypotension and bradycardia, pupillary constriction, sweating and abortion.

The nicotinic effects are the skeletal muscle responses of twitching, tremor and tetany, convulsions, opisthotonos, weakness and flaccid paralysis. There is a difference in the relative muscarinic and nicotinic responses between species, the visceral effects being more marked in ruminants and the muscular effects more evident in pigs in which posterior paralysis is the common manifestation.

### Organophosphorus-induced delayed neurotoxicity
This form of toxicity is manifested by distal axonopathy commencing 1 or 2 weeks after the poisoning incident. There is a dieback of neurons causing regional flaccid paralysis, especially in long nerves. The pathogenesis of this lesion is the toxic end-product produced by the interaction between some OP compounds and the esterase, a phosphorylated neuropathy toxic esterase. Typical examples of this effect are:
- Congenital defects in young carried by poisoned pregnant females
- Bilateral laryngeal hemiplegia in horses
- Possibly the paralytic ileus is associated with chlorpyrifos
- The most severe effects in this category are associated with industrial organophosphorus compounds and are discussed under that heading.

Haloxon has this neurotoxic effect in that it is associated with only a slight depression in cholinesterase levels, but a neurotoxic response in the form of hindlimb ataxia has been reported in a proportion of treated sheep and pigs. The susceptibility of sheep is determined by their ability to metabolize this class of organophosphorus compound and this is genetically controlled.

### CLINICAL FINDINGS

#### Acute poisoning
Illness may occur within minutes of inhalation or ingestion of solutions of the more toxic compounds and deaths may commence 2–5 minutes later. After cutaneous application of dichlorvos to calves clinical signs appear within 30 minutes, peak at about 90 minutes and disappear in 12–18 hours. With less toxic compounds
in solid form signs may not appear for some hours and deaths may be delayed for 12–24 hours.

Cattle, sheep and goats
In acute cholinesterase inactivation cases in ruminants the premonitory signs, and the only signs in mild cases, are salivation, lacrimation, restlessness, nasal discharge, cough, dyspnea, diarrhea, frequent urination, and muscle stiffness with staggering. Grunting dyspnea is the most obvious, often audible from some distance because of the number affected. Additional signs include protrusion of the tongue, constriction of the pupils with resulting impairment of vision, muscle tremor commencing in the head and neck and spreading over the body, bloat, collapse, and death with or without convulsions or severe respiratory distress. In sheep and goats the signs are similar and include also abdominal pain. Signs disappear at 12–18 hours.

In delayed neurotoxicity cases signs do not appear for at least 8 and up to 90 days after the poisoning. Signs include posterior incoordination and paralysis. Chlorpyrifos is a specific example of this kind of poisoning. It should neither be applied to adult dairy cattle nor to any mature bulls. The signs include anorexia, depression, recumbency, a distended abdomen, ruminal stasis and diarrhea, and fluid splashing sounds on percussion of the right flank. Severe dehydration develops and may cause death.

Pigs
Cholinesterase inactivation syndrome. Visceral effects except vomiting are less pronounced than in ruminants and salivation, muscle tremor, nystagmus, and recumbency are characteristic. In some instances, the syndrome is an indefinite one with muscle weakness and drowsiness the only apparent signs. Respiratory distress and diarrhea do not occur.

Delayed neurotoxicity syndromes. Outbreaks of posterior paralysis occur 3 weeks after dosing with an organophosphorous anesthetic; clinical signs vary in severity from knocking in the hindlimbs to complete flaccid paralysis. The hindlimbs may be cragged behind while the pigs walk on the front legs. Affected pigs are bright and alert and eat well.

Piglets with congenital defects of the nervous system manifested clinically by ataxia and tremor are produced by sows dosed with OP compounds during pregnancy. Teratogenicity may be a characteristic of only some organophosphorous compounds, e.g. trichlorfon is teratogenic. Dichlorvos is not.

Horses
Cholinesterase inactivation syndrome. Signs include abdominal pain and grossly increased intestinal sounds, a very fluid diarrhea, muscle tremor, ataxia, circling, weakness, and dyspnea. Increased salivation occurs rarely.

Delayed neurotoxicity syndrome. Bilateral laryngeal paralysis develops in foals after dosing with an organophosphorous anesthetic. It is described under laryngeal hemiplegia.

Miscellaneous OP poisoning
Syndromes include:
- A significant drop in conception rate when the administration is at the beginning of estrus
- The fluid diarrhea which is a transient sign in moderate intoxication in foals may be expanded to a severe gastroenteritis with heavier dose rates
- Most organophosphorous compounds are associated with only temporary interference with cholinesterase and are not associated with any permanent effects in recovered animals but with some compounds, especially coumaphos and rotenone, the recovery period may be quite long, up to 3 months in the case of rotenone, because of slow excretion of the compound and the combined compound-esterase complex
- Absorption of an organophosphorous compound may also be associated with significant changes in the patient’s cholinesterase status without causing clinical signs
- Potentiation of the action of succinylcholine chloride for up to 1 month after the administration of the organophosphorous compound in horses. The administration of the relaxant to a sensitized horse can be followed by persistent apnea and death. This, and a number of other interactions with drugs which may themselves have toxic effects, mean that the manufacturer’s instructions with organophosphorous compounds must be followed explicitly.

CLINICAL PATHOLOGY
The estimation of cholinesterase in body tissues and fluids is the most satisfactory method of diagnosing this poisoning, but it is essential that proper methods and standards of normality be used. Convincing figures are of the order of 50–100% reduction from normal controls. The degree and the duration of the depression of blood cholinesterase levels varies with the dose rate and the toxicity of the compound used. Blood cholinesterase levels are depressed for much longer than the clinical signs, e.g. after dichlorvos poisoning the depression of cholinesterase level in the blood does not reach bottom until 12 hours after application and the return to normal levels takes 7–14 days. Similarly, cholinesterase levels in cattle poisoned with terbufos, an agricultural insecticide, do not commence to rise toward normal until 30 days and are not normal for 150 days after the poisoning incident. Unlike organophosphate insecticides, carbamate insecticide cholinesterase inhibitors may spontaneously reverse binding and cholinesterase depression may not be detectable in recently poisoned animals.

Suspected food material can be assayed for its content of organophosphorous compounds but assay of animal tissues or fluids is virtually valueless and may be misleading.

NECROPSY FINDINGS
There are no gross or histological lesions at necropsy in acute cholinesterase inactivation cases, but tissue specimens could be collected for toxicological analysis. Material sent for laboratory analysis for cholinesterase should be refrigerated but not deep frozen.

Distinctive degenerative lesions in peripheral nerves and spinal cord can be seen in delayed neurotoxicity cases, and hypoplasia is visible in the cerebrum, cerebellum, and spinal cord in congenitally affected piglets.

DIFFERENTIAL DIAGNOSIS
Outbreaks of a syndrome of dyspnea, salivation and muscle stiffness and constriction of the pupils after exposure plus a history of exposure and depressed blood levels of cholinesterase suggest intoxication with these organophosphorous compounds but diagnostic confirmation requires positive assay results on suspected toxic materials. In cattle the morbidity and case fatality rates approximate 100% but in pigs the recovery rate is good and all pigs may recover if the intake has been low and access is stopped. With the other poisons listed below death is much more common in pigs and residual defects, including blindness and paralysis occur in a proportion of the survivors.

Differential diagnosis list:
- Diseases with a similar clinical profile include:
  - in cattle:
    - Sporadic cases of anaphylaxis
    - Groups of cattle affected by acute bovine pulmonary emphysema and edema (fog fever) may show a sudden onset of dyspnea but pulmonary edema is obvious on auscultation, and salivation and muscle stiffness are absent
    - Early stages of nicotine poisoning, with transient muscle tremors and salivation.
  - in pigs:
    - Arsenic poisoning
    - Rotenone poisoning
    - Salt poisoning
    - Mercury poisoning
    - Avitaminosis-A.
TREATMENT

Primary treatment is urgent and critical, especially in cattle because of the usually high case fatality rate. Atropine in large (about double the normal) doses is the rational and approved treatment. Recommended doses are 0.25 mg/kg BW in cattle and 1 mg/kg BW in sheep. In very sick animals one-third of this dose should be given very slowly intravenously in a dilute (2%) solution and the remainder by intramuscular injection. Injections may have to be repeated at 4-5-hourly intervals as signs return, and continued over a period of 24-48 hours. Multiple continued dosing with atropine may not be effective and could result in atropine overdose. Cows that have received very large doses of the poison may not respond to treatment. Atropine does not reverse the nicotinic effects of the OP compound, i.e. the tremor, spasms, and convulsions, but it does block the muscarinic effects. Atropine appears to have low efficacy in sheep. This is not a serious drawback as sheep are much less susceptible than cattle to larger doses of atropine. It should be remembered that reactions in cattle following organophosphorus treatment for warble flies may be due either to the drug or to the damaged grub, and treatment with atropine would be contraindicated in the latter.

Oximes have some efficiency in the treatment of OP compounds, but not all carbamates some of which may have their toxicity enhanced; this is because of their ability to re activate acetylcholinesterase (ACHE) by dephosphorylation. Also their usefulness as antidotes declines rapidly with the passage of time after the poisoning occurs, and they are of doubtful usefulness after 24 hours. For these reasons oximes are not recommended unless their specific relationship to the particular carbamate is known. The oxime trimedoxime bromide is superior to 2-pyridinealdoxime methiodide (2-PAM) and diacetylmonoxime (DAm). Recommended dose rates for 2-pyridinealdoxime methiodide are 50-100 mg/kg BW given intravenously and for trimedoxime bromide 10-20 mg/kg BW. These dose rates can also be used for subcutaneous and intraperitoneal injection. Administration by any route is at 10% solution in normal saline. In horses 2-pyridinealdoxime methiodide at doses of 20 mg/kg BW has given good results. Treatment may need to be repeated for up to 10 days to counteract slower acting compounds such as coumaphos.

Removal of residual toxin. Animals that have been dipped or sprayed should be washed with water to which soap, soda or a detergent is added to remove residual organophosphorus material. When oral intake has occurred activated charcoal will adsorb residual toxin in the gut.

CONTROL

Most outbreaks occur after accidental access to compounds and this cannot always be avoided. Animals to be treated orally with organophosphorus insecticides should be permitted ample fresh drinking water beforehand. Chlorpyrifos is restricted to use in beef cattle and then not in calves less than 12 weeks old nor in bulls over 8 months of age.

REFERENCES

ROtenONE

Rotenone has commonly been used in the past to control bovine Hypoderma larvae (cattle grubs). It has a reputation for low mammalian toxicity but relatively high toxicity to aquatic life. The mammalian oral LD₅₀ is 100-300 mg/kg while the LD₅₀ for fish is less than 100 μg/L of water. Oral absorption in mammals is limited but enhanced by fat in the diet. Rotenone is relatively non-toxic but toxic effects appear in pigs fed a ration containing 2.5% rotenone. Pyrethrins are believed to enhance toxicity of rotenone. Ingesta at necropsy may contain as much as 2000 ppm of rotenone. Signs include salivation, muscle tremor, vomiting, ascending paralysis, incoordination, quadriplegia, respiratory depression, coma, and death. Accidental oral exposure may be treated with activated charcoal and an osmotic cathartic for decontamination followed by control of seizures are needed. Phenothiazine tranquilizers are contraindicated in Ro tenone poisoning.

REVIEW LITERATURE

Osweiler GD. Toxicology, Williams & Wilkins, Philadelphia, 1996; pp. 243-245.

AMITRAZ

This acaricide is widely used in most species but is prohibited in horses; when it is applied to them accidentally it is associated with a syndrome characterized by somnolence, incoordination, depression, reduction of intestinal sounds; impaction of the large intestine may occur within 24-48 hours. The susceptibility of the compound for equids is probably due to its much greater persistence in the body. Salivation, depression, anorexia, ataxia, tremors, and coma are signs attributed to amitraz in other species. Concentration of the dipping fluid, environmental temperature and the condition of the skin may influence absorption of the compound and the susceptibility of the animal. Residual amitraz should be removed from affected animals by hosing with cold water and the animal should be treated with large volumes of lubricant by stomach tube at intervals of 12-24 hours. Oral fluids containing electrolytes should be given by stomach tube to counteract dehydration and in venous fluids may be necessary.

REFERENCES

HERBICIDES

Herbicides vary widely in their composition and also in their toxicity.

- Arsenicals is associated with arsenic poisoning
- Sodium chloride is also toxic by causing methemoglobinemia
- One hazard of the relatively safe organic compounds set out below is their contamination by highly toxic ones as a result of faults in the manufacturing process, e.g. the dioxins which have been found to be significant contaminants of the 2,4,5-T chemical. Today, restrictions on registration and changes in the manufacturing process have drastically reduced contamination by dioxins.
- Some herbicides, e.g. glyphosate, make pasture that is sprayed with them more palatable, thus creating their own toxicity hazard. The phenoxy acetic acid herbicides can increase palatability of some plants after spraying as well as induce elevated nitrate concentration in plants for several days after spraying.

Dinitrophenol compounds

Dinitrophenol. Animals can be poisoned by dinitrophenol if it is absorbed from damaged skin or gastrointestinal tract.
percutaneous absorption of these compounds which have the effect of increasing the basal metabolic rate. Poisoning is manifested by an acute onset of restlessness, sweating, deep rapid respiration, fever, and collapse. In ruminants, but not in non-ruminants, the metabolites of these compounds are associated with intravascular hemolysis, methemoglobinemia and hypoproteinemia. Death may occur 24–48 hours later.

Dinitrophenol (DNP) and Dinitro-orthocresol (DNOC) are the commonest members of this group. In all species, doses of 25–50 mg/kg BW are usually toxic but much smaller doses produce toxicity when environmental temperatures are high. There is no accumulation of the drug within the body. Dinoseb, now rarely used, is a highly toxic DNP.

Hormone weed killers
2,4-D, silvex, MCPA and 2,4,5-T are non-toxic in the concentrations used on crops and pasture but dosing with 300–1000 mg/kg as a single dose is associated with deaths in 50% of cattle. They have also been tentatively linked with the high prevalence of small intestinal carcinomas in sheep. The picolinic acid herbicides picloram and clopyralid have also been suspected of the same relationship.

Barban is toxic at doses of 25 mg/kg, for cattle.
2,4-D at oral doses between 150 and 188 mg/kg BW is fatal to adult cows and at 10 mg/kg BW for sheep. Reversible toxic effects are produced with single doses in calves with doses of 200 mg/kg and in pigs with 100 mg/kg. Repeated administration of 50 mg/kg is toxic to pigs. In adult cows signs are dysphagia, tympany, anorexia, and muscular weakness; in pigs additional signs include incoordination, vomiting, and transient diarrhea. Long-term administration to pigs (500 ppm in the diet for 12 months) is associated with moderate degenerative changes in kidney and liver. 2,4-D may cause poisoning indirectly by its effect on the metabolism of weeds and sugar beets, resulting in a significant increase in the nitrate content of the leaves.

A commonly used mixture of 2,4-D, 2,4,5-T and a brushwood killer, monosodium methyl arsenate, is very toxic by mouth or after application to the skin; signs include anorexia, diarrhea, weight loss, and death in most cases.

Repeated dosing of sheep with silvex for about 30 days at 150 mg/kg BW causes death.

Single doses of the herbicides dichlofluanid, carbamate, triazine, and propionanilide at 250 mg/kg BW are fatal to sheep. Repeated small doses of carbamate are associated with marked alopecia. Acute poisoning with any of these compounds is unlikely unless large amounts are ingested accidentally.

Paraquat is associated with fibrosing pneumonitis in pigs but this does not develop in sheep or cattle with fatal doses. Poisoning with it is unlikely to occur unless it is administered accidentally or maliciously. A dose rate of 100 mg/kg BW is uniformly fatal in pigs with signs of vomiting, diarrhea, and dyspnea. Renal damage may also be a part of acute poisoning by paraquat.

Accidental poisoning of sheep due to contamination of pasture by diquat has been associated with widespread illness with signs of diarrhea and a significant mortality. In cattle accidental poisoning with diquat has been associated with fatal abomasitis and enteritis, hepatic and myocardial degeneration and pulmonary emphysema.

The herbicide triallate is associated with severe illness and some deaths with single oral doses of 300 mg/kg BW to sheep and 800 mg/kg to pigs. Salivation, bradycardia, vomiting, muscular weakness, dyspnea, tremor and convulsions are followed by death in 2–3 days. It is also toxic when given in small amounts continuously.

The triazine herbicides atrazine and prometone appear to be non-toxic at usual levels of ingestion. Accidental poisoning of sheep with atrazine is associated with paralysis, exophthalmos, grinding of the teeth, diarrhea, dyspnea, and tachycardia, and of cattle is associated with salivation, tenesmus, stiff gait, weakness. Experimental dosing of heifers with large doses of atrazine is associated with fatal poisoning, but animals treated with activated charcoal survive.

Simazine and aminonitrazole in combination have been associated with death in sheep, and horses allowed access to pasture sprayed with the mixture. In sheep the signs are staggering, inappetence, and depression. In horses colic is the important feature.

Simazine on its own, with continuous access is associated with tremor, tetany and paraplegia, and a prancing gait with the head held against the chest. Death occurs after 2–4 days and mild-to-moderate myocardopathy at necropsy.

Triclopyr, a selective postemergence herbicide, is toxic to horses at five times the estimated maximum intake from herbage. It is associated with digestive and respiratory signs, ataxia, stiff gait, sometimes tremor and mild to moderate renal damage.

Sodium chlorate
Animals seldom ingest sufficient sprayed plant material to produce clinical illness and the principal danger is from accidental dosing or permitting salt-hungry cattle to have access to the chemical. The lethal oral dose is 2–2.5 g/kg BW for sheep, 0.5 g/kg for cattle and 3.5 g/kg for dogs. Irrigation of the alimentary tract is associated with diarrhea and deep, black erosions of the abomasal and duodenal mucosae. Hemoglobinuria, anemia and methemoglobinemia result and somnolence and dyspnea are characteristic. At necropsy the blood, muscles, and viscera are very dark. No specific treatment is available. Sodium thiosulfate and methylene blue are used in treatment but have little effect but copious blood transfusions have been recommended.

Delrad
This algicide is used to control the growth of algae on ponds and other water reservoirs. Cattle and sheep are unharmed by the ingestion of water containing 100 ppm of the compound. Dose rates of 250 g/kg BW in adult cattle, 150 mg/kg in calves and 500 mg/kg sheep are associated with toxic effects.

DEFOLIANTS
Substances used to remove the leaves from plants to facilitate harvesting of seed may represent a toxic hazard if the residual stalks are fed to livestock.

Monochloroacetate (SMCA) is commonly used for this purpose and, although it is unlikely to cause poisoning unless very large quantities of the stalks are fed, sheep and cattle which gain access to recently sprayed fields may be seriously affected. Toxic signs in cattle include diarrhea, colic, muscular tremor, stiff gait, ataxia, and dyspnea. Terminally there may be convulsions, hyperexcitability, and aggressiveness. The course is short, most animals dying within a few hours.

An organophosphorus compound, tributyl triphosphorotriithioate used as a defoliant for cotton plants, produces typical signs of organophosphorus poisoning.

Thidiazuron, a cotton defoliant, appears not to be toxic for animals, but may enter the human food chain via goat’s milk and chicken eggs.

REFERENCE

FUNGICIDES
Zinc ethylene dithiocarbamate (zineb) may be associated with thyroid hyperplasia and hypofunction, degeneration of myocardium and skeletal muscle, testicular weight reduction, and germ cell depletion.

Thiram (tetramethyl thiuram sulfide) is a widely used agricultural fungicide which is associated with conjunctivitis,
rhinitis and bronchitis on local contact; it is thought to be associated with abortion in ewes on ingestion, and is a known teratogen but no specific poisoning incidents have been recorded in animals.2

REFERENCES

RODENTICIDES
The commonly used rodenticides in some countries are sodium fluoroacetate and alphanaphthylthiourea (ANTU), but their use is banned in other countries. Anticoagulants, include warfarin ((3-acetyloxybenzyl)-4-hydroxycoumarin) and its analogs, as well as newer ‘second generation’ anticoagulants (brodifacoum, bromadiolone, chlorphacinone). Zinc phosphide is often used as an alternative to anticoagulant rodenticides. They are all toxic to domestic animals and may cause death when ingested accidentally. ‘Quintox’, a rodenticide containing cholecalciferol (0.75 g/kg), has been associated with hypercalcemia, hyperphosphatemia, and death in dogs, and could cause death in farm animals.

SODIUM FLUOROACETATE
ETIOLOGY
Fluoroacetate occurs naturally in some plants, and in the form of compound 1080 is used as a rodenticide in agriculture. The toxic dose level for domestic animals is 0.3 mg/kg BW, and 0.4 mg/kg is lethal for sheep and cattle. Sublethal doses may be cumulative if given at sufficiently short intervals.

EPIDEMIOLOGY
Fluoroacetate’s use in agriculture poses a hazard for grazing farm animals because it is usually spread out across fields combined with cereals, carrots, or bread as bait and is attractive to ruminants.

PATHOGENESIS
Its mode of action is by inhibition of the enzyme aconitase, thus blocking the intracellular energy cycle. Two actions are manifest: myocardial depression with ventricular fibrillation, and central nervous system stimulation producing convulsions. In sheep, the predominant effect with acute poisoning is on myocardium; in dogs it is the nervous system.

CLINICAL FINDINGS
In herbivores generally there is sudden death in acute cases, the animals being found dead without evidence of a struggle; or there are tetanic convulsions and acute heart failure with the animals showing weakness and dyspnea accompanied by cardiac arrhythmia, a weak pulse and electrocardiographic evidence of ventricular fibrillation.

In sheep with subacute poisoning the signs are similar but are not apparent when the animal is at rest. When they are disturbed the nervous signs of tremor and convulsions appear but disappear when the sheep lies down.

Pigs manifest the nervous form of the disease, including hyperexcitability and violent tetanic convulsions. In all cases there is a period of delay of up to 2 hours after ingestion before signs appear.

CLINICAL PATHOLOGY/NECROPSY
FINDINGS
There are no specific lesions but the tissues contain elevated levels of citrate.

DIFFERENTIAL DIAGNOSIS
A history of access to toxic material plus appropriate clinical signs and assay of fluoroacetate in ingesta provide good circumstantial evidence and approximate diagnostic confirmation.

Differential diagnosis list:
- Many poisonous plants associated with sudden death linked to acute cardiac arrest
- Lightning strike or electrocution
- Inherited cardiomyopathy
- Ionophore poisoning especially warfarin and in horses
- Other less common causes of sudden death.

TREATMENT/CONTROL
Care in the disposition of baits and highly dependable retrieval of uneaten baits before allowing livestock access to baited fields preempts most mortalities. No specific treatment is available.

ALPHA NAPHTHYLTHIO UREA (ANTU)
Horses, pigs, calves, and dogs are susceptible as well as rats. Tolerance develops after the ingestion of sublethal doses. Death occurs within 24–48 hours after ingestion due to marked pleural effusion, pulmonary edema, and pericardial effusion. The toxic dose rate is of the order of 0.20–0.40 mg/kg BW in a single dose.

WARFARIN AND OTHER ANTICOAGULANT RODENTICIDES
ETIOLOGY
Warfarin is a well known anti-vitamin K anticoagulant rodenticide available since the 1940s and is known as a ‘first generation’ anticoagulant. Related compounds are dicumarol, coumatetralyl, and pindone.1 Brodifacoum, bromadiolone, diphacinone, difethialone, and chlorphacinone are known as ‘second generation’ anticoagulants and may be associated with poisoning from a single dose because of their quite prolonged elimination half lives. Single doses, are less likely to be associated with poisoning but repeated ingestion for some days may do so. Daily doses of warfarin of 0.2–0.5 mg/kg BW are fatal to pigs in 6–12 days. In cattle 200 mg/kg daily for 5 days is associated with 50% mortality. At 0.25 mg/kg for 10 days prothrombin times are depressed 20% and at 0.1–0.3 mg/kg abortions occur. Coumatetralyl was introduced to overcome the problem of resistance to warfarin which developed in some rodent populations. It is more hazardous for domestic animals than the original warfarin because it can be used in a concentrated form by laying it across rodent tracks; the rodents lick it from their paws. Brodifacoum acts over a long period and is detectable in liver up to 128 days after intake.

EPIDEMIOLOGY
These products are used by incorporating them into baits and they are in widespread use because they cause no poison shyness. Although most deaths occur because of misuse by farmers, contamination of feed-stuffs at the milling plant is not unknown. Calves and poultry are not usually affected, most outbreaks being recorded in pigs, cats, and dogs. Horses are not commonly affected, but warfarin poisoning has been produced experimentally in ponies.

PATHOGENESIS
The poisons exert their effects by interfering with reactivation of vitamin K, thus inhibiting the blood-clotting mechanism by preventing the operation of the thrombin to prothrombin complex. Sudden massive hemorrhage into body cavities or brain may cause immediate death, or death may occur slowly with accompanying lameness due to hemorrhage into subcutaneous tissues. Death due to rupture of a major blood vessel may also occur in 3–4-day-old calves born of cows given a non-fatal dose of warfarin during pregnancy.

CLINICAL FINDINGS
Most cases are of sudden death or found dead. The clinical syndrome includes mucosal pallor, weakness, recumbency, mild dyspnea. Coumatetralyl is associated with more specific signs in pigs, with lameness due to hemorrhage in and swelling of the legs.

CLINICAL PATHOLOGY
There are reduced values for packed cell volume, erythrocyte count, and hemoglobin content. Activated clotting time, prothrombin time, and PIVKA assays are prolonged. Anticoagulants or their metabolites can be detected chemically in
blood or urine, or in liver for animals that have died of toxicosis.

**NECROPSY LESIONS**

Table of tissues and massive hemorrhages are characteristic.

---

**DIFFERENTIAL DIAGNOSIS**

Assay of feed supply for the toxin, plus severe anemia evident on clinical, clinicopathological or necropsy findings provide diagnostic confirmation. The differential list includes other causes of acute hemorrhagic anemia.

---

**TREATMENT**

**Primary treatment.** Intravenous injection of a single dose of 50–75 mg/kg BW of vitamin K sub is an effective antidote for a horse. The prothrombin time is returned to normal in 12–24 hours after this treatment and persists at this level for as long as 96 hours. Animals with acute blood loss must be treated for shock and provided plasma or whole blood which will immediately restore clotting factors and provide immediate coagulation factors for clotting.

**Red squills**

Poisoning by red squills seldom occurs because the material is extremely unpalatable and when eaten is usually vomited. In all species large doses (100–500 mg/kg BW) must be administered to produce toxic effects. Young calves are most susceptible and goats least. Experimental poisoning is associated with vomiting, dehydration, prostration, and death due to pulmonary edema. Horses show sweating, dribbling, muscle tremor, and death due to pulmonary edema.

**Zinc phosphide**

Zinc phosphide is also unpalatable to domestic animals, and requires an acid stomach to release its toxic phosgene gas. It is not therefore a likely poison for ruminants, but could be a hazard for pigs and horses. Experimental poisoning with doses of about 40 mg/kg BW is associated with death in most species. A general toxemia with depression, anorexia, and depression rate occurs but there are no diagnostic signs. Necropsy lesions include congestion and hemorrhages in all organs, fatty degeneration of the liver and inflammation in the small intestine. Chemical assay is necessary to establish a diagnosis.

**REFERENCES**

---

**WOOD PRESERVATIVES**

**Phenolic compounds**

Lumber used in the construction of barns, stables, pens and yards is often treated with pentachlorophenol, dinitro-orthodiphenol, dinitro-cholsols, and coal tar creosote, or mixtures of these, and animals that have access to freshly treated material or the neat preservative may be poisoned. The toxic creosols may be imbibed orally or absorbed percutaneously, and contact with freshly treated wood may be associated with local cutaneous necrosis.

Acute fatal doses in all species are in the range of 120–140 mg/kg BW for pentachlorophenol, and chronic fatal doses range from 30 to 50 mg/kg BW. Fatal doses for coal tar creosote are 4–6 g/kg BW as a single dose, or 0.5 g/kg BW daily. A high mortality may be encountered in newborn pigs and there may be a greater than normal incidence of stillbirths when sows are farrowed in treated crates. Weaned pigs may show depression, skin irritation and occasionally death.

**Coal tar sealers**

For concrete floors may be associated with similar phenolic poisoning.

**Creosote**

Applied as a treatment for ring-worm, has shown marked toxic effects in cattle.

Besides the known toxic effects of these chemicals there has been interest in possible subclinical intoxications. There is a lack of definitive evidence on the subject, but horses bedded on shavings from pentachlorophenol-treated wood, prepared wrongly by treating the rough lumber and then dressing it instead of applying the preservative to the dressed lumber, have been poisoned by dioxin, a common contaminant in the preservative. Clinical signs include depression of appetite, severe weight loss, ventral and limb edema, hair loss, anemia, a crusty, scaly dermatitis around the eyes, muzzle, the axilla and inguinal region, and on the neck. Exudation through cracks in the skin is a feature of the lesion. Lesions in liver biopsies include necrosis and severe vascular changes in the hepatocytes.

**Copper–chrome–arsenate**

Softwood preserved against rot by the application of a patented mixture containing copper, chrome, and arsenic, has become very popular for use in yards and buildings used by livestock. The materials have been carefully tested to insure that there is virtually no risk of poisoning. It is recorded that animals would need to eat at least 28 g of the treated wood daily for a month before a chronic poisoning occurred. Horses that have the chewing habit could eat more than that and could theoretically become poisoned. Burning of treated lumber can make arsenic available and toxic to animal. This route of poisoning has occurred in cattle because of their tendency to lick ashes or soil where burning of wood has occurred.

---

**SEED DRESSINGS**

Many poisoning incidents are caused by livestock gaining access to seed which has been treated in some way. The more common ones are listed below, and each is dealt with under the heading of the toxic agent:

- Grain treated with arsenic used to poison birds
Additional poisons associated with farm chemicals include estrogenic substances and antibiotics. For example, zearalenone, a mycotoxin produced by certain fungi, can cause estrogenic effects in animals and humans. Zearalenone can affect the reproductive system, causing problems such as preputial prolapse and vaginal discharge. It can also cause changes in behavior, such as excessive mounting.

In cattle, estrogenic substances can cause problems such as nymphomonia (an increased desire for sex), and in sheep, they can cause problems like prolapse of the rectum and vagina. These problems are particularly common in animals that have been treated with estrogenic substances, such as estrogen implants.

Another example is the use of antibiotics in agriculture. Antibiotics are often used to treat or prevent infections in animals, but they can also have unintended effects. For example, the antibiotic tetracycline can cause problems like skin lesions and kidney damage in cattle.

Other common problems associated with farm chemicals include urolithiasis (bladder stones), which can occur in sheep, and pleural effusion (fluid in the chest cavity), which can occur in horses.

In conclusion, it is important for farmers and veterinarians to understand the potential effects of farm chemicals on animals and to use these substances judiciously to minimize any negative impact.
enlargement and keratinization of vaginal epithelium may be detected, and in mature female swine there may be persistent multiple retained corpora lutea.

**DIFFERENTIAL DIAGNOSIS**

The clinical profile is almost diagnostic, a search of the environment usually reveals a source of estrogen and estrogen assay on blood provides diagnostic confirmation.

Differential diagnosis list:
- Acute, especially traumatic, vaginitis
- Urethral obstruction in males
- Cantharidin poisoning.

**UREA**

**ETIOLOGY**

Urea is a common form of non-protein nitrogen (NPN) used in ruminant rations and as a fertilizer. Accidental access to the powder or liquid form of the compound can cause heavy mortalities. Poisoning occurs when cattle or sheep accidentally gain access to large quantities of urea, or are fed large quantities when they are unaccustomed to it, or when feeds are improperly mixed, or the water supply is polluted. Feed grade urea contains improperly mixed, or the water supply is polluted. Feed grade urea contains approximately 45% nitrogen and protein is approximately 16% nitrogen, and each gram of urea is equivalent to 2.81 g of protein. Thus, a ration containing 1% urea supplies the protein equivalent of 2.81% natural protein. Some care is required in bringing the animals onto urea gradually and an adequate proportion of carbohydrate must be included in the ration.

**EPIDEMIOLOGY**

Urea is used in agriculture as a feed additive for ruminants to provide a cheap protein substitute in the diet, and as a fertilizer on crop and pasture fields. Protein production from urea is dependent on rumen microorganisms assimilating the ammonia released from urea and converting it to bacterial protein useful to the animal. Natural urease in the rumen supports the hydrolysis of urea to release ammonia. The degree of toxicity of urea depends on the rapidity with which ammonia is released from the urea in the rumen, and this may be increased if soybean meal is being fed; soybeans contain urease which facilitates the breakdown of urea to ammonia. Ruminants are better able to assimilate ammonia into protein when adequate amounts of readily available carbohydrates are provided. This is usually from grain or a sugar source such as molasses. In the absence of sufficient digestible carbohydrate, as when only roughages are fed, urea is more toxic. At one time mixtures of molasses and urea were popular as feed supplements for cattle and are associated with outbreaks of poisoning with signs similar to those of urea poisoning and those associated with feeding ammoniated hay.

**Toxic dose levels**

In cattle which have been starved beforehand, dose levels up to 0.33 g/kg BW is associated with increases in blood levels of ammonia and dose levels of 0.44 g/kg BW produce signs of poisoning within 10 minutes of dosing and dose rates of 1–1.5 g/kg BW are associated with death.

**Tolerance to urea**

Animals unaccustomed to urea may show clinical illness when fed 20 g/50 kg BW, but by gradually increasing the quantity fed this amount can be tolerated. This tolerance is lost rapidly and animals which receive no urea for 3 days are again susceptible. Tolerance is also reduced by starvation, by lack of readily available dietary carbohydrate and by a low protein diet. SHEEP can eat 6% of their total ration as urea provided it is well mixed with roughage and fed throughout the day, preferably by spraying the urea mixed with molasses onto the roughage. Much more urea is tolerated if given to sheep in molasses (18 g), than if given as a drench (8 g) and prior feeding on lucerne further increases the tolerance and fasting for 24 hours reduces it. A dose rate of 1 g/kg BW to sheep appears to be non-toxic, but 2 g/kg is quickly fatal. In general, urea should not constitute more than 3% of the concentrate ration of ruminants.

**Horses**

Appear to be tolerant to relatively large doses of urea but the disease has been produced experimentally in ponies by administering 450 g by stomach tube. The clinical picture is similar to that in cattle, being largely related to the central nervous system. There is a sharp increase in blood ammonia levels after ingestion of the urea, and it is assumed that hydrolysis of the urea occurs in the cecum.

**Pigs**

Are quite unaffected by very large doses of urea unless they are deprived of water or have developed a cecal flora which produces urease.

**PATHOGENESIS**

The toxic effects are due to the sudden production of large quantities of ammonia and its rapid absorption from the rumen results in the onset of signs in 10–30 minutes after feeding. The severity of signs is related to blood ammonia levels and not to levels of ammonia in the rumen. However, the alkaline conditions in the rumen created by rapid release of ammonia can be associated with more of the ammonia to be present in a non-ionized form which favors rapid absorption from the rumen with resultant increase in blood ammonia concentration. Excess blood ammonia is toxic to intermediary metabolism and results in systemic lactic acidosis and elevated blood potassium, which can lead to hyperkalemic heart failure.

**CLINICAL SIGNS**

Cattle and sheep. Signs of toxicity commence as early as 10 minutes after the urea is eaten and include severe abdominal pain, frothing at the mouth and nose, hypersensitivity to sound and movement to the point of being aggressive, muscle tremor, incoordination, weakness, dyspnea, bloating, and violent struggling and bellowing. In severe cases the course is short and death occurs sometimes in a few minutes but usually in about 4 hours after ingestion. Less severe cases are drowsy and recumbent. The case fatality rate in affected animals is high.

**CLINICAL PATHOLOGY**

**Cattle.** Signs are visible when rumen ingesta levels of ammonia are 1000 mg/L, serum levels of ammonia nitrogen (NH₃-N) are 10–13 mmol/L (10–18 mg/dL)² and when blood ammonia nitrogen concentrations reach 0.7–0.8 mg/dL.

**Sheep**

Deaths occur at levels of ammonia nitrogen of 33 μg/mL of blood; the ruminal contents are alkaline when tested with litmus paper (pH elevated from 6.94 to 7.90) and ruminal ammonia levels rise from 6 to 50 mg/dL.

**NECROPSY FINDINGS**

There are no characteristic lesions at necropsy, but most cases show generalized congestion, hemorrhages, and pulmonary edema. Death is thought to result from respiratory arrest due to ammonia intoxication.

**Pigs.** Encephalomalacia has been produced by feeding a ration containing 15% urea. The clinical picture and histopathological findings were similar to those of salt poisoning except that no eosinophilic aggregations are present in the cerebral lesions.

**DIFFERENTIAL DIAGNOSIS**

Outbreaks of this poisoning are usually closely linked to known exposure to urea and achieve diagnostic confirmation by assay of high blood levels of ammonia.

Without the historical link to a source of urea the differential list is very long because of the similarity of the syndrome to other diseases in which nervous excitation is accompanied by muscle tremor, dyspnea, convulsions, and a high case fatality rate.

**Differential diagnosis list:**
- Acute hepatic insufficiency
- Anaphylaxis
TREATMENT

No primary treatment is likely to be effective but the oral administration of a weak acid such as vinegar (0.5–1 L to a sheep, 4 L to a cow), or 5% acetic acid is recommended. Cold water (10–30 L for adult cattle) will dilute excess urea and temporarily lower rumen pH. This may reduce the amount of ammonia absorbed but it must be administered as soon as the first clinical signs appear and repeated dosings may be necessary as clinical signs tend to recur about 30 minutes after treatment. The only really effective treatment is prompt and efficient emptying of the rumen, either via a large bore stomach tube or by rumenotomy, but the results are indifferent because the damage has usually been done already.

CONTROL

Urea is highly toxic and care is essential when handling it in the vicinity of animals. Feed manufacturers’ recommendations about maximum concentration of urea in prepared rations and acclimatization to the diet with inclusion of adequate readily available carbohydrates should be adhered to.

Propylene glycol poisoning

Propylene glycol is an unlikely poison but it is used extensively as an oral treatment for acetonemia in cattle and can be associated with poisoning if it is accidentally administered to horses, usually in mistake for mineral oil. Dose rates of 3 L to horses of 500 kg BW by stomach tube is associated with an immediate but short duration episode of abdominal pain, sweating, salivation, severe ataxia and depression, and a fetid odor of the feces. Much larger doses (8 L) can be fatal. Moderate-to-severe inflammation of the lining of the gut and edema of the brain are noticeable at necropsy examination.

Dried poultry wastes

Feeding dried poultry wastes to ruminants provides them with a source of nitrogen, and gets rid of the chicken farmer’s disposal problem. Deleterious effects include:

- Copper poisoning when the chickens are fed on diets supplemented with copper
- Estrogen poisoning when the chickens are fed on estrogen-supplemented diets
- An unidentified problem arises of hepatic necrosis, hypoalbuminemia, and ascites in lambs fed large amounts of poultry waste from hen batteries
- Litter from broiler houses is associated with renal damage but not to the point of causing mortality
- Botulism.

Brewer’s residues

Diseases associated with the feeding of by-products of brewing and distilling include:

- Carbohydrate engorgement in cattle fed wet brewe’s grains
- Possibly spinal cord degeneration in adult cattle fed sorghum beer residues contaminated with Aspergillus flavus and containing aflatoxin
- Excess sulfur (>0.45% in the diet) from some methods of processing which can lead to polioencephalomalacia.

Chemically treated natural feeds

Formalin-treated grain

This is a special diet fed to dairy cows to produce dairy products containing an increased proportion of polyunsaturated fats for special human diets. Fats in the grain are protected against hydrogenation in the rumen by coating the grains with formalin. If the formalin and the grain are not properly mixed, the free formalin left as a residue is associated with rumenitis and severe diarrhea.

Caustic-treated grain

Grain treated with caustic to improve its digestibility is recorded as causing focal interstitial nephritis, rumenitis, and abomasal ulceration in feedlot steers. The lesions have been produced experimentally. They may not be detected until the animals are slaughtered.

Ammoniated forage

Anhydrous ammonia is added to hay to improve its digestibility and nitrogen content. Environmental risk factors enhancing the production are low dry matter content of the feed, high environmental temperature, and high concentrations of ammonia in the treatment mixture. If the forage is high quality and has a high carbohydrate content it may undergo chemical change, possibly with the formation of a substituted imidazole, 4-methylimidazole (Mel) which is associated with hystera (bovine bonkers) in the cattle eating it. Calves sucking cows fed ammoniated hay may also be affected by this same syndrome. Experimental feeding with Mel produces the same syndrome but it is not the sole cause; other substances are also involved.

Clinical signs include hyperexcitability, hyperesthesia, restlessness, rapid blinking, pupillary dilatation, ear-flicking, frequent urination and defecation, dyspnea, frothing at the mouth, bellowing, charging, circling, and convulsions. Tremor, commencing at the head and opisthotonos are obvious early signs. Between convulsions affected sheep walk in circles and have a stiff gait. Nursing calves may show signs even though their dams are unaffected. No clinicopathological abnormalities occur, blood ammonia levels are normal, and no specific necropsy lesions have been identified.

Treatment consists of sedation but many patients do not respond to agents such as acepromazine. Dilution of toxic forage with normal feed is not recommended because the toxin may be cumulative. The maximum rate of ammoniation to avoid toxicity, for poor forage is 3% and 1% for high-moisture forage.

Newsprint

Newsprint is fed commercially to ruminants as an alternative roughage. Toxicological hazards of the material in sheep fed colored magazines for 6 months and comprising 23% of their ration included a significant deposition of lead in tissues and an increase in enzyme activity in liver, but there were no clinical signs and no histopathological lesions. Feeding for periods of several weeks has no detectable clinicopathological effects and there is evidence that the known toxins are not secreted in cows’ milk.

Sewage sludge

Urban sewage sludge is used as topdressing for pasture and may be associated with the spread of infectious disease as well as goiter. Sewage sludge may also be fed directly to animals, but may lead to dissemination of lead, cadmium, and polychlorinated biphenyls to animals and the food products derived from them. Potential damage due to illness or contamination of animal-produced feed can be minimized by leaving treated pasture exposed to weather for a period of several weeks before allowing animals access to it.

IONOPHORE POISONING

Synopsis

Etiology

Carboxylic ionophores used commercially as coccidiostats and growth promotants are associated with poisoning if dose rate is excessive; horses are very susceptible.
EPIDEMIOLOGY

Occurrence
All animal species are affected, including zoo ruminants.9 Poisoning incidents are most often reported in countries where animal husbandry is intensive and high levels of stall feeding are practiced.

Source of toxin
The poisonous properties of the agent are well known and poisoning is usually accidental due to failure to dilute a concentrate, poor mixing or because of wrong identification of containers. Also some liquid preparations settle out and need to be constantly mixed before and during mixing with a batch of feed. Cattle carrying reticular retention bovules of monensin to controlloat by delivering accurate daily doses of the drug, may die suddenly of acute heart failure due to myocardopathy, a condition likely to be associated with the monensin but by an unknown mechanism. The compound’s main use as a coccidiostat is in poultry, and deaths from congestive heart failure have occurred in cattle and sheep fed dried poultry litter from farms feeding salinomycin or maduramicin.10

Risk factors
These compounds are specifically prohibited for use in horses at any time because of their toxicity for that species. Concurrent administration of monensin or salinomycin and tiamulin or chloramphenicol or triacetyloleandomycin at safe doses can be associated with ionophore poisoning in pigs. Outbreaks may occur when tiamulin is introduced into the pigs’ drug regimen to control swine dysentery when the pigs’ ration already includes the ionophore as a growth promotant, or when the two drugs are combined as a coccidia prevention package. The dose and time relationships are complicated and are dealt with separately. The concurrent administration of monensin and selenium to lambs also enhances the toxicity of the selenium.11

PATHOGENESIS

The principal pathogenesis of monensin poisoning is damage to muscles. The origin of muscle damage appears due to loss of ion control and balance in cells and mitochondria leading to impaired intermediary metabolism.12 In cattle, the cardiac and skeletal muscles are affected about equally; in sheep and pigs the skeletal muscle is most seriously affected; in horses the myocardium is the focus of the damage. In the latter case acute or congestive heart failure may result, signs often being delayed for weeks until additional stress, such as late pregnancy or parturition, precipitates cardiac insufficiency. When the damage is principally to skeletal muscle the syndrome is one of weakness, ataxia, and recumbency; myoglobinuria is a common accompaniment.

Besides these major involvements of monensin and lasalocid there are a number of less well-known ones. There is a risk that cattle fed on a nitrogen-rich diet will be likely to suffer an outbreak of nitrite poisoning if they are also fed monensin. Another undesirable outcome may be a fall in butterfat because of shift from acetate to propionate production in the rumen. Continuous feeding of monensin to male pigs (50 ppm for 52 days) reduces blood levels of testosterone, and is associated with dystrophy of seminiferous tubules and reduced sperm counts.

CLINICAL SIGNS

In cattle signs commence within 24 hours with heavy doses but may be delayed for up to 5 days when the intake is lower. Signs commence with feed refusal followed by diarrhea, tremor, weakness, tachycardia, and ruminal atony, and animals may die at this stage from acute heart failure. Those that survive for a day or two develop congestive heart failure manifested by brisket edema, engorgement of the jugular veins, ascites, fluid feces, dyspnea, and tachycardia. Deaths may occur months after the major outbreak, usually due to the exertion of calving. When smaller doses are taken over a long period the syndrome is one of congestive heart failure in all of the cases.13

In sheep the syndrome may be acute followed by hyperesthesia, tremor, especially of the head, disappearance of the pupillary light reflex, recumbency, and convulsions with death occurring during a convulsion.14 More commonly the disease commences with feed refusal, diarrhea, rumen stasis and depression, followed by muscle weakness, a stiff gait, and recumbency. Chronic cases show atrophy of the muscles of the hindquarters and a still gait.

In pigs monensin poisoning is associated with dyspnea, anorexia, ataxia, paresis, myoglobinuria and cyanosis, diarrhea, tympany, and pruritis. Death follows in about 6 hours. Salinomycin is associated with the same general syndrome but includes also unwillingness to stand and, when forced to stand, tremor, especially in the hindlimbs, swaying, fetlock knuckling, and abrupt lying down. Exercise exacerbates the signs. Respiratory distress is in the form of irregular breathing. Feed intake is down 50% and sham drinking is characteristic. Red urine is evident for up to 5 days after the drug is discontinued.15
In horses cardiac and skeletal muscle are affected. In most cases it is the myocardium that creates the prominent syndrome. Horses affected by the cardiac disease may be found dead. In others there is restlessness, respiratory distress, diarrhea, mucosal congestion, profuse sweating, sometimes myoglobinuria, cardiac irregularity, and tachycardia (50–60/min). The course of the cardiac disease is short and affected horses may not show much clinical evidence of heart failure at the time of the poisoning but survivors, and survivors of an acute attack, may develop a poor performance syndrome or congestive heart failure up to several months later.16

Horses with skeletal muscle involvement have a syndrome including anorexia, fever, and red or dark urine, due to the extensive muscle breakdown, frequent lying down, difficulty in rising, stiff gait, especially the hindlimbs, and with knuckling of the fetlocks, followed by final recumbency after a period of as long as several months. Colic is also recorded during the acute phase but this may be the restlessness and frequent lying down and getting up of acute myositis. Euthanasia is the common outcome of these cases because of irreparable muscle damage.

**CLINICAL PATHOLOGY**

In all species tests show increases in serum levels of creatinine phosphokinase, lactate dehydrogenase and aspartate aminotransferase; myoglobinuria is frequent and often prolonged. However, results of clinical pathology tests may vary substantially among individual affected animals. Samples of feed and stomach contents, obtained by stomach tube, are desirable specimens for analysis. Some feeds fed to horses have contained as much as 125–250 g/tonne of feed and several months. Colic is also recorded during the acute phase but this may be the restlessness and frequent lying down and getting up of acute myositis. Euthanasia is the common outcome of these cases because of irreparable muscle damage.

**NECROPSY FINDINGS**

In cattle there is myocardiopathy, pulmonary edema, and enlargement of the liver and heart, hydropericardium, hydrothorax, and ascites. Gross lesions at necropsy are not always evident, and multiple samples of susceptible tissues should be collected and preserved in formalin for microscopic evaluation.

In sheep postmortem changes include necrosis in both skeletal and cardiac muscles but there are no lesions suggestive of heart failure. Lambs less than 1 month old show only gastrointestinal hemorrhage.

In horses necropsy lesions in acute cases include acute myocardial necrosis, pulmonary congestion, hepatic swelling, and in some cases pulmonary petechiation. Skeletal muscle necrosis may also be evident. Myoglobinuric nephrosis and myoglobinuria are secondary lesions. Chronic cases show marked cardiac myopathy, and possibly skeletal myopathy with obvious fibrosis.

**Stomach contents** are an obligatory sample in cases likely to go to litigation.

### **Differential Diagnosis**

In all species syndromes of acute or congestive heart failure due to acute cardiac myopathy or limb paralyis or recumbency due to skeletal myopathy are sufficiently common to necessitate a positive assay for one of the ionophores in the feed or stomach contents for **diagnostic confirmation**.

**Differential diagnosis list:**
- *Cattle*
  - Nutritional deficiency of vitamin E or selenium
  - Poisonings with such plants as *Karwinskia humboldtiana*, *Cassia occidentalis* and *Vicia villosa*

In pigs additional diagnostic alternatives include:
- Gossypol poisoning
- Porcine stress syndrome.

In horses there are clinical similarities to:
- Colic
- Laminitis
- Rhabdomyolysis.

### **Treatment**

There is no effective primary treatment and only supportive procedures are recommended. Selenium and vitamin E are ineffective after signs begin, although selenium or vitamin E given prior to appearance of clinical signs may be beneficial. Activated charcoal or mineral oil has been standard treatments aimed at removing the residue of the poison from the alimentary tract. They are of no value if the poison has already been absorbed; recovery is unlikely once the myocardium is affected.

### **Control**

Horses are very susceptible to poisoning by these antibiotics and great care is needed to insure cattle rations containing them are not left around for horses to eat. Pretreatment with vitamin E–selenium reduces the effects of monensin poisoning without completely preventing it.

### **Monensin-tiamulin or Salinomycin-Tiamulin Poisoning in Pigs**

The myotoxicity of monensin for pigs is enhanced by the simultaneous administration of the two antibiotics (monensin or salinomycin and tiamulin). All three of the substances are used as coccidiostats and it is not unusual for farmers to combine them. However, all of the agents use the same detoxication pathways in the liver with tiamulin having the priority. Tiamulin inhibits mitochondrial CYP3A enzymes that stimulate monensin metabolism, allowing accumulation of monensin.17 Monensin (or salinomycin) accumulates to the point of being toxic. The clinical syndrome consists of anorexia and weight loss and at necropsy there are lesions of myonecrosis in the tongue, diaphragm, and limbs. A similar toxicological situation arises in pigs with simultaneous dosing with tiamulin and salinomycin in which the toxic interaction is dose-related.

When tiamulin is used at therapeutic levels, in feed, water, or by injection and salinomycin is used at 60 ppm, toxic reactions and some deaths occur. The interaction does not occur when the two antibiotics are used concurrently and the tiamulin is used at the recommended prophylactic (30–40 ppm) or growth promotant (11 ppm) levels, and independently of whether the administration is oral or by injection,18 but only if a gap of 72 hours has elapsed between the last exposure to salinomycin and the first exposure to therapeutic levels of tiamulin and *vice versa*.

### **Pluronic Poisoning**

These substances are administered to adult cattle in their feed as prevention against bloat. They are unpalatable and unlikely to be consumed in dangerous amounts unless they are well masked in feed. When they are fed accidentally to calves in their milk they are associated with dyspnea, ruminal tympany, bellowing, protrusion of the tongue, nystagmus, opisthotonos, recumbency, and convulsions. Death after 24 hours is the usual outcome.

### **Carbadox Poisoning**

Carbadox, Mecadox or Fortigo – methyl 3-(2-quinoxalinylmethylene)carbazate-N°, is used in pig feeds as a growth promotant and in the treatment of swine dysentery and other enteric diseases at the recommended rate of 50 mg/kg of feed/head per day. Toxic effects occur at rates of 150 mg/kg. A related compound *olaquindox* is similarly toxic. Affected pigs refuse the ration, but will eat other rations, are gaunt and emaciated, pass hard fecal pellets, and have a long rough coat, pale skin, severe tachycardia, weak hindquarters, and a swaying walk, followed by knuckling of the hind fetlocks, posterior paralysis, and death in 8–9 days. In the early stages the pigs screech frequently. Sows are agalactic, and produce stillborn or weak, undersized piglets.

---

**References:**
Necropsy lesions are diagnostic, with extensive damage to the zona glomerulosa of the adrenal gland accompanied by renal tubular necrosis. The resulting hypoaldosteronism is manifested by low serum sodium levels, elevated serum potassium (8 mmol/L) and elevated blood urea nitrogen levels. The condition is irreversible and the outcome is severe disability or death.19

**Bronopol poisoning**

Bronopol – 2 bromo-2-nitropropoane-1, 3-diol – is used as a laboratory preservative for milk, e.g. in milk samples used for butterfat estimation. This milk is usually fed to calves or pigs and may be toxic on occasional feedings. Affected calves salivate, are depressed, collapse and die within 24 hours of feeding. Necropsy lesions include severe necrotizing atherosclerotic and local peritonitis on the serosal surface of the abomasum.0

**REFERENCE**

**Polychlorinated biphenyls**

Mixtures of polychlorinated biphenyls find a great deal of use in industry, particularly as flame retardants. They are not especially poisonous, nor are they a greater risk to farm animals because of degree of exposure, than many other industrial chemicals, but they happen to have found their way into the cattle food chain in much discussed incidents in the USA.

Cattle. Experimental dosing with 67 mg/kg BW daily for long periods is associated with poisoning but levels of 10 mg/kg BW are not toxic. Clinical signs of illness are anorexia, diarrhea, lacrimation, salivation, emaciation, dehydration, depression, and abortion. Similar signs plus extensive cutaneous hyperkeratosis occur in natural cases. Necropsy lesions include mucoid enteritis, degenerative renal lesions in natural and experimenatal cases, hyperkeratosis in the glands, and epithelium of the eyelids.

Pigs. Experimental poisoning in pigs causes no ill-effects in sows, but high concentrations of polychlorinated biphenyls (PBB) develop in the sow's milk with death of some nursing pigs resulting.

Most of the losses due to these compounds are due to destruction of animals because they are contaminated and there is fear of adverse effects on humans who consume them or their products. However, neither animals nor humans exposed to the biphenyls showed any signs of illness. PBBs pass the placenta and are found in fetuses but appear to be associated with no health problems in the offspring. The excretion of these compounds occurs principally in feces and urine but as much as 25% of ingested substance may be present in the milk. Also these compounds are lipotrophic and accumulate in fat depots, especially in the liver. Attempts to hasten excretion have not produced a satisfactory method. Grazing wool sheep on contaminated ground may be an option for utilization of contaminated land.7

**REFERENCES**

**Polybrominated biphenyls**

These substances have a number of industrial uses and are common environmental contaminants. They are lipophilic so that they accumulate in body fat, and have low rates of biotransformation and excretion so that they persist in animal tissues for long periods. Although deleterious effects of the compounds in animal tissues are not often recorded, their presence in animal tissues is likely to cause rejection of meat from the human food chain. Recorded damage refers to unidentified reproductive inefficiency and reduction in efficiency of food conversion and possibly hepatic hypertrophy and gastric erosion, but in the same species a positive growth stimulating effect has also been recorded. Experimental poisoning of gnotobiotic pigs has been associated with diarrhea, erythema of the nose and anus, distension of the abdomen, growth retardation and, at doses of more than 25 mg/kg BW, coma and death.

**Soil fumigant: methyl bromide**

Soil fumigants used to prepare fields for planting may be associated with toxicity hazards in animals grazing them or in feed harvested from them. Methyl bromide has been associated with poisoning in horses, cattle, and goats when used in this way. Clinical signs in horses, cattle, and goats include ataxia, stumbling, and somnolence.

**Oil- and petroleum-product poisoning**

Crude oil or petroleum distillates, including diesel oil, lamp oil, kerosene, and gasoline, are all poisonous to animals. Cattle will drink all of them and appear to have a positive liking for some products, especially used sump oil and liquid paraffin (mineral oil).

**Oil-well installations**

Crude oil coming directly from wells is usually repellent to animals, but they can consume lethal quantities of it if they are salt-deficient and salt-hungry: a characteristic of crude oil is that it is usually mixed with salty water which is often left lying in ponds nearby. After extraction most crude oils are temporarily stored in installations where lead paint is available so that salt and lead poisoning commonly occur with oil poisoning and may be confused with it.
crude) are most unpalatable and most toxic

- Amongst the commercial oil products those with the highest content of volatile and inflammable components, especially naphtha and petrol (gasoline) fractions, are the most toxic
- Gasoline up to the level of 3 ppm in the drinking water does not appear to depress water intake or to interfere with growth performance of pigs
- With commercial gasoline and oily lubricants the additives used, especially lead, may also contribute significantly to the poisoning
- Other toxic agents of all kinds can be encountered when reject sludge oil is available to animals.

Accurate dose levels are difficult to determine in field outbreaks. In experimental trials crude oil at the rate of 37 mL/kg BW in a single dose or 123 mL/kg in 5 divided daily doses were poisonous to cattle. Kerosene at 20 mL/kg BW as a single dose and 62 mL/kg BW in 5 equal daily doses was poisonous. Tractor paraffin (kerosene) at a single dose rate of 13 mL/kg BW is associated with severe illness and at 21 mL/kg was fatal to cattle.

**Epidemiology**

On farms access to tractor fuel (paraffin, gasoline, kerosene) is the most likely hazard. When highly chlorinated naphthalenes were used as lubricants, access to oil dumps could lead to hyperkeratosis.

Kerosene has an unwarranted reputation as a therapeutic agent for bloat and constipation, but it is unlikely to be given in amounts sufficient to be associated with more than slight illness, unless it is given repeatedly.

The common occurrence of natural cases is in cattle, but sheep and goats can also be affected.

**Pathogenesis**

The early signs are thought to be due to regurgitation of the oil, aspiration of it causing pneumonia, and absorption of the volatile components through the pulmonary mucosa causing toxemia. The later signs are thought to be associated with the direct effect of the oil on the alimentary tract.

**Clinical Findings**

Natural cases. When large volumes of crude oil are consumed by cattle and goats, there are signs of toxemia and incoordination; regurgitation (vomiting) may or may not occur; death is quick. Bloating is inconstant. In the terminal stages the pupils are dilated and tachycardia, hyperpnea, and hyperthermia are evident. The animals smell of oil, and oil is often present on the skin around the mouth and anus, and in the feces. The feces vary from constipation to diarrhea.

Recovered animals usually do so poorly after the incident that they are slaughtered after a history as long as 6 months. The oil persists in the alimentary tract for very long periods and may be found in the cud and feces, and at postmortem as long as 16 days after ingestion. Animals that survive the acute toxic syndrome eat poorly, lose weight and die at variable periods from 16 to 36 days later. Oil appears at the anus on about the 8th day after administration. It may also appear in the nasal discharge, reaching there via the lungs. The vomitus always contains the oil. The feces are usually oily, often soft to semifluid, and frequently black if the oil taken has been crude oil. With kerosene the feces are often dry and firm in the later stages and the regurgitus may be in the form of gelatin-like cuds, smelling strongly of kerosene.

**Experimental cases.** Early signs include incoordination, shivering, head-shaking, and mental confusion. Within 24 hours anorexia, vomiting, and moderate-to-severe bloating occur. Experimental kerosene inhalation is associated with persistent severe intrapulmonary physiological shunting resulting in prolonged hypoxemia and acidemia and may account for the clinical disease in survivors.

**Differential Diagnosis**

The clinical syndrome of aspiration pneumonia, bloat, regurgitation, and obvious fouling with oil or kerosene in an environment where access is permitted to the oil products provides diagnostic confirmation.

**Differential diagnosis list:**

- Aspiration pneumonia due to other causes
- Misguided owner medication with kerosene.
- Recovered animals usually do so poorly after the incident that they are slaughtered after a history as long as 6 months. The oil persists in the alimentary tract for very long periods and may be found in the cud and feces, and at postmortem as long as 16 days after ingestion. Animals that survive the acute toxic syndrome eat poorly, lose weight and die at variable periods from 16 to 36 days later. Oil appears at the anus on about the 8th day after administration. It may also appear in the nasal discharge, reaching there via the lungs. The vomitus always contains the oil. The feces are usually oily, often soft to semifluid, and frequently black if the oil taken has been crude oil. With kerosene the feces are often dry and firm in the later stages and the regurgitus may be in the form of gelatin-like cuds, smelling strongly of kerosene.

**Clinical Pathology**

There are no specific clinicopathological findings but hypoglycemia, acetonemia and transient hypermagnesemia are all recorded.

**Necropsy Findings**

In crude oil or kerosene poisoning aspiration pneumonia is recorded constantly in naturally occurring and experimentally produced cases. It is thought to be the result of vomiting and aspiration from the alimentary tract of already swallowed oil. In long-standing cases of kerosene poisoning in cattle the lungs are colored gray-blue and are enlarged and firm but there are no significant histopathological changes, neither are there in the kidney or liver. Oil is always still present in the alimentary tract and there may be thickening and inflammation of the alimentary mucosa. Degenerative changes in liver and kidney are recorded in some cases.

**TREATMENT**

No primary treatment is undertaken. Supportive treatment if the animal survives the initial acute phase should include the replacement of the ruminal contents with material from a normal rumen.

**Review Literature**

**Tin Poisoning**

Dibutyltin dilaurate is a coccostidost fed to chickens in their feed. Errors in mixing may lead to cattle receiving toxic amounts in concentrates or pellets. Calves usually die acutely with signs of tremors, convulsions, weakness, and diarrhea. Older animals usually suffer a chronic illness characterized by persistent diarrhea, severe weight loss, inappetence, polyuria, and depression, reminiscent of arsenic poisoning. Affected animals may not be suitable for human consumption because of the high content of tin in their tissues.

**Sodium fluorosilicate**

A white, odorless, and tasteless powder used as a poison in baits for crickets, grasshoppers, and the like. Because of the way it is prepared in pellets in a bran base it is attractive to all animal species and poisoning is recorded in cattle, sheep, and horses, usually because unused baits were not retrieved after baiting programs.

In sheep mild illness occurs after doses of 25-50 mg/kg BW and death after 200 mg/kg. Clinical signs include drowsiness, anorexia, constipation, ruminal stasis, teeth grinding, abdominal pain, and diarrhea.

**Highly chlorinated naphthalenes**

The naphthalenes were extensively used in industry as lubricants, insulators, and wood-preserving agents. Recognition of their toxicity resulted in their exclusion from the farm environment and virtual elimination of the disease.

Local application or ingestion of highly chlorinated naphthalenes to cattle produces hyperkeratosis characterized by thickening and scaliness of the skin, emaciation, and eventual death. The pathogenesis of the skin lesions is due to interference with the conversion of carotene to vitamin A, causing hypovitaminosis-A. When poisoning results from accidental emission
from industrial plants there are additional signs due to ocular, nasal, and tracheobronchial irritation; infertility and abortion also occur.

**Coal tar pitch poisoning**
Pigs may be exposed to coal tar pitch and its toxic cresols when housed in pens with tarred walls or floors, which they nibble, or when they have access at pasture to fragments of 'clay pigeons' used as targets by gun clubs. Bitumen and asphalt appear to be non-toxic. Young pigs 6–20 weeks of age are most commonly affected.

Clinical findings include an acute illness of a few days or a chronic course of some weeks. In the *acute illness* there are non-specific signs of inappetence, rough coat, tucked-up abdomen, weakness, and depression. The *chronic illness* is characterized by anorexia, depression, weakness, anemia, and jaundice. A subclinical syndrome includes a reduction in growth rate of up to 20–30%, a severe reduction in hemoglobin concentration and erythrocyte count, and reduced vitamin A storage.

**Necropsy findings** include jaundice, ascites, and anemia but the characteristic finding is a red and yellow mottling of the hepatic surfaces, and histologically a hepatic lesion of severe centrifibular necrosis. Cresols can be detected in the ingesta and liver of affected pigs.

**Methyl alcohol**
Accidental ingestion of methyl alcohol by cattle is associated with vomiting, recumbency, death, and a high concentration of methyl alcohol in the ruminal contents. Methyl alcohol is used as antifreeze in gasoline engines for pumps working continuously on oilfields in cold regions. Accidental access to the pump enclosure may result in a poisoning incident.

**Ethylene glycol**
Accidental poisoning with antifreeze mixture containing ethylene glycol may occur in swine, goats, and calves. The treatment recommended for companion animals, ethanol or preferably 4-methylpyrazole, should be worth trying.

**Industrial organophosphates**
Principal industrial uses of organophosphates are as fire-resistant hydraulic fluids, as lubricants, and as coolants. A number of compounds including tri-o-tolyl phosphate, tri-o-cresyl phosphate (TOCP), and triaryl phosphates (TAP) have come to veterinary notice as being associated with poisoning in animals. Triaryl phosphates contain a number of isomers as well as TOCP, e.g. m-cresol, p-cresol, o-cresol, all of them more poisonous than TOCP. They have also been associated with serious outbreaks of poisoning in humans when they accidentally contaminate food. Poisoning may occur by ingestion or cutaneous absorption.

**Clinical signs** of delayed neurotoxicity do not occur until several weeks after contact and comprise irreversible neurological signs of respiratory stertor, dyspnea, dysuria, knuckling, leg weakness, and posterior paralysis.

**Necropsy lesions** characteristically include neuronal degeneration in the spinal cord and peripheral nerves.

**Diagnostic confirmation** depends on evidence of exposure to the toxicant, signs referable to the nervous system lesions, and a positive assay for the toxicant in the animal's tissues.¹

**REFERENCE**

**Superphosphate**
This is the usual form in which phosphorus-rich fertilizers are applied to the soil and is therefore available to animals on most farms in most countries. It is not highly palatable but sheep will eat it when it is in pill form (small granular, resembling grain in texture and particle size). The fertilizer is also used to prepare ‘superjuice’ which is administered to cows as a phosphorus supplement. Higher than normal intakes of the fertilizer either by dosing or by pasture application will cause poisoning, due largely to the fluorine present.¹ Calcium pyrophosphate and calcium orthophosphate also contribute to the toxicity causing proximal renal tubular nephrosis.² The LD₉₀ of superphosphate for sheep is 100–300 mg/kg BW.

**Clinical signs** of poisoning include anorexia, thirst, diarrhea, weakness, ataxia, and death in about 48 hours.

**REFERENCES**

**MANURE-GAS POISONING AND RELATED CONFINEMENT EFFECTS**

**ETIOLOGY**
Confined housing of cattle and swine is accompanied by manure storage for varying periods of time, in large holding pits, usually under slatted floors. Oxygen is excluded from the storage so that anaerobic bacteria degrade the organic and inorganic constituents of manure yielding *hydrogen sulfide*, *ammonia*, *methane*, and *carbon dioxide* as major gases. When diluted with water to facilitate handling, liquid manure in storage separates by gravity. The solid wastes form sediment, the lightweight particles float to the top leaving a middle layer which is relatively fluid. Thorough remixing is necessary before pits are emptied to prevent the fluid fraction from flowing out and the solids remaining. The remixing or agitation results in the release of large quantities of toxic gases from the slurry.

Besides the well-established gaseous toxicants listed, certain other agents with detrimental inhalation risks are present in confinement operations, and have been best characterized for swine confinement operations. Total dust is a major contaminant in swine barns and may range for 2–7 mg/m³. Particulates may adsorb gases and be part of the objectionable odors released and reaching neighbors near confinement operations. Respirable dusts may be 10% or more of the total dusts generated in swine barns. Such dust is contaminated with bacteria, fungi, endotoxins, and glucans.¹ Dusts are primarily composed of feed or fecal material. Both endotoxins and glucans have been suggested as potential contributors to swine respiratory disease as well as respiratory complications for workers in swine buildings. So far, however, high mortality and acute death losses in confinement operations are most commonly due to excessive concentrations of hydrogen sulfide and carbon dioxide, while subacute or chronic irritation and disease of the upper respiratory tract may also be contributed by elevated ammonia levels. Methane is explosive and may act as an asphyxiant, but is not implicated as a toxicant.

Additional factors that must be considered in a differential diagnosis include possible power loss during electrical storms or equipment failure; this results in the cessation of the artificial ventilation required to cool the building and exhaust carbon dioxide from the respiration of animals. In these situations, CO₂ levels build rapidly and environmental temperatures increase dramatically as well, especially when weather conditions are hot and humid. Acute losses from
Hyperthermia or heat stroke may be mistaken for manure gas poisoning. This is important for veterinarians, as they may be called to establish a diagnosis that affects insurance claims for many thousands of dollars. Besides overheating and CO₂ accumulation, electrocution should be considered whenever there are large numbers of acute losses in a confinement building.

**PATHOGENESIS**

The exposure of humans, cattle, and swine to high concentrations (above 700 ppm of H₂S) of manure gases, particularly hydrogen sulfide, can be associated with peracute deaths in cattle and swine. Hydrogen sulfide is both an irritant as well as an acute toxicant. The inhalation of H₂S causes interaction with moist mucous membranes of the upper respiratory tract and lungs. Fatal or severe exposure often is associated with respiratory distress and pulmonary edema. Exposure to low concentrations of hydrogen sulfide over long periods is thought to be associated with reduced performance in cattle and swine. At high concentrations, from 500 to 1000 ppm, carotid body receptors are stimulated causing rapid breathing. As high concentrations continue or increase the respiratory center is depressed, animals become depressed and comatose, and die. High concentrations of H₂S depress olfactory sensors and the offensive rotten egg odor is no longer detected as a warning sign.

High concentrations of ammonia (100–200 ppm) combine with moisture in the air and at mucous membranes with the production of ammonia, which is associated with irritation to the conjunctiva and respiratory mucosa. An increased incidence of pneumonia and reduced daily weight gains in pigs are associated with exposure to a combination of ammonia at levels of 50–100 ppm and the presence of atmospheric dust in barns.

**CLINICAL FINDINGS**

In acute hydrogen sulfide poisoning the animals die suddenly. Affected animals may be found dead throughout a building in various postures of lateral or sternal recumbency. There may be little or no evidence of struggle or excitement, since high concentrations can be associated with nearly immediate respiratory paralysis. In acute ammonia poisoning the syndrome includes conjunctivitis, sneezing, and coughing for a few days but pigs will soon acclimatize after which no effects may be detectable. At very high ammonia concentrations (>500 ppm) there is pharyngeal and laryngeal irritation, laryngospasm, and coughing. Concentrations above 2000 ppm can be associated with death within 30 minutes. Carbon dioxide overexposure first is associated with mild-to-moderate excitement followed by depression, weakness, coma, and death. Concentrations above 30% in air are serious and 40% CO₂ for more than a few minutes can cause death.

**NECROPSY FINDINGS**

In cattle which have died from acute hydrogen sulfide poisoning, lesions include pulmonary edema, extensive hemorrhage in muscles and viscera, and bilaterally symmetrical cerebral edema and necrosis. Ammonia exposure results in lacrimation, conjunctivitis, corneal opacity, tracheal hyperemia or hemorrhages, and pulmonary edema. Secondary bacterial pneumonia may be evident in exposed animals. For carbon dioxide, the principal lesions are of cyanosis.

**CONTROL**

Production of hydrogen sulfide in manure can be inhibited by aeration using air as the oxidizing agent or the use of chemical oxidizing agents. The use of ferrous salts virtually eliminates hydrogen sulfide evolution. Adequate ventilation with all doors and windows wide open during remixing and agitation of the slurry will reduce the concentration of hydrogen sulfide to non-toxic levels. Animals and personnel should not enter closed barns when the pits are being emptied. In confinement buildings, ammonia usually does not accumulate to fatal levels, but much of the economic loss is from reduced feed consumption and possibly increased susceptibility to acute or chronic respiratory disease. Limiting protein supplementation to actual needs has been considered a means for reducing nitrogen losses and the resultant production of ammonia in feces and urine.

DISEASES ASSOCIATED WITH major phytotoxins
Plant poisonings in farm animals have particular importance in areas where extensive pastoral management is practiced; therefore, this part of the book has limited appeal to veterinarians who work in intensive farming areas except when feedstuffs are contaminated by poisonous weed seeds or dried poisonous plants in hay. Conversely, the amount of information on the subject of phytotoxins is very great because of the large number of poisonous plants. In order to maintain parity with the other parts of the book, material related to the pathogenesis of these diseases has been restricted. No botanical material has been included and only a minimum of the plant chemical information available. It is the botanical and chemical material which is best founded. The clinical data are often fragmentary, much of it anecdotal, a limited number of plants having been subjected to careful experimental scrutiny. Many plants are included in lists because they have been found to contain dangerous amounts of known toxins, without cases of poisoning ever having been recorded. Because the world list of definitely poisonous plants includes about 1500 species, only a limited number of them – those considered to be common or important enough, or whose identity as poisonous plants has been well established – have been included.

METABOLIC POISONS
Poisonous substances produced in the animal, especially the rumen, from innocuous substances in the plants ingested are not dealt with in this chapter. Examples are:
- Lactic acid produced in the rumen by anaerobic fermentation of starch and the cause of acute carbohydrate engergment

HUMAN FOOD CHAIN
Besides the damage to animals associated with plants, there is the additional passage of plant poisons into the human food chain through animal products, especially eggs, meat, milk, and honey. Plant toxicants for humans originating in this way are not subjects for this book.

PHYTOTOXINS
The material in the chapter is arranged on the basis of the toxin present in the plant. This has been prompted by developments in the diagnosis of plant poisoning in countries with advanced technologies in which the toxin is identified by physicochemical examination of clinical or necropsy samples, usually by spectrometry, the plants containing the toxin are listed, and the environment then examined for...
them. The procedure avoids the difficulty of trying to identify plants botanically from fragments of plants in the alimentary tract, but requires sophisticated laboratory techniques which are not universally available. It does not and cannot replace thorough field investigation.

DIFFERENTIAL DIAGNOSIS

Establishing a diagnosis of plant poisoning depends on the completion of all or several of the following tasks:

- Matching the circumstances of the case and the clinical signs, clinical pathology, and pathological lesions with those known to be associated with poisoning by the suspected plants.
- Establishing that the suspected plants have been eaten or that the affected animals had access to them.
- Precisely identifying the suspected plants through professional botanists.
- Demonstrating the presence of the suspected plants in the stomach contents of affected animals.
- Demonstrating hazardous concentrations of particular toxins in the plants, the stomach contents, or the tissues of affected animals.
- On rare occasions, conducting feeding experiments.

CONTROL

Prevention of plant poisonings by restricting grazing of, or hay-making on, land areas containing poisonous plants needs no explanation but presents the difficulty that large areas of rangeland suited to domestic animal production are then not used. Control measures under development which limit toxin intake by grazing animals or provide effective defense within the animal’s body include:

Immunization against toxins for a number of phyto- and mycotoxins including phytoestrogens, pyrrolizidine alkaloids, sporidesmin, and *Pimelea* spp. toxins, all of which have failed so far. Rare successes have been achieved with phomopsins and corynetoxins. Important attributes of candidate toxins for attempted commercial immunogen production include producing syndromes with little initial tissue damage, slow onset, wide (preferably international) distribution, and frequent occurrence, being readily degraded by the body’s detoxification mechanisms after capture by antibodies, and having potentially large, steady and cheap supply sources. Genetic engineering of ruminal microbes for selective catabolism of ingested toxins has been successful with bacteria which break down fluoroacetate. Obstacles to be overcome in such work include finding the required microbial gene and a suitable recipient organism, survival of the modified organism in the rumen, and obtaining permission to release it. The simpler technique of introducing ruminal bacteria which naturally detoxify mimosine into ruminant populations that do not have them, has solved toxicity problems with *Leucaena leucocephala*.

Creating a conditioned aversion to specific plants is under trial in a number of centers in the USA. Groups of animals are penned and fed intensively on the plant to which an aversion is to be created, or on a chemical component of it identified as an aversion-creating chemical, e.g. ingenol in *Euphorbia* spp.\(^1\) The method has a number of deficiencies, including the difficulty of managing hard-to-handle livestock in this sort of intensive conditioning program. Also, a conditioned aversion can be retained in the animals’ memories for years but can be quickly lost if the averted cattle are grazed with non-averted ones which readily consume the target plant.\(^4\)

Naturally acquired aversion may be the mechanism permitting cattle to graze infested pasture, and to consume small amounts of the target plant, without developing a significant intoxication.\(^5\) An interesting side issue from this work is the observation that adversity conditioning varies between animal species, being easy to create in cattle and sheep, but much less so in goats. This may be related to the ability of the ruminal microflora of goats to digest the aversion-creating chemical.\(^6\) Other range plants against which aversion conditioning control methods have been attempted are *Delphinium* and *Astragalus* spp.

CYANOGENIC GLYCOSIDE POISONING (CYANIDE, HYDROXYCANCYDISMIC ACID)

**Synopsis**

Etiology Ingestion of specific plant species containing cyanogetic glucosides.

Epidemiology Seasonal and other variations in glucoside content lead to periods of enhanced toxicity of pasture.

Clinical findings Acute poisoning—soon after access to toxic material sudden onset of dyspnea, tremor, recurring convulsions, death within a few minutes to an hour. Chronic poisoning—neonatal goiter or arthrogryposis, adult posterior ataxia, dysuria, frequent urination.

Clinical pathology Assay of hydrocyanic acid in body tissues and fluids and in feed.

Necropsy lesions Nil.

Diagnostic confirmation Positive assay on rumen contents (difficult).

Treatment Primary treatment with sodium thiosulphate with or without sodium nitrite or other antidote.

Control Test feed for cyanide content.

ETIOLOGY Most outbreaks of hydrocyanic acid (HCN) poisoning are associated with the ingestion of plants that contain cyanogetic glucosides. The glucosides are non-toxic but HCN may be liberated from them by β-glycosidase and lyase present in the plant tissue. Ruminal microorganisms also produce β-glycosidase. Horses and pigs are much less susceptible to the glucosides because the acidity of the stomach in monogastric animals inactivates β-glycosidase and is not great enough to be associated with acid hydrolysis of the glucosides.
Plants that contain enough cyanogenic glycosides to cause poisoning number about 120. The following list contains only the genera recognized as hazardous:

- *Acacia* (a few spp. only) - wattle trees
- *Adenia*, e.g. *A. digitata*
- *Amelanchier alnifolia* - Saskatoon serviceberry
- *Amygdalus communis* - almond
- *Aquilegia vulgaris* - columbine
- *Bahia oppositifolia*
- *Brachyachne spp.*, e.g. *B. convergens* - Gulf salt grass
- *Breynia oblongifolia* - coffee bush
- *Bridelia spp.*, e.g. *B. leichhardtii* - scrub ironbark
- *Calotis scapigera* - tufted burd berry
- *Carex vulpina*
- *Castalis spectabilis* - Transvaal bitou
- *Ceratocephalus*, e.g. *C. breviflorus* - mountain mahogany
- *Chenopodium spp.*, e.g. *C. carinatum* - green crumbweed (see also nitrate-nitrite poisoning)
- *Cynodon*, e.g. *C. dactylon* - Yorks fog grass
- *Drosera* spp. - *D. rubicunda* - tufted burr daisy
- *Eucalyptus*
- *Eriobotrya japonica* - loquat
- *Eremophila maculata* - scrub ironbark
- *Euphorbia*
- *Euphorbia cyparissias* - rank grass
- *E. helioscopia* - common apple
- *E. lathyris* - red crumbweed (see also nitrate-nitrite poisoning)
- *Euphorbia cyparissias*
- *E. helioscopia* - common apple
- *Fodder storage*
- *Glishrocaryon andingae*
- *Goodia* spp., e.g. *G. maxima* - cowsfoot
- *Heterodendron*, e.g. *H. oleifolium* - boonne
- *Holcus lanatus* - Yorkshire fog grass
- *Jatropha spp.*, e.g. *J. multifida* - umbrella tree
- *Juncus spp.*, e.g. *J. effusus* - blue rush
- *Lotus*, e.g. *L. culiciflorum* - linseed or flax
- *Mimosa spp.*, e.g. *M. invisa* - giant sensitive plant
- *Nandina domestica* - nandina, sacred bamboo
- *Oxal benthamiana*
- *Osteospermum spp.*, e.g. *O. ecklonis* - South African daisy
- *Papaver nudicaule* - Iceland poppy
- *Passiflora spp.*, e.g. *P. aurantia* - red passion flower
- *Perridalia coronopifolia* - tafes
- *Phaseolus cuneatus* - Java bean
- *Phytoecia spp.* - Christmas berry
- *Phyllanthus spp.*, e.g. *P. gasstroemia* - vine
- *Pomax umbellata*
- *Prunus spp.*, e.g. *P. laurocerasus* - cherry laurel
- *Sambucus spp.*, e.g. *S. nigra* - common elder
- *Sorghum spp.*, e.g. *S. halepense* - Johnson grass (see also nitrate-nitrite poisoning)
- *Stillingia treculeana* - Queen's delight
- *Suckleya suckleyana* - poison suckleya
- *Triglochin spp.*, e.g. *T. maritima* - arrowgrass
- *Tritonias mollis* - purple plum grass
- *Vicia sativa* - vetch
- *Ximenia americana* - yellow plum
- *Xylometalum spp.*, e.g. *X. pyrifforme* - woody pear
- *Zea mays* - maize, corn (see also nitrate-nitrite poisoning)
- *Zieria laevigata*.

**Toxic variability**

The content of cyanogenic glucosides in these plants varies widely between seasons and between different parts of the plant, with young, growing leaf usually having the greatest concentration.

**Differences between plant species**

Varieties of the same species often have different toxicities, e.g. *Amelanchier alnifolia* var *cuscii* has three times the toxicity of *A. alnifolia* var *alnifolia.* Of greatest importance are the cultivated and pasture plants. Sudan grass (*Sorghum sudanense*) and sorghum (*S. bicolor*) are used extensively in some countries for forage and may be associated with heavy mortalities in particular circumstances. Sugar cane contains a cyanogenic glucoside from which HCN can be released. Release occurs through the action of an enzyme in algarrobo pods (*Prosopis glandulosa*) when the two are fed together.

**Plant products**

Linseed in the form of cake or meal may also be highly toxic if eaten in large quantities.

**Fodder storage**

Drying, hay-making, and physical factors, such as chilling and freezing, may appear to reduce the toxicity of cyanogenic material through destruction of β-glucosidase, but the plant material remains as potentially toxic as it was originally, requiring only the enzyme from ruminal microbes to become actively poisonous. Ensiled toxic forage loses much of its cyanide content and on exposure to air may give off large quantities of free HCN.

**Glycosides**

A number of specific glycosides have been isolated and include linamarin from linseed and flax, lotaustralin from *Lotus australis,* dhurrin from sorghum, lotusin from *Lotus arabicus,* and amygdalin from bitter almonds. The glycosides are byproducts of the plant's metabolism and probably form part of its defense system against herbivores such as insects and molluscs. Their concentration in the different plant species is variable depending upon climatic and other conditions which influence plant growth.

The minimum lethal dose of HCN is about 2 mg/kg BW for cattle and sheep when taken in the form of a glycoside. The minimum lethal dose (MLD) of lotaustralin for sheep approximates 4 mg/kg BW. Plant material containing more than 20 mg of HCN per 100 g (200 ppm) is likely to have toxic effects, and highly poisonous samples may contain as much as 6000 ppm. The toxic doses quoted must be accepted with some reservation, as the toxicity of a particular specimen varies with a number of factors including the concentration of the hydrolyzing enzyme in the plant, the preceding diet of the animals, and particularly the speed with which the material is eaten.

**EPIDEMIOLOGY**

**Occurrence**

Hydrocyanic acid poisoning occurs in most countries because of the common occurrence of plants containing toxic quantities of cyanogenetic glycosides. When the disease occurs, most affected animals die and, although the overall economic effects are not great, the losses may be heavy on individual farms.

**Risk factors**

**Plant factors**

Poisoning is most likely to occur when the cyanide content of the material is high and it is eaten quickly. Plants with a cyanide potential of more than 200 mg HCN/kg plant dry matter are potentially toxic. Plants must be unwilted at time of testing or falsely low results may be obtained. The glucoside content is highest when:

- Plants grow rapidly after a previous period of retardation, e.g. after autumn rains on drought-stunted pasture, after a crop is eaten back by livestock or grasshoppers, or after spraying with herbicides
Plants are wilted, frostbitten, or just young.

In drought years²

Plants are growing in soil with a high nitrogen content.

Plants growing in soil with low phosphorus content.

**Animal factors**

The greatest danger exists in the following circumstances:

- Hungry animals allowed access to dense plant growths.
- Traveling, recently introduced or other animals unaccustomed to local plants; animals accustomed to the plants and the poison can tolerate increasing doses with experience.
- Cattle or sheep may break out of dry, summer pastures into fields of young, lush, immature sorghum or Sudan grass and gorge on it.

**Speed of cyanogenesis**

The rate of conversion of the glycoside to HCN in the rumen also affects the toxicity of the feed³; factors affecting the conversion rate include:

- High pH values increase the rate and the risk of poisoning.
- The rate is less when the diet includes grain and long hay rather than fresh or cubed pasture or hay.
- The rate of conversion, and onset of signs, may be delayed if the ingested material is relatively indigestible, such as crabapples.

**Linseed meal or cake**

Deaths due to the ingestion of excessive amounts occur when:

- Sheep are fed large quantities of linseed meal at the end of a period of starvation.
- Calves are fed on milk replacer containing linseed that has been soaked but not boiled.

**Other sources**

Occasional cases of HCN poisoning occur when animals are exposed to:

- Chemicals used for fumigation.
- The fertilizer, calcium cyanamide.

**PATHOGENESIS**

**Acute intoxication**

This is associated with tissue anoxia by its inhibition of the cytochrome a₃ moiety of complex IV (the terminal cytochrome c oxidase) in the electron transport chain, thus preventing cellular aerobic respiration. Oxygen exchange is suspended and oxygen is retained in the blood. If the course is prolonged the blood may be dark red due to inhibition of respiration and restriction of oxygen intake. The major manifestation of cyanide poisoning is cerebral anoxia resulting from heart failure.

**Chronic poisoning**

Doses which do not produce clinical effects appear to be well-tolerated. HCN is volatile and is exhaled or converted to thiocyanate by hepatic rhodanese and then excreted in the urine. The tolerance appears to increase with experience. Cyanides ingested in small amounts, however, are known to be goitrogenic through the effects of thiocyanate, e.g., pregnant ewes grazing on star grass (*Cynodon nlemfuensis*) develop goiter due partly to a low iodine intake and partly to the cyanide intake. Their lambs may also be goitrous and have skeletal deformities. *Leucomyelomalacia* (cystitis-ataxia syndrome) in ruminants and horses is also attributed to chronic cyanide intake. Urinary incontinence, loss of hair due to scalding, and incoordination (ataxia syndrome) in ruminants and horses may be tested by placing a drop of ruminal fluid on a test paper. A red discoloration is a positive reaction. The test is designed to detect free HCN and may not be positive even when cyanides are present if the gas is not liberated. Commercial test papers may give superior results.

**Necropsy findings**

In very acute cases the blood may be bright red in color, but in most field cases it is dark red due to anoxemia. The blood clots slowly, the musculature is dark, and there is congestion and hemorrhage in the trachea and lungs. Patchy congestion and petechiation may be evident in the abomasum and small intestines. Subepicardial and subendocardial hemorrhages occur constantly. A smell of "bitter almonds" in the rumen is described as typical of HCN poisoning. It may occur with some plants but is not apparent with others. There are no characteristic histological changes. Specimens submitted for laboratory examination should include rumen contents, liver, and muscle. Much HCN may be lost from specimens during transit unless the samples are shipped in a very tightly stoppered, air-tight bottle. Muscle is least likely to lose its HCN and is the preferred tissue if the delay between death and necropsy has been long. To be satisfactory, liver samples must be taken within 4 hours of death and muscle tissue within 20 hours. A level of HCN of 0.63 μg/mL in muscle justifies a diagnosis of poisoning. Serum and rumen fluid of poisoned cattle have been assayed using GC-MS.

**Chronic cases**

In arthropoysis and in cystitis-ataxia there is focal axonal degeneration and demyelination in the spinal cord, with some cases of pyelonephritis in the cystitis-ataxia patients.
Samples for confirmation of diagnosis

Toxicology – 50 g rumen content, liver, muscle in air-tight container (ASSAY (cyanide)).

DIFFERENTIAL DIAGNOSIS

The development of an acute anoxic syndrome in ruminants grazing on plants, or being fed on feeds known to be cyanogenic, usually suggests the occurrence of HCN poisoning. Diagnostic confirmation is dependent on a positive assay for hydrogen cyanide in blood or cyano-organic glucosides in rumen contents. The differential list for acute poisoning includes:

- Acute pulmonary edema and emphysema may resemble it but is less acute, and auscultation of the lungs usually indicates the presence of fluid and emphysema
- In nitrite poisoning the blood is dark and tends to be brown
- Poisoning by cyanobacteria associated with obvious blooms in water sources
- Occasional cases of anaphylaxis and respiratory stimulants and artificial respiration are unlikely to have any effect on the course of the disease.

Clinical findings

- Sudden onset of dyspnea, brown mucous and blood, short course, high case fatality rate.
- Very high blood levels of methemoglobin.
- Brown blood in some.

TREATMENT

The standard primary treatment is the IV injection of a mixture of sodium nitrite and sodium thiosulfate (5 g sodium nitrite, 15 g sodium thiosulfate in 200 mL water for cattle; 1 g sodium nitrite, 3 g sodium thiosulfate in 50 mL water for sheep), and field experience with it has been very good. However, the results in cattle can be improved by using:

- Sodium thiosulfate in a much heavier dose (660 mg/kg BW compared to the previous level of 66 mg/kg)
- Sodium thiosulfate heavy dose combined with sodium nitrite (22 mg/kg BW)
- Sodium thiosulfate heavy dose combined with p-aminohippuric acid (1.5 mg/kg)
- Sodium thiosulfate heavy dose plus cobalt chloride (10.6 mg/kg BW).

Treatment, whichever product is used, may have to be repeated because of further liberation of HCN. There is an upper limit of safe methemoglobinemia beyond which anemic anoxia occurs and doses of nitrite greater than those recommended may exacerbate the tissue anoxia. The inclusion of cobalt is based on its marked antagonistic effect against cyanide, which is enhanced by combination with thiosulfate or nitrite.

In all cases and in animals exposed but showing no signs, doses of 30 g of sodium thiosulfate are given orally to cattle and are repeated at hourly intervals.

Non-specific supportive treatment, including respiratory stimulants and artificial respiration are unlikely to have any effect on the course of the disease.

CONTROL

Hungry cattle and sheep should not be allowed access to toxic plants, especially cultivated Sorghum spp. when they are chronically drought-stressed, immature, wilted, frosted, or growing rapidly after a stage of retarded growth. For most Sorghum cultivars, stock should be allowed to graze them, or be fed green chop made from them, only after the plants exceed 75 cm in height. Hay should not be made from Sorghum which is potentially toxic, as toxicity may persist. Sorghum silage is much safer than hay.

Sulfur deficiency in ruminants causing depressed feed intake and animal production may result from grazing Sorghum with high cyanide potential. This results from ruminal detoxification of cyanide with sulfur to form thiocyanate. Supplementation with salt licks containing 5% sulfur can counter this problem.

If there is doubt as to the toxicity of a field of these plants, a sample may be tested by the method described under clinical pathology, or the field can be tested to a small group of animals. Linseed meal can be fed in small quantities without soaking, but gruel containing linseed should be thoroughly boiled to drive off any free HCN.

REVIEW LITERATURE

NITRATE AND NITRITE POISONING

ETOLOGY

The toxic principle as it occurs in growing plants is always nitrate, usually as potassium nitrate, and may be ingested in sufficient quantities to be associated with gastroenteritis. Ruminal microbes convert nitrate to nitrite. Toxic doses are hard to compute because of variation in susceptibility, and in the rate of production of nitrite from nitrate.

Roots and stems usually contain more nitrate than leaves, and a total plant content of 6000–10 000 ppm dry matter (DM) of nitrate is considered to be potentially toxic. Plants that accumulate more than 1.5% potassium nitrate in dry matter are potentially toxic. For animals at pasture probably 2% DM as nitrate is safe. Levels of potassium nitrate in plants may be as high as 20% of DM and 3% is not uncommon in recognized forage plants such as sorghum and Sudax, and heavy mortality has occurred on them. Dried plants retain their toxicity.

Cattle

The minimum lethal dose of nitrate is 88–110 mg/kg BW or about 0.6 g of potassium nitrate per kg BW. Daily doses of about 0.15 g potassium nitrate have been associated with death after 3–13 doses. Cattle can eat sufficient quantities of toxic plants to be associated with death in 1 hour.

Sheep

The lethal dose of nitrate is 40–50 mg/kg BW. Continued low-level dosing does not appear to affect sheep. Drinking water containing 1000 ppm of nitrate nitrogen is associated with appreciable methemoglobin formation but has no obvious clinical effect.

Pigs

The lethal dose of sodium nitrate is 88 mg/kg BW. Doses of 48–77 mg/kg will be associated with moderate-to-severe,
but not fatal, methemoglobinemia. Potassium nitrate in doses of 4–7 g/kg BW is associated with fatal gastritis, and the lethal dose of potassium or sodium nitrite is about 20 mg/kg. Measured as nitrate nitrogen, the LD_{50} is 19–21 mg/kg BW. At dose levels of 12–19 mg/kg BW clinical signs occur but the pigs recover.

**EPIDEMIOLOGY**

**Source**

The common sources of nitrate for farm animals include:

- Cereal crops used as pasture, e.g. immature green oats, barley, wheat, and rye or hay; or green fodder, e.g. Sudan grass, corn. Oat hay may contain 3–7% nitrate
- Very heavy growths of rye-grass (Lolium spp.) in pastures
- Freshly pulled mangels. Turnip tops contain 8% nitrate, and sugar beet tops and rape have been associated with nitrite poisoning
- Water from deep wells, contaminated with fertilizer or from reservoirs created with explosives
- The plants listed below are recognized important sources of hazardous nitrate concentrations:
  - *Alternanthera denticulata*
  - *Avena sativa* - oats
  - *Betula alba* - white birch
  - *Bidens frondosa* - beggar tick
  - *Brassica spp.* - cabbage family
  - *Bromus catharticus* - prairie grass
  - *Carduus spp.* - ragweeds
  - *Chenopodium spp.* - pigweed
  - *Cleome serrulata* - spider flower
  - *Commelina communis* - garden dayflower
  - *Echinochloa* spp. - barnyard grass
  - *Ehretia membranifolia*
  - *Eupatorium perfoliatum* - purpletop vervain
  - *Galium pubescens* - white ragweed
  - *Glaucium corniculatum* - wallflower
  - *Glycine max* - soybean
  - *Graptolebium purpureum* - purple cudweed
  - *Helianthus annuus* - sunflower
  - *Lolium spp.*, e.g. *L. multiflorum* - ryegrasses
  - *Lygodesmia juncea* - skeleton weed
  - *Malva parviflora* - small-flowered mallow
  - *Medicago sativa* - alfalfa, lucerne
  - *Milletia greggii* - creeping millet
  - *Montia perfoliata* - miners lettuce
  - *Panicum capillare* - wiregrass
  - *Parsonia spp.*, e.g. *P. lilacina*
  - *Pennisetum spp.*, e.g. *P. clandestinum* - kikuyu
  - *Plagiobothrys spp.* - popcorn flower
  - *Polygonum aviculare* - pigweed (also see oxalate poisoning)
  - *Raphanus sativus* - radish
  - *Saccharum officinarum* - sugar cane
  - *Sesbania alata* - white sesame
  - *Sonchus spp.* - sow thistle
  - *Sorghum spp.*, e.g. *S. bicolor* - grain sorghum
  - *Spartothamnella juncea*
  - *Stellaria media* - chickweed
  - *Tephrosia variegata* - false mallow
  - *Triticum aestivum* - wheat
  - *Urochloa spp.*, e.g. *U. panicoides* - wiregrass
  - *Vigna unguiculata* (catjang) - cowpea
  - *Zea mays* - maize, corn
  - *Zygophyllum spp.*, e.g. *Z. ammophilum* - twin leaf.

**Risk factors**

**Environmental factors**

Higher than normal levels of nitrate in plants are usually associated with:

- Application of excessive nitrogen-containing fertilizer, human sewage, animal manure from intensive accommodation units, or with high levels of nitrogen-fixing bacteria
- Soil nitrate being taken up but not used by plants because weather conditions are unsuitable for photosynthesis which would provide the energy to convert the nitrogen into protein. Conditions which retard photosynthesis include cloudy or cold weather, at night, herbicide application, disease in the plants, wilting of plants, after a prolonged drought.1 High levels of nitrate accumulate in the soil during the drought and are not leached out by rain. Plants absorb large amounts of nitrate when the drought ends
- Green chop fed indoors is more hazardous than grazing material, probably because the intake is more rapid
- Cereals and root crops are likely to contain high concentrations when heavily fertilized with nitrogenous manures, especially crude sewage, and when growth is rapid during hot, humid weather
- Ensiled material usually contains less nitrate than the fresh crop, because normal silage fermentation destroys nitrate, but juices draining from silos containing high-nitrate materials may be toxic
- Hay made from nitrate-rich material contains almost as much as when it was made, unless some of it is converted to nitrite by overheating and the activities of molds
- Heavily fertilized grass made into grass cubes
- Nitrate combined with possible iodine deficiency is statistically associated with congenital deformities and hypothyroidism in foals in western Canada where mares were fed oaten hay or green oat forage during pregnancy.2

Cereal hay, especially oat hay, grown under drought conditions and cut when sappy, may develop a high concentration of nitrite when the stacked material develops some heat. Dry oat hay that is damp for some time before it is eaten, either in the stack or loose in the field in the hot sun, is also likely to contain a high concentration of nitrite.

Nitrate-nitrite poisoning by drinking polluted water can result from:

- Industrial contamination from rubber processing plants
- Nitrogenous fertilizer contamination
- Effluent from butchers' shops and meat processors where sodium nitrate is used in meat-pickling brine
- Effluent from premises where cheese is manufactured; the whey may contain potassium nitrate
- Deep wells filled by seepage from highly fertile soils may contain levels as high as 1700–3000 ppm of nitrate
- Open surface storage tanks collecting rain runoff from roofs may also contain toxic amounts of nitrite in the plant debris which collects at the bottom
- Juices draining from silage containing high-nitrate material may be toxic
- Water of condensation in barns may trap ammonia and eventually contain 8000–10000 ppm of nitrate.
Differences in susceptibility
- The most important factor influencing susceptibility appears to be the rate of ingestion of the nitrate-bearing plant.
- Poorly fed animals, especially traveling or recently transported stock, are more susceptible to nitrate poisoning than those on good diets, probably because of the greater intake in hungry animals, and possibly their need to adapt their ruminal flora to the conversion of nitrate to ammonia.
- Prior exposure to nitrate reduces susceptibility under experimental conditions, and cattle on high nitrate hay taken off the hay for a few days and then returned to it in self-feeders where they can gorge on it may be poisoned.
- Monensin facilitates the conversion of nitrate to nitrite in the rumen and may result in poisoning in cattle or sheep on high nitrate fodder.

Animal factors
Species differences
There is considerable variation between species in their susceptibility to nitrate poisoning, pigs being most susceptible, followed by cattle, sheep, and horses in that order. The susceptibility of cattle relative to sheep is due either to their ability to convert nitrate to nitrite in the rumen or because of the known greater ability of sheep to convert nitrite to ammonia. Pigs are highly susceptible to nitrite poisoning but are affected only if they ingest it preformed.

Dietary differences
Cattle reduce nitrate to nitrite in the rumen and their capacity to do this is enhanced by continued feeding of nitrate. The enhanced capacity, due to changes in microbial activity, is transferred naturally to nearby animals not receiving additional nitrate. Cases of nitrate poisoning that occur in sheep are associated with either the ingestion of preformed nitrate or ruminal conditions, which favor reduction of nitrate. A diet rich in readily fermentable carbohydrate reduces nitrite production in the rumen of the sheep. Nitrite poisoning also occurs in sheep fed an inadequate ration after dosing with nitrate at a level innocuous to sheep fed on a good ration. There is often a delay of a few days in the appearance of signs of poisoning after sheep go onto toxic forage. It seems likely that ruminal flora need to adapt to the changed nutrients. The degree of methemoglobinemia also varies with the quality of the diet.

Composition lining board in animal barns may become highly impregnated with nitrite and is associated with poisoning if chewed.
- Water containing 2300 ppm of nitrate and less than 10 ppm of nitrite when mixed into a swill, stored in tins and then cooked has resulted in the production of a mixture containing 1200–1400 ppm of nitrite.
- Boiling does not reduce the nitrate content of water.
- Accidental poisoning with commercial nitrate compounds occurs sporadically when:
  - Sodium or potassium nitrate is used in mistake for sodium chloride or magnesium sulfate, or when ammonium nitrate solution is used instead of whey.
  - Nitrate used as explosives to blast out water holes used to store drinking water for cattle can be dangerous if the nitrate is left in the hole and the dam fills soon afterwards.

Anchored poisonings, pigs being most susceptible, are affected only if they ingest nitrate.

Animal factors
Species differences
There is considerable variation between species in their susceptibility to nitrate poisoning, pigs being most susceptible, followed by cattle, sheep, and horses in that order. The susceptibility of cattle relative to sheep is due either to their ability to convert nitrate to nitrite in the rumen or because of the known greater ability of sheep to convert nitrite to ammonia. Pigs are highly susceptible to nitrite poisoning but are affected only if they ingest it preformed.

Dietary differences
Cattle reduce nitrate to nitrite in the rumen and their capacity to do this is enhanced by continued feeding of nitrate. The enhanced capacity, due to changes in microbial activity, is transferred naturally to nearby animals not receiving additional nitrate. Cases of nitrate poisoning that occur in sheep are associated with either the ingestion of preformed nitrate or ruminal conditions, which favor reduction of nitrate. A diet rich in readily fermentable carbohydrate reduces nitrite production in the rumen of the sheep. Nitrite poisoning also occurs in sheep fed an inadequate ration after dosing with nitrate at a level innocuous to sheep fed on a good ration. There is often a delay of a few days in the appearance of signs of poisoning after sheep go onto toxic forage. It seems likely that ruminal flora need to adapt to the changed nutrients. The degree of methemoglobinemia also varies with the quality of the diet.

Differences in susceptibility
- The most important factor influencing susceptibility appears to be the rate of ingestion of the nitrate-bearing plant.
- Poorly fed animals, especially traveling or recently transported stock, are more susceptible to nitrite poisoning than those on good diets, probably because of the greater intake in hungry animals, and possibly their need to adapt their ruminal flora to the conversion of nitrate to ammonia.
- Prior exposure to nitrate reduces susceptibility under experimental conditions, and cattle on high nitrate hay taken off the hay for a few days and then returned to it in self-feeders where they can gorge on it may be poisoned.
- Monensin facilitates the conversion of nitrate to nitrite in the rumen and may result in poisoning in cattle or sheep on high nitrate fodder.

PATHOGENESIS
Nitrites have a direct caustic action on alimentary mucosa and the ingestion of sufficiently large quantities is associated with gastroenteritis. Absorption of nitrites is associated with methemoglobinemia and the development of hypoxia. Nitrites are also vasodilators which may contribute to the development of tissue hypoxia by causing peripheral circulatory failure, but this effect appears to be of little significance compared to that of methemoglobin formation. When nitrite is ingested preformed, the effects may be very rapid, but when conversion of nitrate to nitrite occurs in the rumen there is a delay of some hours before clinical illness occurs. In cattle and sheep, the maximum methemoglobinemia occurs about 5 hours after ingestion of nitrate. In pigs, it is 90–150 minutes after nitrate is ingested. Death usually occurs within 12–24 hours of ingestion of the toxic material, although in acute poisoning the duration of illness may be even shorter, and clinical signs may not be observed.

Death does not occur until a certain level of methemoglobinemia is attained. In farm animals, lethal levels in cattle are about 9 g/L of blood, in pigs death occurs when 76–88% of hemoglobin has been altered to methemoglobin.

In cattle, prolonged ingestion of sublethal amounts of nitrite is not known to have any significant effect on productivity. However, abortion is commonly recorded as a sequel to an acute outbreak of poisoning, and it is possible that severe anoxic episodes could damage the conceptus.

CLINICAL FINDINGS
In animals poisoned by nitrate there is salivation, abdominal pain, diarrhea, and vomiting, even in ruminants. The more typical syndrome is that associated with the anoxia of nitrite poisoning. Dyspnea, with a gasping, rapid respiration is the predominant sign. Muscle tremor, weakness, stumbling gait, severe cyanosis followed by blanching of the mucosa, a rapid, small, weak pulse, and a normal or subnormal temperature are other typical signs. In the most severe cases the mucosal and conjunctival vessels and the mucosa generally, are brown because of the high content of methemoglobin in the blood.

Fatally affected animals go down, show severe depression and terminal clonic convulsions, and death occurs from a few minutes to an hour after onset. Frequent urination and abortion are other recorded signs, and in some outbreaks in cattle the principal problem is abortion a few days after exposure.

CLINICAL PATHOLOGY
Nitrite poisoning is difficult to diagnose unless blood samples are collected during life and their content of nitrite, or more commonly nitrate, is estimated by the diphenylamine test. Blood and ocular fluid levels of nitrate are stable for 24 hours at 23°C (73.4°F), 1 week at 4°C (39.2°F), and 1 month at −20°C (~4°F). Contributory information is provided by blood levels of methemoglobin, but inaccuracy creeps in because of the rapid reversion of methemoglobin to hemoglobin. Methemoglobinemia may be detected by examination of the blood in a reflection spectrometer but it is not diagnostic of nitrite poisoning, and results are not dependable unless the blood has been collected for less than 1 or 2 hours. Methemoglobin levels of 9 g/dL of blood are lethal in cattle; levels of 1.65–2.97 g/dL are recorded in association with obvious clinical signs compared to normal levels of 0.12–0.2 g/dL. An alternative method is the diphenylamine blue test, which is very sensitive to the presence of nitrite but not entirely specific. A satisfactory test can be conducted on a thick, air-dried blood smear. Laboratory tests are available for the rough estimation of the nitrite or nitrate content of fodder but they are neither sufficiently simple for field use nor accurate enough for critical assay. A modified diphenylamine reagent provides a qualitative test suitable for field use. The test solution (0.5% diphenylamine, 20 mL distilled water and concentrated sulfuric acid to make up to 100 mL) is placed on the tissues of the inside of the stem (to avoid contact with possible iron contamination on the outside surface). An intense blue color within 10 seconds indicates a concentration of greater than 1% of nitrate. Commercial test strips are...
available for detection of nitrate and nitrite in the field. The diphenylamine test does have disadvantages and can give inaccurate results. To avoid these errors it is recommended that the blood be diluted with phosphate buffer (1 part in 20). It is also worthwhile submitting a sample of urine, as nitrite appears to pass unchanged into the urine.

**Necropsy Findings**

In nitrate poisoning, the gastrointestinal mucosa is congested and hemorrhagic. In nitrite poisoning, the blood is dark red to coffee-brown in color, and it clots poorly. Petechial hemorrhages may be present in the heart muscle and trachea, and there is general vascular congestion. There are no characteristic microscopic changes. Specimens for laboratory examination should include blood for methemoglobin estimation, ingesta and suspected plants or water, with added chloroform or formalin to prevent conversion of nitrates by bacterial fermentation. If the animals have been dead for some time, chemical analysis should be attempted on the aqueous humor of the eye and the cerebrospinal fluid. All of these specimens are subjected to the diphenylamine test. Postmortem blood specimens for methemoglobin assay must be collected within 1–2 hours of death to be of any value.

**Samples for confirmation of diagnosis**

- **Toxicology** — 1 cc aqueous humor (frozen); 1 cc urine (frozen), suspect forage material (dry) or other possible source of poison; 100 g ingesta (with chloroform or formalin added) (ASSAY [nitrate/nitrite]); 2 cc blood in 4 cc phosphate buffer (ASSAY [methemoglobin]).

**Differential Diagnosis**

The acute dyspnea, short course, and nervous signs of tremor and convulsions resemble the signs of other forms of anoxia. Although the rapid response to treatment with methylene blue is a good criterion for field use, diagnostic confirmation is by a positive assay for nitrite in body fluid and tissues. The differential diagnosis list includes:

- Hydrocyanic acid poisoning
- Acute bovine pulmonary edema and emphysema
- Anaphylaxis occurs only as sporadic cases
- Cyanobacterial poisoning

**Treatment**

Methylene blue is the specific antidote; in large amounts it is associated with rapid reversion of methemoglobin to hemoglobin. The standard dose rate is traditionally 1–2 mg/kg BW, injected IV as a 1% solution, but in ruminants it has been shown that high dose rates of methylene blue are not associated with dangerous methemoglobinemia; a higher dose rate of 20 mg/kg BW can be used, but the standard dose rate appears to be adequate. Treatment may have to be repeated when large amounts of toxic material have been ingested. The half-life of methylene blue in tissues is about 2 hours, and a repetition of treatment is recommended if necessary at intervals of 6–8 hours. Methylene blue has come under a cloud because of claimed mutagenic properties, but alternative treatments for methemoglobinemia have so far proved inadequate.

**Control**

Ruminants likely to be exposed to nitrites or nitrates should receive adequate carbohydrate in their diet, and traveling or hungry animals should not be allowed access to dangerous plants. Haylage or silage suspected of dangerous levels of nitrate should be allowed to aerate overnight before feeding.

**Toxic levels**

Less than 0.6% of nitrate in the total diet is recommended. Plants, to be safe for feeding, should contain less than 1.5% potassium nitrate on a dry matter basis. For safety it is recommended that cows not be grazed on feed containing more than 1% nitrate, and slightly less when zero grazing. Cattle can eat material containing up to 8% potassium nitrate in dry matter if introduced to it gradually to allow ruminal microbes to adapt.

**Dietary supplements**

If hazardous feed is to be fed, supplementation of the diet of sheep and cattle with chlorotetracycline (30 mg/kg of feed) or potassium nitrate in the total diet is recommended. Plants, to be safe for feeding, should contain less than 1.5% potassium nitrate on a dry matter basis. For safety it is recommended that cows not be grazed on feed containing more than 1% nitrate, and slightly less when zero grazing. Cattle can eat material containing up to 8% potassium nitrate in dry matter if introduced to it gradually to allow ruminal microbes to adapt.

**Etiology**

Plants usually contain soluble oxalate in the form of the potassium salt, and this is much less toxic than if it is given experimentally as the pure salt. High concentrations are present in about 70 plants included in the world list, of which important examples are listed below:

- *Aegothelium vulgaris* — sheep sorrel
- *Amaranthus* spp., e.g. *A. cruentus* — redshank (see also nitrate-nitrite poisoning)
- *Arriplex* spp., e.g. *A. muelleri* — annual saltbush (see also nitrate-nitrite poisoning)
- *Bassia* spp., e.g. *B. hyssopifolia* — red burr
- *Beta vulgaris* — fodder beet, sugar beet, mangel
- *Cenchrus ciliaris* — buffel grass
- *Chenopodium* spp., e.g. *C. album* — fat hen (see also nitrate-nitrite poisoning)
- *Delosperma* spp.
- *Drosanthemum* spp.
- *Emex australis* — spiny emex

**Diagnosis**

Confirmation is by a positive assay for nitrite in body fluid and tissues. The differential diagnosis list includes:

- Hydrocyanic acid poisoning
- Acute bovine pulmonary edema and emphysema
- Anaphylaxis occurs only as sporadic cases
- Cyanobacterial poisoning

**References**

**Oxalate (Soluble Forms) Poisoning**

**Etiology**

Ingestion of soluble oxalates in specific poisonous plants.

**Epidemiology**

Occurrence limited to habitats of the specific plants. Sheep most susceptible. Most severe when plant was recently eaten and sheep was hungry.

**Clinical Findings**

In ruminants — hypocalcemic recumbency, nephrotic syndrome, cimetitis.

**Clinical Pathology**

Low blood calcium; azotemia; proteinuria.

**Necropsy Findings**

Nephrosis associated with calcium oxalate crystals.

**Diagnostic Confirmation**

High oxalate content of ingesta, plants. Nephrosis with oxalate crystals.

**Treatment**

Calcium borogluconate parenterally.

**Control**

Limit access to toxic plants; dilute feed with non-toxic materials.
Oxalate is normally metabolized by ruminal bacteria and the continued ingestion of oxalate in small quantities results in increased ability to decompose the oxalate to the point where relatively large quantities can be ingested without toxic effects. The ruminal microflora requires 3-4 days to adapt to the introduction of oxalate into the diet. Thus, sheep and cattle may be very susceptible when they are grazed for the first time on pasture containing the toxic plants. Of the factors in the rumen which will affect the amount of oxalate rendered insoluble as calcium oxalate or digested to bicarbonate, the level of calcium in the diet and the activities of bacteria in the rumen are considered to be important.

Susceptible animal groups

Plants containing oxalates in dangerous quantities grow prolifically in specific areas, and heavy mortalities occur in traveling and recently introduced animals and other very hungry animals whose intake of potentially toxic plants is likely to be higher than normal. As a group, pregnant and lactating animals are probably more susceptible than others.

Environmental factors

State of pasture

Young, rapidly growing, fresh plants may contain as much as 17% potassium oxalate whilst old, dry plants rarely contain more than 1%, but Haloegeton, one of the most dangerous plants, becomes more toxic as the growing season progresses, and is most dangerous when frosted and dried, when it may contain as much as 16.6% of soluble oxalate. The grass Setaria sphacelata, much favored for tropical conditions, may contain up to 7% oxalate and be associated with acute poisoning in cattle and horses.

PATHOGENESIS

Clinical effects vary with the amount of oxalate ingested. With large quantities the major effect is the absorption of free oxalate and precipitation of blood calcium as calcium oxalate to produce a hypocalemia. Severe nephrosis occurs with precipitation of calcium oxalate crystals in renal tubules. There may be marked damage to vascular tissues, especially in the alimentary tract and lungs. Invasion of the chemical rumenitis that results may lead to an irreversible fungal or bacterial rumenitis or hepatitis. Continuous ingestion of smaller amounts of soluble oxalates from pastures dominated by Oxalis pes-caprae over 2-12 months is associated with a chronic nephrosis with precipitation of oxalate crystals in the renal tubules. Up to 25% of sheep may be affected in some flocks. Such damage is likely to be cumulative if the sheep are periodically exposed to oxalate-bearing plants.

Other syndromes

Include urolithiasis, and renal dysfunction due to changes in pH of its contents and interference with cellulose digestion.

CLINICAL FINDINGS

Clinical signs may appear within 2-4 hours of eating oxalate-containing plants if the animals are hungry and consume large quantities.

Hypocalcemia syndrome

In acutely poisoned sheep, the clinical signs include anorexia, hyposensitivity, paroxysms, muscle tremor, especially of facial muscles, clear mucus dripping from the nostrils, ruminal atony, dyspnea, hypothermia, dry gait, and finally recumbency with the head turned into the flank, pupillary dilation, and death in coma. The heart rate is rapid, and the ruminal movements are decreased. There may be slight bloating, frequent getting up and lying down, eventually recumbency, frequent attempts to urinate, frothy blood-tinged nasal discharge, and occasionally red-brown urine. In sheep, chronic cases of nephrosis show poor appetite, failure to grow, poor bodily condition, ascites, and a significant anemia. Acute nephrosis in cattle is marked by hyposensitivity leading to coma, recumbency, proteinuria, and elevated blood urea nitrogen levels.

CLINICAL PATHOLOGY

Suspected plants should be assayed for soluble oxalate content. Hypocalcemia is a key finding in the acute disease with azotemia in cases with significant kidney damage. In sheep with chronic nephrosis, albuminuria, and sometimes hematuria may be observed, the packed cell volume may be as low as 15-20%, the blood urea nitrogen is of the order of 85 mg/dL (30.3 mmol/L) and there may be an accompanying elevation of blood potassium. The proteinuria is almost diagnostic of the disease in sheep grazing Oxalis spp.

NECROPSY FINDINGS

There are no gross findings at necropsy which are characteristic of acute oxalate poisoning, but perirenal edema and ascites may be evident in chronic cases. Nephrosis is the standard finding at histopathological examination, and there is usually deposition of, birefringent rosettes of crystals in the renal tubules and pelvis, and even in the ureters and urethra. In experimental acute poisoning in the horse...
and sheep, severe gastroenteritis and dehydration have been observed.

Samples for confirmation of diagnosis
- Toxicology – samples of suspect feed/forage for identification of plants and assay for soluble oxalate
- Clinical pathology – serum or plasma for calcium, urea, and creatine assays
- Histology – formalin-fixed kidney (LM).

Differential Diagnosis
Diagnostic confirmation is provided by a positive assay of toxic levels of soluble oxalate in the pasture plus the presence of nephrotic kidneys containing calcium oxalate crystals.

Differential diagnosis lists:
- For the acute syndrome:
  - Parturient paresis
  - Hypocalcemia due to starvation or forced exercise
  - Lactation tetany
  - Transport tetany
  - Severe toxemia due to coliform mastitis
  - Carbohydrate engorgement
  - Uremia.
- For the chronic syndrome:
  - Pyelonephritis
  - Obstructive urolithiasis
  - Amyloidosis.

Treatment
Primary
The parenteral injection of solutions of calcium salts is a specific treatment of the acute hypocalcemic disease. Calcium borogluconate as a 25% solution given IV or SC in doses of 300–500 mL in cattle, and 50–100 mL in sheep usually effects recovery. A proportion of cases will succumb to kidney failure despite treatment.

Supportive
Treatment should include the provision of ample fluids to decrease precipitation of oxalate crystals in the urinary tract. There is no recommended treatment for chronic cases.

Control
Hungry sheep and cattle should not be allowed to feed on large quantities of the toxic plants. Ample water should be available at all times to facilitate the elimination of the oxalate, but poisoning is likely to occur when hungry sheep are watered and then allowed to graze. Alternative sources of food should be provided for animals grazing pasture dominated by one of the oxalate-bearing plants. Prophylactic feeding of dicalcium phosphate is effective, other calcium salts and bone meal being ineffective, and adequate salt should be made available.

Pathogenesis
Water-insoluble calcium oxalate crystals (prismatic or druse types) in the leaf cells of these grasses store most of their calcium. These crystals are not digested in the horse’s alimentary tract until they reach the large intestine. Because the main site of calcium absorption in horses is the duodenum, the calcium is unavailable for absorption, thus producing a negative calcium balance in the horse and leading to hyperparathyroidism.

Clinical Findings
Affected horses have a stiff, stilted action, most evident at gait faster than walking. This progresses to reluctance to move, and recumbency in severe cases. Exercise initiates or exacerbates the lameness. Some affected horses lose weight despite an ample supply of feed. There is bilateral firm swelling of the maxilla, the mandible or both, over the roots of the cheek teeth.

Clinical Pathology
Concentrations of parathyroid hormone in blood will be abnormally increased. Concentrations of calcium, phosphorus, magnesium, and alkaline phosphate in plasma do not change consistently from normal. Some horses will have increased concentrations of alkaline phosphatase. Biopsy of the jaw swellings will reveal lesions of osteodystrophia fibrosa.

Necropsy Findings
Swellings of the jaws, erosions or pitting of joint surfaces, and enlargement of both the upper and lower parathyroid glands are seen. Fractures of bones may occur. Histological lesions of osteodystrophia fibrosa are seen in the jaw swellings, osteoporosis in long bones, and hyperplasia in the parathyroid glands.

Differential Diagnosis
The syndrome of lameness and bony swelling of the head is distinctive and, in the presence of the plants in the pasture, confirms the diagnosis. The differential list includes:
- Nutritional secondary hyperparathyroidism is identical but is associated with excessive phosphorus intake in hand-fed horses
- Renal hyperparathyroidism is very rare in horses and will be accompanied by signs of uremia.

Treatment
Affected horses should be moved to non-hazardous pasture if possible. Remineralization of the bones can be effected by feeding each horse 2 kg of rock phosphate of low fluoride content, or 2 kg of a mixture of 1 part calcium carbonate and
family of plants is the basis for their irritant effects on the buccal mucosa. Calcium oxalate crystals in grasses are structurally different and are prismatic or druses, neither of which are sharp or likely to penetrate mucosa.

ETIOLOGY
Calcinoic glycosides occur in very small quantities in plant leaves. The aglycone (non-sugar) radical is a vitamin D₃, sterol, a 1,25-(OH)₂D₃-like compound. Hydrolysis of the glycoside releases the vitamin D₃ analog causing the development of calcification of soft tissues, reminiscent of hypervitaminosis D. The plants in which these glycosides have been identified are Solanum malacoxylon (i.e. S. glaucophyllum, S. glaucum, S. glaucescens, S. glaucum-frutescens), Nierembergia veitchii, and Cestrum diurnum (wild jessamine). Other plants known to be associated with the same disease, and in which the presence of calcinoic glycosides is suspected, are Stenotaphrum secundatum (crab grass) in Jamaica, S. latifolium (= S. hermannii), S. sordidum (apple of Sodom), S. tortum (devils fig), and Trisetum flavescens (yellow or golden oat grass) in Europe.

Other plants known to be associated with the same disease, and in which the presence of calcinoic glycosides is suspected, are Stenotaphrum secundatum (crab grass) in Jamaica, S. latifolium (= S. hermannii), S. sordidum (apple of Sodom), S. tortum (devils fig), and Trisetum flavescens (yellow or golden oat grass) in Europe.

The plants are weeds of pasture and are readily eaten by livestock. The glycosides are very stable and resist drying and storage for periods of longer than 1 year. Heating reduces the toxicity of Solanum malacoxylon significantly, but has little effect on that of Trisetum flavescens.

EPIDEMIOLOGY
Occurrence
Enzootic calcinosis and its caustive plants occur in most countries. The disease associated with Solanum spp. occurs in tropical and subtropical regions including Africa, Argentina, Brazil, Papua New Guinea, West Indies, and Hawaii, and Cestrum diurnum poisoning in southern United States, especially Florida, Texas, and California. Tentative diagnoses have been made in India and Israel. In Japan the disease is known as 'Manchester wasting disease', in Hawaii as 'naalehu', and in South America as 'epishamento' or 'equipe seco'.

In Austria and Germany, Trisetum flavescens is a common component of alpine pasture and is associated with the disease about 18 months after cattle are put onto the infested pasture. Resident cattle show clinical signs at about 3 years of age. The grass is most toxic when it is young and the clinical signs are worst when the cattle are at pasture. Silage made from the grass is toxic but hay is not.

Animal risk factors
Both sexes and all ages of all animal species are affected; ruminants most commonly, horses less so. Pigs and sucking lambs are least susceptible.

PATHOGENESIS
The glycoside ingested in the plant is hydrolyzed in the rumen by microbial activity, by intestinal mucosal enzymes, and by bone cells, to form the vitamin D₃ analog. Absorption of the active substance results in a dramatic increase in the uptake of calcium from the diet. Blood levels of calcium are markedly increased and this is followed by deposition of calcium in soft tissues. The mode of action of the glycoside is consistent with it having a mode of action similar to that of 1,25-dihydroxycholecalciferol.

CLINICAL FINDINGS
The disease is chronic and may persist for several years. It is characterized by wasting, reluctance to walk, a stiff gait, constant shifting of the weight from foot to foot, and a disinclination to get up or to lie down. Forced exercise is associated with severe distress; some animals may become aggressive. Affected animals stand for long periods with the back arched and the legs stiffly extended. Calcification of blood vessels may be palpable, for example during rectal examination. Cardiac murmurs are audible. Clinical signs subside if the animals are removed from the causative feed, but resorption of calcium deposits in tissues is minimal even 5 years after removal from the affected pastures. Animals left on the toxic pasture eventually become recumbent and die. Fetuses may be affected.

CLINICAL PATHOLOGY
There are 20–25% increases in serum calcium (up to 34 mmol/L) and serum
phosphorus (up to 4 mmol/L) concentrations. Tissue calcification should be detectable radiologically. Anemia is common in animals poisoned by Solanum malacoxylon.

Necropsy findings
Non-specific emaciation, anasarca, and ascites are common. Calcification of all blood vessels, including the aorta and coronary arteries, and of the endocardium is the most readily visible, characteristic lesion. Calcification is also present in the pleura, and the lung parenchyma, which is usually emphysematous, in most other viscera, and in tendons and ligaments. Degenerative arthritis occurs in the limb joints.

Differential diagnosis
The history, clinical findings, and discovery of specific toxic plants provide diagnostic confirmation. Repeated overdosing with vitamin D, by injection or administration in compounded feeds, replicates the clinical and necropsy findings.

TREATMENT AND CONTROL
No practicable treatment is available. Careful management of affected pasture in Europe has been shown to significantly reduce the losses due to the disease.

Cardiac glycoside poisoning

Synopsis

Etiology Poisoning associated with naturally occurring organic compounds (cardenolides and bufadienolides) found in specific plants which have specific effects on the myocardium.

Epidemiology Widespread, in most countries, all species affected. Many toxic plants unpalatable but hay and garden waste containing them are toxic; so are seeds in grains and meals contaminated by them.

Clinical findings Two syndromes — acute heart failure and krimpsiekte, comprising poor exercise tolerance, tachycardia, dyspnea.

Clinical pathology Significant electrocardiographic abnormality, azotemia.

Necropsy findings Multifocal myocardial degeneration.

Diagnostic confirmation Identification of plant and toxin.

Treatment Activated charcoal and fluids by mouth, parenteral atropine and propranolol; plus spasmytics and analgesics in horses.

Control Avoid pasture or stored feed containing toxic plants.

Etiology
Cardiac glycosides consist of an aglycone, related chemically to the steroideal hormones, and one or more sugar molecules. There are two groups of the very large number of these compounds, the cardenolides and the bufadienolides, with different chemical characteristics. Bufadienolides in some plants from southern Africa are cumulative and produce chronic nervous system damage, others are found in other plants producing acute toxicity. Toxins in toads, e.g. Bufo marinus, have affinities with the aglycones of bufadienolides and can poison dogs but poisoning of farm animals seems unlikely.

The plant genera with species known to contain cardiac glycosides and which can be associated with an acute syndrome or a chronic cumulative disease (cotyledonosis or krimpsiekte) are listed below.

Acute poisoning:
- Acocantha (Carissa)
- Adenium
- Adonis
- Antiaris
- Apocynum
- Araujia
- Asclepias
- Berberis
- Bowera
- Bryophyllum
- Calotropis
- Cascabela (Thevetia)
- Cerbera
- Convallaria
- Corchorus
- Cotyledon
- Cryptostegia
- Digitalis
- Diplarrhena
- Euonymus
- Euphorbus
- Gynandriris
- Haemanthus
- Helleborus
- Homeria
- Hyacinthus
- Iris
- Kalanchoe
- Lathyrus
- Linaria
- Melampyrum
- Melianthus
- Moraea
- Morgania
- Nerium
- Orthosiphon
- Oreithogalum
- Parsonia
- Scilla
- Scrophularia
- Sisyrinchium
- Strophantus
- Taenazza
- Thesium
- Uringa
- Vinca

Chronic poisoning — Cotyledonosis or krimpsiekte:
- Cotyledon
- Kralanchoe
- Orthosiphon
- Oreithogalum
- Tylecodon

Epidemiology
Occurrence Poisoning occurs wherever the plants grow and local plant-lists need to be consulted for exact details. Many other related plants, and some in other species, are associated with clinical illness similar to those of cardiac glycoside poisoning. The acute poisoning syndrome is seen in several parts of the world, principally in southern Africa, northern America, and in Australia, but chronic poisoning (cotyledonosis or krimpsiekte) is confined to southern Africa.

Risk factors
Animal factors
Ruminants are most commonly affected, horses less so. Wild animals appear to avoid the plants and some are reputed not to be susceptible. Morbidity rates vary with the intake; case fatality rates are very high.

Plant factors
Some of the plants are most readily eaten when they are in the flowering stage. Many are so unpalatable that they are unlikely to be eaten unless they are cut in with other plants and fed as hay, or seed contaminates a crop of feed grain. Some of them, like Nerium oleander (oleander), are decorative plants, and animals get access when they break into gardens or are fed prunings. The plants do not lose their toxicity when dry. Insects and other plants that eat or parasitize plants containing cardiac glycosides may contain the substances in significant amounts.

Pathogenesis
Cardiac irregularity and insufficiency, leads to acute or subacute heart failure. Animals that live for several days also develop severe diarrhea. The cardiac arrhythmia is probably the result of the acute effects of cardiac glycosides on the heart, including inhibition of the sodium pump (Na⁺–K⁺ ATPase) of the cardiac muscle cell membrane, enhanced vagal activity and
Diseases associated with major phytotoxins

reduced coronary artery blood flow through vasoconstriction. Prolonged intake of small amounts of toxic material from the cumulative bufadienolide-containing plants in Southern Africa, produce the paraplegic syndrome known as cotyledonosis or krimpieskte.

CLINICAL FINDINGS
Acute poisoning
Common signs are apathy, a tendency to stand with head bowed and abdomen tucked up, teeth grinding or groaning, cardiac arrhythmia (tachycardia or brady-cardia, heart block), dyspnea, ruminal atony, bloating, diarrhea with mucoid or blood-stained feces, dehydration, and posterior paresis. Sudden death may occur, particularly during exertion. Poisoning by Homoeria spp. in some parts of southern Africa only results in constipation rather than diarrhea. Additional signs include drooling of saliva, tenesmus, dribbling of urine, muscular tremors, dilated pupils, and seizures. Pigs are likely to vomit.

Chronic poisoning
Cotyledonosis or krimpieskte in small ruminants is characterized by animals lagging behind the flock, tiring easily, walking with the head loosely dangling and then lying down, usually with the head and neck stretched flat along the ground. Many assume a characteristic posture with the feet gathered together beneath the body, the back arched, the head down, and the neck sometimes twisted towards one side. This torticolis can persist for months or years. Signs are aggravated by exertion: hyperesthesia, trembling, and tetanic spasms may also occur. Additional signs include drooping of the lower jaw, drooling of saliva, paralysis and protrusion of the tongue, and dysphagia with accumulation of half-masticated feed at the back of the mouth. Horses have pronounced torticolis and hyperesthesia and may show signs of colic or be paralyzed. Secondary intoxication of dogs or humans who eat meat from affected livestock occurs even after cooking.

CLINICAL PATHOLOGY
Acute poisoning of sheep by Homoeria pallida produces progressive hemoconcentration, hyperkalemia, hypocloremia, progressive hyperglycemia associated with rises in catecholamines, cortisol and lactate, and progressive increases in plasma creatinine concentration, plasma α-hydroxybutyrate, dehydrogenase, and lactate dehydrogenase activities. Acute poisoning of cattle by Bryophyllum ssp. also produces hemoconcentration, pro-
gressive hyperglycemia, glycosuria, and progressive increases in plasma urea and creatinine concentrations.9

Electrocardiographs (ECGs) may show significant changes in the ECG of affected animals indicating the presence of ventricular fibrillation and ectopic foci in the myocardium. These effects of cardiac glycosides on the ECG of livestock include prolonged P-R interval, depressed or elevated ST segment and increased amplitude and inverted T wave. The QRS complex may widen from delayed AV conduction. Other effects include AV dissociation, varying degrees of heart block, evidence of ectopic foci, and runs of ventricular tachycardia.

Because of the sudden death in many cases, the toxic plant can often be identified in stomach contents by botanical characteristics. In digitalis poisoning, the digitoxin can be assayed in the ruminal contents.

NECROPSY FINDINGS
In acute poisoning, mild-to-severe multifocal myocardial degeneration and necrosis is often present if the patient survives for more than 12 hours. Subendocardial and subepicardial hemorrhages and hemmorhages into the mucosa and lumen of the large intestine are common in acute cases. Atelectasis of lung lobules is common, and pulmonary congestion and edema secondary to cardiac failure may be seen. Fragments of the plants responsible for poisoning may be recognized in stomach contents. Nephrosis has been seen occasionally. Hemorrhages of the rumen wall, and necrosis and ulceration of the omasal leaves have been seen in animals affected for several days. Evidence of hepatic insufficiency, including jaundice, is present in some poisonings, but its pathogenesis is unclear.

Toxins may be detected in rumen or stomach contents using chromatographic techniques.10-12

DIFFERENTIAL DIAGNOSIS

The diagnosis depends on the detection of one of the toxic plants, either in the pasture or in conserved roughage, in the environment of animals showing characteristic clinical signs, or sudden death. Diagnosis confirmation is established by identification of the plant, the cardiac glycoside in it, or both, in ingesta in association with myocardial lesions.

Differential diagnosis list
Other poisons which are associated with cardionmyopathy and similar clinical signs include:

- Urechites lutea
- Alisma tanganyicense, A. versicolor
- Fedagom homae (F. monticola)

TREATMENT AND CONTROL
Primary treatment
Removal of animals from the suspect pasture or changing the source of conserved roughage is usually obligatory. Activated charcoal is effective. A dose of 5 g/kg is recommended for ruminants and may need to be repeated.

Supportive treatment
Oral fluid replacement therapy for rehydration (150 mL/kg in divided doses over 24 hours) and parenteral antiarrhythmic drug therapy with atropine (0.5 mg/kg) for heart block and propranolol (5 mg doses to effect) for tachycardia are also recommended.9 The recovery rate declines sharply with the lapse of time between ingestion of the plant and treatment.

DICOUMARIN DERIVATIVES (INCLUDING SWEET CLOVER) POISONING

**ETIOLOGY**
Coumarin, ferulenol and melilotin, normal constituents of some plants, are converted to dicoumarol in the process of infection by molds of the cut plant during the making or storage of hay or ensilage.

**EPIDEMIOLOGY**
Outbreaks occur on exposure to toxic plants or moldy hay made from specific plants, especially Melilotus spp. Insignificant trauma is associated with massive hemorrhage.

**Clinical findings**
Palor, weakness especially newborn calves. Hemorrhage may be internal and not visible.

**Clinical pathology**
Severe anemia, prolonged clotting, prothrombin times, dicoumarol assay on feed is positive.

**Necropsy findings**
Massive subcutaneous, subserosal hemorrhages, hematomas.

**Diagnostic confirmation**
High dicoumarol content of feed.

**Treatment**
Primary: change feed. Supportive: Blood transfusion.

**Control**
Avoid feeding moldy sweet clover hay or ensilage; dilute with other feed.

A common introduction to the diseases is the occurrence of severe bleeding after surgery or injury, or subcutaneous swelling of the head and neck in newborn animals. A short course (24–48 hours) and a high case fatality rate are usual.

**EPIDEMIOLOGY**
Occurrence
Sweet clover poisoning is recorded most commonly in North America where sweet clover is grown as a fodder crop. In affected herds the morbidity rate is about 12%, with a case fatality rate of 65%. Aborted fetuses and calves less than 2 weeks of age are the common subjects in some herds. The disease occurs most commonly during the winter months when stored hay or ensilage is fed to cattle. Its occurrence has brought the plant into disfavor and the disease incidence has been greatly reduced for this reason.

**Risk factors**
Plant factors
Not all moldy sweet clover hay or silage contains dicoumarol and the degree of spoilage is no indication of the toxicity of the hay sample. Varieties of sweet clover differ in their content of coumarol and thus in their potential toxicity. For example, the Cumino variety has a low, and the Arctic variety a high, coumarol content.

Grazing the crop is not dangerous but making it into hay or ensilage without the development of mold is difficult because of the succulent nature of the plant.

Dicoumarol concentrations in sweet clover hay, bales, or silage vary widely, being highest in small bales; round bales contain more than hay stacks, and the levels are low in silage. Properly cured silage contains less still because of its anaerobic conditions; dicoumarol-producing fungi require oxygen. The levels of dicoumarol are highest in the outer parts of hay bales, presumably because they are exposed to moisture.

**Animal factors**
The disease can occur in all species, but is most common in cattle, less so in sheep and very rare in horses. Clinical signs may appear without apparent precipitating cause, but trauma, surgery (castration, dehorning), and warble fly migration are often followed by deaths from hemorrhage. Severe losses occur in newborn calves during the first few days of life when their dams have been fed poisonous hay without the dams being clinically affected.

**Importance**
In most outbreaks heavy mortalities occur without warning.

**PATHOGENESIS**
Dicoumarol competitively inhibits vitamin K epoxide reductase. Reduced vitamin K is essential for final carboxylation and activation of clotting factors II (prothrombin), VII (proconvertin), IX (Christmas factor), and X (Stuart factor). Inadequate synthesis of these factors results in impaired fibrin stabilization of platelet plugs, and affected animals are subjected to internal and external hemorrhage and anemia. The degree of hypoprothrombinemia is directly related to the amount and duration of dicoumarol ingestion. Coagulation system activity is maintained until the natural decay of the clotting factors in place at the time that poisoning occurs (24–36 hours after the intake of toxin). Large extravasations of blood into tissues may provide signs of disease because of the pressure exerted on internal organs. Large hemorrhages in the pelvic cavity and broad ligament of postpartum cows often delay uterine involution and shedding of fetal membranes.

**CLINICAL FINDINGS**
Extensive hemorrhages into subcutaneous tissues, intermuscular planes, and under serous surfaces is associated with discomfort. The hemorrhages may be visible and palpable as hematoma, but are not painful or hot and do not crepitate. They may be associated with stiffness, lameness, disinclination to move, and even recumbency. One limb may be severely swollen. There are no signs of toxemia, the affected animal continues to eat well and the temperature, respiration, and heart rate are normal until the terminal stages, but the mucosae are pale and often show hemorrhages. Hematuria, epistaxis, and dysentery occur rarely. Accidental and surgical wounds are associated with severe bleeding, but frank hemorrhages from the mucosae seldom occur. Newborn calves may show extensive swelling of the head and neck and become weak from internal or external hemorrhages within a few hours of birth.

When the loss of whole blood is severe, signs of hemorrhagic anemia appear. The animal is weak, the mucosae pallid, the heart rate increases, and the absolute intensity of the heart sounds increases markedly. A short course of 24–48 hours and a high case fatality rate are usual.

**CLINICAL PATHOLOGY**
Severe anemia with markedly increased clotting and prothrombin times are characteristic of the disease. Extension of prothrombin times occurs before there is any increase in clotting time or clinical evidence of bleeding, and is therefore a useful prognostic test.

**Dicoumarol analysis**
Representative samples of suspected feed should be submitted for analysis of the content of dicoumarol. Clinopathological
Evidence of toxicity in sheep occurs on diets containing 10 mg/kg of dicoumarol. However, significant changes in clotting time do not occur on diets containing less than 20–30 mg/kg. Similar changes commence in lambs and calves when the dietary intake of dicoumarol rises to above 2 mg/kg BW.

Quantitative determination of dicoumarol levels in blood and tissues are now available, and are especially valuable in aborted fetuses and newborn calves in which there may have been inadequate opportunity for clinical examination. High levels of dicoumarol in the feed (20–30 ppm) and in the liver (1 ppm) are supportive evidence.

**Necropsy Findings**

Subcutaneous hemorrhages and large hematomata occur in areas where normal activity produces mild contusion, such as the flanks, carpal and tarsal joints, and the side of the body where the animal exerts pressure while lying down. Hemorrhages of the peritoneal surface of the rumen and massive retroperitoneal hemorrhage around the kidneys are frequently observed. In contrast to hemorrhages typical of septicemia, extravasation is uncommon in the lungs, kidneys, and adrenals. The carcass is pale and there is no intravascular hemolysis, jaundice, hemoglobinuria, or hemosiderosis. Histological examination is unrewarding, other than as a means of eliminating other potential causes of diathesis, such as vascular diseases. The collection of feed samples and tests required for confirmation of the diagnosis are as described for clinical pathology.

**Differential Diagnosis**

Diagnostic confirmation is based on detection of dicoumarol, or similar compound, in the feed. Differential list includes those diseases characterized by blood loss anemia resulting from spontaneous hemorrhage.

- Poisoning by other specific plants, with or without their contamination by molds (see above)
- In purpura hemorrhagica, but this disease is uncommon except in horses and rarely affects more than one animal in a group; clotting and prothrombin times are not abnormal, the defect being one of vascular damage
- Angioneurotic edema cases are not usually accompanied by anemia
- Ptaquiloside poisoning
- Trichloroethylene-extracted soybean meal poisoning, but large extravasations of blood are unusual.

**TREATMENT**

Primary Feeding of the suspected hay or silage should be stopped immediately, but new cases may continue for up to about 6 days. Vitamin K₁ (naturally occurring vitamin K₁) is an effective antidote for sweet clover poisoning. A single dose of vitamin K₁ at a rate of 1.1–3.3 mg/kg BW intramuscularly is effective in restoring the prothrombin times to within normal range within 24 hours in cattle which have been fed moldy sweet clover hay containing 90 mg/kg of dicoumarol. Vitamin K₃ (synthetic vitamin K₁, menadione sodium bisulfite) is ineffective as treatment or prevention.

Supportive treatment Animals with clinical evidence of severe hemorrhage should be given a whole blood transfusion at the rate of 10 mL/kg BW. This will usually return the prothrombin time to normal within several hours.

**CONTROL**

Sweet clover forage must be carefully prepared, and not fed if it is damaged or spoiled during curing. Moldy portions of hay or silage should be discarded and representative samples of suspected feed should be submitted for analysis of dicoumarol content.

If the disease is suspected, discontinue the feed immediately. After 3 weeks, the sweet clover forage may be fed alone, but preferably mixed with another type of forage. Animals with clinical evidence of severe hemorrhage should not receive sweet clover during gestation or in the last 3 weeks of pregnancy. Vitamin K₁ (synthetic vitamin K₁, menadione sodium bisulfite) is ineffective as treatment or prevention. However, significant changes in clotting time do not occur on diets containing less than 20–30 mg/kg. Similar changes commence in lambs and calves when the dietary intake of dicoumarol rises to above 2 mg/kg BW.

Quantitative determination of dicoumarol levels in blood and tissues are now available, and are especially valuable in aborted fetuses and newborn calves in which there may have been inadequate opportunity for clinical examination. High levels of dicoumarol in the feed (20–30 ppm) and in the liver (1 ppm) are supportive evidence.

**Necropsy Findings**

Subcutaneous hemorrhages and large hematomata occur in areas where normal activity produces mild contusion, such as the flanks, carpal and tarsal joints, and the side of the body where the animal exerts pressure while lying down. Hemorrhages of the peritoneal surface of the rumen and massive retroperitoneal hemorrhage around the kidneys are frequently observed. In contrast to hemorrhages typical of septicemia, extravasation is uncommon in the lungs, kidneys, and adrenals. The carcass is pale and there is no intravascular hemolysis, jaundice, hemoglobinuria, or hemosiderosis. Histological examination is unrewarding, other than as a means of eliminating other potential causes of diathesis, such as vascular diseases. The collection of feed samples and tests required for confirmation of the diagnosis are as described for clinical pathology.

**Clinical Findings**

Tremor, incoordination, paralysis; salivation, vomiting, ruminal tympany; death due to respiratory paralysis or heart failure.

**Clinical Pathology**

Toxic alkaloids in blood, tissues, and plants.

**Diagnostic Confirmation**

Toxic alkaloids in blood and tissues (Delphinium). Treatment Physostigmine (Delphinium). Control Pasteure on mature Delphinium plants; avoid all consumption of Erythrophleum plants.

**Etiology**

Diterpenoid alkaloids occur in Delphinium spp. (larkspurs), Erythrophleum and Aconitum spp. and are associated with poisoning in grazing animals. There are a very large number of alkaloids (not identified here) in five types: aconitine, barbitine, lycocotine, delphine, and heteratrina. The number of alkaloids in a single plant species may also be large, e.g. D. glaucens contains 14. All of the alkaloids exert the same effect but they vary widely in their toxicity and in their concentration in plants at different times.

There are over 100 species of these plants but a full alkaloid content profile has been completed in only a few. The commonest species known to contain toxic diterpenoid alkaloids and to be associated with disease in livestock are:

- *Aconitum napellus* - monkshood, wolfsbane
- *Delphinium barbeyi*
- *D. bicolor*
- *D. geyeri*
- *D. glaucens*
- *D. glaucum*
- *D. nuttallianum*
- *D. occidentale*
- *D. tricolor*
- *D. virens* – larkspurs
- *Erythrophleum spp.*, e.g. *E. chlorostachys* - Cocktown ironwood.

Some of the species assumed to contain the alkaloids because of their known association with the disease are:

- *Delphinium ajacis*
- *D. andersonii*
- *D. consolida*
- *D. elatum*
- *D. hybridum*
- *D. nelsoni*
- *D. parryi*
- *D. ramosum*
- *D. robustum*
- *D. trollifolium*.

The taxonomy of *Delphinium* spp. is unsettled and the nomenclature used may vary from other sources.

**Synopsis**

**Etiology** Toxins in genera Aconitum, Delphinium, Erythrophleum spp. Toxins include aconitine, delphine.

**Epidemiology** Delphinium spp. occur over extensive range lands in USA. Toxic Erythrophleum spp. occur in northern Australia, Asia, Africa. Poisoning commonest in cattle, all species susceptible.
EPIDEMIOLOGY

Occurrence
North America and Europe are the principal locations of Delphinium and Aconitum spp. poisonings. Erythrophleum spp. occur in Africa, Asia, and Northern Australia.

Risk factors
Plant factors
Aconitum spp. are found in the UK and Europe but poisoning occurs rarely. Rangeland larkspurs (Delphinium spp.) are important pasture plants in North America. Many of them are associated with heavy mortalities in livestock. The incidence of poisoning varies widely with season and climate, due probably to wide variations in the concentration and chemical composition of specific alkaloids in the subject plants.

Animal factors
All animal species are susceptible but most cases are seen in cattle, less often in sheep, and rarely in horses. Cattle may develop a strong aversion, up to 40%, to larkspur plants in the pasture and refuse to eat them after the first exposure. The aversion is associated with identifiable substances in the plant and these are being used experimentally to attempt to control ingestion of the plants. Continued exposure to larkspurs does not reduce either the animals’ sensitivity, or their ability to metabolize the alkaloids.1

PATHOGENESIS

Experimentally, tall larkspur administered to cattle produces muscle tremor, ataxia, recumbency, and death from respiratory paralysis. Cattle are more susceptible than sheep. Methyllycaconitine acts as a postsynaptic cholinergic blocker in cattle. Physostigmine appears to be an effective antidote. The skeletal muscle weakness and, later, paralysis, result from the inactivation of the motor unit of the muscle fibers. Some of the alkaloids are known to be associated with malfunction of the neuromuscular junction, but interference with the other parts of the neuromuscular arc is also possible. At sublethal doses, signs peak at 5–9 hours after first appearance, but the effects can be cumulative. The signs in the herd disappear about 4 days after the plant is withdrawn from the diet.2 The alkaloids in Erythrophleum chlorostachys have a cardiac glycoside-like action.

CLINICAL FINDINGS

Initially in larkspur poisoning there is an episodic weakness with muscle tremor and staggery gait, followed by paralysis of the limbs and recumbency. There is drooling of saliva, vomiting, and ruminal tympany, all probably due to paralysis of the striated muscle of the esophagus. Bloated animals can still belch. Constipation is a common sign and is thought to be due to failure to drink any water. Diarrhea is reported in Aconitum spp. poisoning, possibly due to the presence of additional toxins. Cases that have ingested a lethal dose usually die of paralytic respiratory failure.3 This may happen after a very short course if the intake of toxin is high. Aspiration of ruminal contents after regurgitation also causes some deaths. In the terminal stages, the pupils are dilated and the pulse and respiration may be barely perceptible.

Erythrophleum chlorostachys (ironwood) and E. guineense are both poisonous to all animal species. Clinical signs include anorexia, a staring expression, partial blindness, tremor, ataxia, contraction of abdominal muscle, increased heart sounds, mucosal pallor, and terminal dyspnea. Horses poisoned by E. chlorostachys have loud and often irregular heart sounds, dyspnea, sporadic contraction of abdominal muscles, and die rapidly.

CLINICAL PATHOLOGY

There are no specific findings in larkspur poisoning other than identification of toxic alkaloids in plants, ingesta, blood, and tissues. Many cases will be dehydrated because of the inability to drink.

NECROPSY FINDINGS

There are no specific findings. Aspiration pneumonia may be an incidental finding in some cases.

Differential Diagnosis

Differentiation from other plant poisonings causing incoordination, recumbency, and death in cattle on extensive grazing is usually based on botanical identifications. Diagnostic confirmation of larkspur poisoning depends on chemical identification of the causative alkaloids in the rumen contents and the plants. The differential diagnosis list includes:

- Phalaris spp. (tyramine poisoning)
- Paspalum spp. Infested with Claviceps paspali (paspalitrem poisoning)
- Lolium rigidum, Agrostis avenacea infested with grass nematodes, and Clavibacter toxicus (tunicamycinuracil poisoning)
- Lead poisoning
- Organophosphorus compounds.

TREATMENT

Primary
Physostigmine and carbachol are effective antidotes for Delphinium spp. poisoning, but require repeated injections and will have only limited practical value.4 No specific treatment has been identified for Erythrophleum spp. poisoning, but access to immature plants, suckers, and foliage of mature trees should be prevented.

CONTROL

Control of Delphinium spp. poisoning is only possible by careful management of pasture and denying animals’ access to badly infested areas. Deferring grazing until after the flowering stage, when the concentration of toxin has declined, avoids poisonings but the quality of the forage has declined badly. Sheep are more resistant to the poisoning than cattle, but are not fond of the plant and may have to be restricted to areas where it does not occur. Weedicides are variable in their efficacy against Delphinium spp. and have low efficacy against the deep-rooted perennial species.5 Attempts to create and maintain a long-standing aversion to the plants to prevent ingestion of them and allow grazing of infested pastures have encountered disabling difficulties.6 Long-term administration of carbachol and supplementation of the diet with salt also have no value as control measures.3

GLUCOSINOLATE POISONING

Synopsis

Etiology Glucosinolates in Brassica spp. and related plants used as fodder.

Epidemiology Outbreaks in cattle grazing fodder crop or fed crop by-products, especially cake or meal made from residues of oil extraction from seeds.

Clinical signs Two syndromes — goiter and reduced growth rates, or diarrhea, depending on the chemical composition of the glucosinolate.

Clinical pathology Assay of blood levels of glucosinolate or metabolic end-products.

Necropsy findings Goiter.

Diagnostic confirmation Positive blood assay of glucosinolate.

Treatment Primary: Nil. Supportive: symptomatic.

Control Avoid toxic plants, meals.
ETIOLOGY
Glucosinolates are organic substances containing a sulfonated oxime group, combined with glucose in the form of glycosides. The metabolic by-products include isothiocyanates, nitriles, oxazolidinethiones, and carbinols. These plants also contain thiglucosidase (myrosinase), the enzyme needed to hydrolyze the glucosinolate to glucose and the toxic radical. Although the toxic substances may be excreted in cows’ milk, the observed goitrogenic effect when the milk is fed may be due to the low iodine content of the milk.

A special group, mustard oil glucosinolates, occurs in the foliage of some plants and is concentrated in their seeds and the seeds of some of the others. Plant sources of glucosinolates are mostly from the family Brassicaceae (Cruciferae) as listed in Table 33.1.

EPIDEMIOLOGY
Occurrence
Outbreaks of glucosinolate poisoning are common wherever intensive animal husbandry is practiced, especially where plant wastes from the food industries are fed to livestock in feedlots.

Risk factors
Plant factors
Plants in several uncommon botanical families contain glucosinolates, but animal poisoning is largely limited to the agriculturally important members of the Brassicaceae (Cruciferae) family, all members of which contain these substances. The common fodder plants and commercial vegetables listed in Table 33.1 have all been associated with poisoning. Seed oil crops, such as seed rape and mustard seed, may be fed as roughage after the seed has been harvested, and represent a possible source of poison. Large quantities of seed also become available for animal feed, and because of the large quantity fed may be associated with the enteric form of the disease. Glucosinolates are present in the vegetative parts of these plants but are in much higher concentration in the seeds. The glucosinolate concentration varies widely between species of plants, e.g., *Brassica napus* is much more goitrogenic than *B. campestris*, and even between cultivars of the same species at different times of the year and under different conditions of growth. Including the rapeseed in ensilage does not reduce its goitrogenicity. Plant stress, including drought and overcrowding of plants, and the feeding of high sulfate diets are known to increase the concentration of the toxin, and small young leaves may contain as much as five times more glucosinolate than large, mature leaves. The high content of sulfate and glucosinolates in cabbages makes it a damaging feed. The commonest and most serious cases of poisoning occur in animals fed rapeseed or rapeseed meal. Diets containing as low as 3% of rapeseed meal may be associated with goiter and reduced weight gain in pigs. The meal is often fed in amounts up to 20% of the diet. An extensive plant-breeding program has produced varieties of seed rape that have very low concentrations of glucosinolate.

PATHOGENESIS
Glucosinolates are organic substances containing a sulfonated oxime group, which, when taken in small amounts over long periods, is a goitrogen. It is likely to be associated with goiter only when the iodine status of the diet is low. This substance reduces iodine capture by the thyroid gland and the condition can be alleviated by the administration of iodine (see also cyanogenic glycoside poisoning). Glucosinolates producing principally isothiocyanates – some of these (e.g., allyl-isothiocyanate, 3-butenyl isothiocyanate) are the irritant components of mustard oils, contained in plant seeds, and are irritant to alimentary tract mucosa causing gastroenteritis, diarrhea, and dysentery. Others, present in the leaves of the plants, are hydrolyzed further to form thiocyanate ion. Glucosinolates producing principally thiocyanate ion, which, when taken in small amounts over long periods, is a goitrogen. They interfere with the synthesis of thyroxin, and iodine is ineffective in the treatment of the poisoning. Clinically, the effects of low levels of goitrogenic substances include goiter and a reduced growth rate in the young, and possibly an indirect, depressing effect on reproduction in adults. The reduction in growth rate may be due to the observed hypothyroiditis but there is, in addition, a reduction in palatability with diets containing high levels of glucosinolates. This effect is most noticeable in young pigs but may also be evident in high-producing cows. Polioencephalomalacia – there is a positive correlation between cruciferous plants (*Brassica* spp.) and polioencephalomalacia in ruminants, e.g., in rape blindness, but the brain lesion is probably associated with the high sulfur content of the plant.

NB: The taxonomy of the *Brassica* spp. varies between countries.
Tainting of milk occurs in cows fed plants, more commonly plant seed by-products, containing glucosinolates. The odor and off-flavor are due to volatile thiocyanates and not to isothiocyanates. Treatment of the feed with caustic soda prevents the tainting. Tainting of chicken with violent diarrhea, sometimes dysentery, usually occurs but may take several weeks. After animals have access to large amounts of seeds. The rape blindness is increased three-fold, due to poor vigor and plant by-products known to contain glucosinolates. The clinical pathology of goiter, weight loss or failure to gain weight. In bad outbreaks the thyroid is enlarged by 50% in most lambs, with more than 10% showing gross enlargement. Affected flocks have longer than usual gestation periods and lamb mortality is increased three-fold, due to poor vigor of the lambs.

Enteritis
Abdominal pain, salivation, vomiting in some cases, diarrhea, dysentery, and a short course with a fatal outcome is common after animals have access to large amounts of reject seeds of these plants.

Polioencephalomalacia (rape blindness)
Frank polioencephalomalacia, characterized by blindness, head pressing, aimless walking, ataxia, and recumbency, occurs in cattle, and rape blindness is manifested by the sudden appearance of blindness in cattle and sheep grazing these crops. The eyes are normal on ophthalmoscopic examination; the pupils show some response to light and may or may not be dilated. Complete recovery usually occurs but may take several weeks.

Acute pulmonary emphysema and interstitial pneumonia
This has been observed only in cattle. Affected animals show severe dyspnea, with stertorous rapid respiration, mouth breathing, and subcutaneous emphysema.

The temperature may or may not be elevated. Affected animals may survive but often remain chronically affected and do poorly.

Other unrelated diseases

Digestive disturbances in steers on rape are usually accompanied by anorexia, the passage of small amounts of feces, absence of ruminal sounds, and the presence of a solid, doughy mass in the rumen. Only a small quantity of sticky, black material is present on rectal examination. Photosensitization and bloat are also encountered in cattle grazing rape.

CLINICAL PATHOLOGY
The clinical pathology of goiter, weight loss, diarrhea, and dysentery are included in the articles on those diseases. Assays of blood levels of glucosinolates and their metabolite products are available. The diet and the pastoral environment should be examined for the presence of the plants and plant by-products known to contain glucosinolates.

NECROPSY FINDINGS
The goiter, enteritis, pulmonary emphysema, and interstitial pneumonia are non-specific and dealt with at other points in the text. In Thlaspi arvense poisoning there may be massive edema of the forestomach walls.

Differential diagnosis
Diagnostic confirmation is detection of glucosinolates in the blood of animals with access to relevant plants or feedstuffs made from them.

Differential diagnosis list:
Goiter:
- Nutritional deficiency of iodine
- A low-level but continuous intake of cyanogenic glucosides in, e.g., pasture plants such as Cynodon aethiopicus, C. niliuenfusis (couch grasses), and Trifolium repent (white clover)
- Inherited goiter.

Diarrhea with or without dysentery. There are many infections and toxins associated with diarrhea and dysentery. Those most commonly associated with outbreaks include:
- Arsenic poisoning
- Salmonellosis
- Other poisonous plants in which the toxin has not been identified.

TREATMENT
Primary
There are no specific treatments.

Supportive
Attention should be directed at relieving the clinical signs.

CONTROL
Avoidance of losses can be best achieved by avoiding the use of the poisonous substance or the grazing of the affected area. Some of the goiters can be relieved by the administration of iodine (see under nutritional deficiency of iodine), and avoidance of high sulfate diets reduces the level of glucosinolate production. Plant by-products containing glucosinolate derivatives can be treated with alkali solutions to destroy their toxicity.

INDOLE ALKALOID POISONING
A large number of indole alkaloids occur in fungi, especially the Claviceps and Acremonium spp. In plants there are also some groups of toxins with similar toxic effects, and similar to those of the fungi. The important two are the β-carbolines and the dimethyltryptamines; and then there are hydroxymethyltryptamines, and a miscellaneous group of alstonine and related toxins. Plants included in the latter group and which are associated with an incoordination syndrome like phalaris staggers are Gelsemium sempervirens (yellow jessamine), Alstonia constricta (bitter bark tree) and the mushroom Psilocybe spp (mad or magic mushroom). Pto hueca, Urtica spp. (stinging nettle) are associated with a more acute syndrome of convulsions and sudden death. Phalaris spp. are unusual in that they contain both β-carbolines and methylated tryptamines. Related indole alkaloids of the pyroli- dinoindoamine type have poisoned livestock in Australia (idiopermin in Isolparvatum aurantiense) and North America (calycanthine in Calycanthus spp.), producing tetanic convulsions.

β-CARBOLINE INDOLEAMINE
ALKALOID POISONING
There is a long list of carbolines in plants, including harmaline, norharmane, tetra-hydronorharmane, harmine, harmol, and 3-methyl harmine. Administration of synthetic forms of these compounds is associated with the appearance of clinical symptoms.
signs identical with those occurring in poisonings with *Peganum harmala* (African or Turkish rue), *Peg. mexicana* (Mexican rue), *Phalaris* spp., *Tribulus terrestris* (caltrop, catsead burl), *T. micrococcus* (yellow vine), *Kallstroemia hispersisima* (hairy caltrop, carpet weed) and *K. parviflora*. The characteristic syndrome, similar to that of an upper motor neuron lesion, includes hyper- or hypomotility, sometimes sequentially in the same patient, muscle tremor, partly flexed paresis of the thoracic and/or the pelvic limb, hypermetria, a wide-based stance, crossing of the limbs, extension of the neck, swaying of the head, walking backwards, sudden jumping movements, sham eating, and terminal convulsions. The net effect, seen in all farm animal species and camels, is one of easy stimulation, by harassment, of gait incoordination and stumbling, fetlock knuckling, easy falling, and recumbency. The signs appear gradually, are similar to, but less severe than, those associated with the methylated tryptamines and are irreversible. There is axonal degeneration in peripheral nerves. Long-term cases of *T. terrestris* poisoning pivot on their front limbs while their hindlimbs trace a circle. The pivoting is related to the unilateral muscle atrophy of limbs of one or other side.

**DIMETHYLTRYPTAMINE AND PHENYLETHYLAMINE POISONING**

**Synopsis**

**Etiology** Associated with the ingestion of the *Phalaris* spp. grasses containing dimethyltryptamine (causing an incoordination syndrome), phenylethylamines (causing a cardiac arrest-sudden death syndrome), a thiamine analog (causing a polioencephalomalacia).

**Epidemiology** Outbreaks on lush, rapidly growing pasture; sheep most commonly affected.

**Clinical findings** Incoordination, later convulsions in sheep. In cattle also incoordination of tongue and pharynx. Sudden death cases have very brief course with little to observe.

**Clinical pathology** Isolation of tryptamines in plants and affected animals.

**Necropsy lesions** Green-gray discoloration of renal medulla, medulla oblongata, brain stem.

**Diagnostic confirmation** By detection of tryptamines in body fluids or cadaver.

**Treatment** Nil.

**Control** Limitation of access to causative plants.

**ETIOLOGY**

The incoordination syndrome is associated with dimethyltryptamines in:

- *P. arundinacea* – reed canary grass
- *P. caroliniana*
- *P. brachystachys*
- *P. canariensis* – common canary grass
- *P. minor* – wild canary grass
- *P. paradoxa* – paradoxa grass and *Rhompha grass* (a hybrid).

Acute death due to cardiac arrest, originally ascribed to the methylated tryptamines, is now thought to be the related phenylethylamines, and the sudden death-polioencephalomalacia to thiamin analogs produced by the ruminal flora.

**EPIDEMIOLOGY**

**Occurrence**

The disease has been recorded in many parts of Australia, New Zealand, South Africa, Spain, California, and South America where the *phalaris* grasses are in common use as pasture plants. Heavy losses occur on individual farms due to sudden deaths, but careful management relieves the burden of the incoordination syndrome.

**Risk factors**

**Plant factors**

The individual tryptamine alkaloids associated with the disease vary significantly in their toxicity so that plants in a pasture can vary greatly in the danger they present. The concentration of tryptamines in the grass is increased by high environmental temperature and their growing in the shade, and toxicity is greatest when the plants are young and growing rapidly, especially after a break in a dry season. Provision of cobalt appears to stimulate the proliferation in the rumen of microorganisms which are capable of destroying the causative agent, but sheep affected with *phalaris* staggerers do not usually show any signs of cobalt deficiency. Under some circumstances, plants with low tryptamine content will be associated with the syndrome.

**Animal factors**

Up to 30% of a flock may be affected when the *P. aquatica* dominates the pasture or is preferentially grazed. On lightly stocked pastures the sudden death syndrome, with signs appearing within 4 hours but usually between 12 and 72 hours after going onto the pasture, is most likely to occur. Deaths are most common in hungry sheep in the early morning or in foggy or cloudy weather. This syndrome is also recorded in cattle on irrigated *Phalaris* spp. pasture in hot humid weather.

The incoordination syndrome occurs in similar circumstances, but in sheep that have prostrated or repeated exposure. In this case, clinical signs appear 2–3 weeks after sheep are put onto pasture showing new growth, usually in the autumn or early winter. Both forms may occur in the one flock of sheep, and also in feedlots. Sheep of all ages are affected and mild cases may occur among cattle.

**PATHOGENESIS**

The tryptamines, structurally similar to serotonin, are present in the grass under certain conditions and are associated with the incoordination syndrome by a direct action on serotonergic receptors in specific brain and spinal cord nuclei. By interfering with the functions of serotonin, a chemical transmitter in the autonomic nervous system with functions analogous to those of acetylcholine, the alkaloids are associated with both neurological signs and the cardiac abnormalities of tachycardia and ventricular block. The nervous disturbances of the incoordination syndrome are the direct result of dimethyltryptamine, and the cardiorespiratory disorder by phenylethylamine. The nervous disturbance appears to be functional in contrast to that associated with β-carbolines, which is accompanied by axonal degeneration and an irreversible syndrome. The nervous signs are probably tremorgenic, rather than convulsive, so that the limb movements observed are the result of the patient attempting to regain its feet rather than a centrally mediated convolution.

A characteristic of the disease is a greenish-gray discoloration of the brain stem, diencephalon and dorsal root ganglia, and kidneys. The pigmentation is due to the accumulation of indole-like pigments at the locations where the causative alkaloids act, but the pigments themselves do not have any effect on the signs.

The variability in the numbers affected and the severity of the disability in sheep flocks from day to day appear to be due to the variation in the amount of toxin absorbed, possibly affected by the degree of detoxication of the tryptamines in the rumen. The reduction in severity of an outbreak associated with dietary supplementation with cobalt is thought to be effected in this way.

**CLINICAL FINDINGS**

The sudden cardiac death syndrome is manifested by sudden collapse, especially when excited, a short period of respiratory distress with cyanosis, and then death or rapid recovery. During the stage of collapse there is arrhythmic tachycardia followed by ventricular fibrillation and cardiac arrest. Consciousness is retained.

The sudden death-polioencephalomalacia syndrome cases are rarely observed alive, but occur commonly after short periods of feed deprivation.

In the initial stages of the incoordination syndrome in sheep, signs appear only when the animals are disturbed. Hyperexcitability and generalized muscle...
tremor, including nodding of the head, occur first. On moving, the limb movements are stiff and the hocks are not bent, causing dragging of the hind feet. Incoordination and swaying of the hind-quarters follow. Some cases walk on their knees, others bound or hop, others knuckle at the fetlocks; some show spaying of the digits. In the most severe cases collapse into lateral recumbency is accompanied by paddling movements of the legs and irregular involuntary movements of the eyeballs. There is rapid respiration and irregular tachycardia. The sheep may die at this stage but if left undisturbed they may recover and walk away apparently unaffected. If the sheep are left on the pasture the condition worsens in individual cases, the animal becoming recumbent and manifesting repeated convulsive episodes until death supervenes.

There is a great deal of variation from day to day in the number of sheep showing signs and in the severity of the signs observed. Even after sheep are removed from the pasture the clinical state may deteriorate and, although some appear to recover, clinical signs can usually be elicited by forcing them to exercise. Deaths are reported to continue for 1 week after removal of sheep from toxic pasture and clinical signs of the nervous form of the disease may persist for as long as 2 months. The extraordinary situation is recorded where new cases continue to occur for as long as 12 weeks after sheep are moved onto pasture that contains no Phalaris spp.

In cattle, the signs may be restricted to stiffness of the hocks and dragging of the hind toes, but severe cases similar to the common syndrome in sheep also occur. Additional, and more common, signs observed in cattle include an extraordinary incoordination of the tongue and lips in prehension so that the hungry animal, trying desperately to eat, can only prehend a few stalks of grass at a time. The jaw movements are quite strong but the tongue stabs and darts, and lacks the sinuous curling movements normally present. There may also be an inability to put the muzzle to the ground so that prehension can only be effected from a raised manger or hayrack. Affected cattle are often hyperexcitable and difficult to handle.

**CLINICAL PATHOLOGY**

Laboratory tests on antemortem material can detect the presence of the causative tryptamines in plant material but are unlikely to be generally available.

**NECROPSY FINDINGS**

Other than the characteristic green-gray pigmentations of tissues in the renal medulla, brain stem, midbrain and dorsal root ganglia, gross lesions are absent. Degeneration of spinal cord tracts and of the ventral portion of the cerebellum has been observed in terminal cases of the incoordination syndrome, but is not a consistent finding. In the sudden death or cardiac syndrome sheep are usually found dead on their sides with their heads strongly dorsiflexed and legs rigidly extended. Some sheep have blood-stained nasal discharges and many have been frothing at the mouth. Abdominal visceral congestion, epicardial and duodenal hemorrhages are present and indicate acute heart failure. Polioencephalomalacia is characteristic of the sudden-death-polioencephalomalacia syndrome.

**DIFFERENTIAL DIAGNOSIS**

The association between the nervous disease and the plants should suggest the diagnosis. The appearance of these signs only on exercise is significant, suggesting a functional rather than a physical lesion. Diagnostic confirmation rests on the identification of the causative tryptamines in the feed materials and the tissues and fluids on antemortem or postmortem examination. Differential diagnosis lists for the incoordination syndrome:

- Faspalum staggerers
- Ryegrass staggerers
- Floodplain staggerers (tunicaminylarasil poisoning)
- Poisoning associated with marshmallow, stagger weed, and other plants produces a very similar syndrome and the diagnosis must depend on the identification of the toxic plant.

For the sudden death syndrome:

- Annual ryegrass toxicity
- Cyanogenic glycoside poisoning
- Nitrite poisoning.

For the sudden-death-polioencephalomalacia syndrome is as for polioencephalomalacia.

**TREATMENT**

Flocks of affected sheep should be removed immediately from the toxic pasture. There is no specific antidotal treatment.

**CONTROL**

No preventive measures are available against the sudden death syndrome, but the nervous form can often be prevented by the oral administration of cobalt. Affected pastures may be grazed if sheep are dosed with cobalt (at least 28 mg per week) at intervals of not more than 1 week, or if alternative grazing is provided in rotation. Dosing at too long intervals or with inadequate amounts may account for some failures in prevention. The parenteral administration of cobalt or vitamin B12 is not effective. The additional cobalt can be provided by drenching the sheep individually or spreading it on the pasture mixed with fertilizer as described under cobalt deficiency. Unfortunately, the genetic selection of *P. aquatica* cultivars with low contents of methylated tryptamines favors a significant increase in toxic β-carbolines.

**REVIEW LITERATURE**

**REFERENCES**

**INDOLIZIDINE ALKALOID POISONING**

The two indolizidine alkaloids of plant origin are swainsonine and castanospermine both of them affecting cellular enzymic activity. Slaframine is a mycotoxin in this group.

**SWAINSONINE POISONING**

**Synopsis**

**Etiology** Poisoning by *Astragalus, Oxytropis, Swainsona* spp. is associated with induced mannosidosis.

**Epidemiology** Grazing toxic plants for 2–6 weeks is associated with signs, reversible if pasture changed.

**Clinical signs** Incoordination, paresis, star-gazing posture.

**Clinical pathology** Urine content of mannose-containing oligosaccharides elevated.

**Necropsy findings** Vacuolation of neurones.

**Diagnostic confirmation** Swainsonine can be detected in animal tissues or fluids, but the tests are not widely available.

**ETIOLOGY**

Swainsonine is an indolizidine alkaloid found in *Astragalus, Oxytropis* and *Swainsona* spp., and some *Iponoea* spp. plants. Ingestion of the toxic plants over a long period is associated with an induced lysosomal storage disease in all animal species. The common plants in which the alkaloid’s presence has been identified are:

- *Swainsona galegifolia*, *S. brachycarpa*, *S. canescens*, *S. grayana*, *S. luteola*, *S. procumbens*, *S. swainsonoides* *Astragalus lentiginosus*, *A. emoryanus*.

Plants of this genus that are associated with a similar disease, and in which the presence of swainsonine is assumed, are *A. mollissimus*, *A. norhxicys*, *A. lentiginosus var. wahpeapensis*, *A. lusitanicus*, *A. wootoni*, *A.thurberi* *Oxytropis sericea*, *O. ochrocephala*.

Plants of this genus that are associated
with a similar disease, and in which the presence of swainsonine is assumed, are *O. besseyi*, *O. condensata*, *O. lambertii*, *O. puberula*.

Swainsonine is synthesized by the fungus *Rhizoctonia leguminicola*, but the disease associated with this fungus is due to its slaframine content.

**Epidemiology**

The disease is most common in North America (as locoism associated with *Astragalus* and *Oxytropis* spp.) and in Australia as Darling pea (*Swainsona* spp.) poisoning, but *Oxytropis* spp. have been associated with poisoning in China. Grazing animals must ingest the plants for at least 2 weeks, more usually 6 weeks, before clinical signs appear. Addiction to these plants, in preference to other available pasture is generally accepted but there is no initial preference for or subsequent addiction to *A. lentiginosus*.

All grazing animal species are affected, and experimental administration of the alkaloid to monogastric, farm, and laboratory animals is associated with the typical neuronal lesions. The death rate need not be high if access to the source plants ceases.

**Pathogenesis**

Swainsonine is a specific inhibitor of lysosomal α-mannosidase causing accumulation of mannose in lysosomes and thus widespread neurovisceral cytoplasmic vacuolation. The vacuoles are accumulations of mannose-rich oligosaccharides, including abnormal glycoproteins. Vacuolation reaches its greatest intensity in the central nervous system and this is probably related to the predominance of nervous signs in the disease. Vacuolation of the chorionic epithelium may be related to the occurrence of abortion, and a transient infertlity suspected in rams to the lesion appears quickly and is reversible if the swainsonine intake ceases. There is no information available about the mechanism by which the accumulated oligosaccharide causes the nervous dysfunction which characterizes the disease. The lesions and clinical syndrome are identical with those in the inherited mannosidoses in cattle and goats except that fetal deformity and abortion occur in the poisoning. The mechanisms for those occurrences are also unknown, although there appears to be a direct link with the combined maternal and fetal mannosidosis.

**Clinical Signs**

After several weeks of grazing affected pasture adult animals begin to lose condition and young animals cease to grow.

The appetite is diminished and the coat becomes dull and harsh. Several weeks later nervous signs of depression, gait incoordination, muscle tremor, difficulty in rising, in eating and drinking become apparent. Sheep commonly adopt a 'star-gazing' posture, and horses may show ventroflexion of the head and rearing over backwards if handled. Cases may become exacerbated if harressed. Recovery is likely if the animal is removed from the source of the toxin soon after signs appear. Recovery may be complete or there may be a residual gait incoordination if the animal is excited. Advanced cases may show no improvement and others become recumbent and die. Calves at high altitudes and fed *A. lentiginosus* or *O. sericea* develop a higher incidence of congestive heart failure than calves not fed on the plants.

Pregnant ewes ingesting *Astragalus* spp. plants may abort or produce abnormal offspring. The defects take the form of small, edematicous or dead fetuses or skeletal deformity. There are no such abnormalities recorded with *Swainsona* spp.

**Clinical Pathology**

Vacuolation in circulating lymphocytes occurs in poisoning due to *Swainsona* spp., and may have diagnostic significance. Serum levels of α-mannosidase are significantly reduced and swainsonine levels increased. Swainsonine levels reflect the amount being ingested and not the duration of exposure, and quickly return to normal when ingestion of the plants ceases. The urine content of mannose-containing oligosaccharides is greatly increased during the period of intake of swainsonine.

**Necropsy Findings**

The characteristic microscopic lesion is fine vacuolation of the cytoplasm in neurons throughout the central nervous system. Similar vacuolation is present in cells of other organs, especially the kidney, and the fetus in animals poisoned by *Astragalus* spp. High blood and tissue levels of swainsonine are detectable, including in frozen material.

In aborted calves, lambs, and foals there is extensive vacuolation of the chorionic epithelial cells. The skeletal deformities include arthrogryposis and rotation of the limbs about their long axis.

**Treatment**

Removal of the affected animals from access to source plants may result in partial or complete recovery, provided the cases are not too advanced.

**Control**

Pregnant animals should not be exposed to sources of swainsonine, but other stock may be grazed on the plant without ill effect for short, specified periods, namely 4 weeks for sheep and cattle, and 2 weeks for horses. Attempts to reduce consumption of the toxic plants by creating conditioned reflex aversion, to reduce absorption of ingested swainsonine, or by supplementing the diet with bentonite, have not been rewarding.

**Castanospermine Poisoning**

Found in the seeds of *Castanospernum australe* (Moreton Bay chestnut), castanospermine inhibits mononuclear cell α-glucosidase activity so that affected cattle have been misdiagnosed as heterozygotes for generalized glycogen storage type II (Pompe's disease). The seeds are also associated with hemorrhagic gastroenteritis if eaten in large quantities, causing the passage of bloody diarrhea but the cause, originally thought to be saponins, is unknown.

**Review Literature**

DITERPENE ACIDS AND VASOACTIVE LIPOSIDS

Phytotoxic abortion, in which serum progesterone levels of the patient are reduced by the effects of the ingested agent, is associated with the ingestion of *Pinus ponderosa* (yellow pine), *P. cebensis*, *P. radiata*, *Cupressus macrocarpa* (Monterey cypress), *Cupressus sempervirens*, and *Cupressocyparis leylandii* (Leyland cypress). These plants are associated with abortion in cows, but not ewes. Poisoning is most likely to occur when cattle graze amongst the trees and have access to the wilted foliage on lopped or broken branches. Denial of access to pasture by heavy snowfalls may force intense browsing of trees. The fetus in cases of poisoning by *Cupressus* spp. has a typical leukoecephalomalacia.

ETIOLOGY

Nitrocompounds (nitrotoxins) poisonous to animals occur in a number of plants, especially *Astragalus* spp. They are all glycosides of 3-nitro-1-propionic acid (NPA), or of 3-nitro-1-propanol (NPOH). The only common one is miserotoxin. The best known occurrences of the nitrocompounds are:

- Miserotoxin in *Astragalus canadensis*, *A. emoryanus*, *A. miser*, *A. pterocarpus*, *A. tetrapetala*, and others.
- Karakin in *Corynocarpus laevigatus* (karaka tree).
- Oxytropis spp., a plant genus very similar botanically to *Astragalus* spp., is associated with the same diseases as the latter but its toxic agent has not been identified.
- *Coronilla varia* also contains a nitrocompound.
- *Indigofera linnaei* (Birdsville indigo), also contains karakin and other nitrocompounds.

EPIDEMIOLOGY

Occurrence

The occurrence of these plant poisonings is determined by the presence and ingestion of the specific plants. *Astragalus* and *Oxytropis* spp. are, for the most part, limited in distribution to North America, but poisoning of sheep by *A. lusitanicus* is recorded in Morocco, and of all species by *Oxytropis puberula* in Kazakhstan. *Corynocarpus* spp. occur in New Zealand and *Indigofera* spp. are widespread, occurring in North America, Australia, Africa, and Southeast Asia.

Risk factors

Plant factors

*Astragalus* and *Oxytropis* spp. are herbaceous legumes, most of them perennial, and they dominate the desert range over large areas of the United States. They provide excellent forage. Only some species contain miserotoxin, but this makes them very destructive and very heavy losses of sheep and cattle may occur.

Animal factors

Cattle are the more susceptible. Lactating animals are more susceptible than dry. There are reports of the disease in horses in North America, and a similar disease in horses in China after grazing *Oxytropis kansuensis*.

Importance

Miserotoxin and its metabolic end-products may be excreted in the milk of cows eating these plants.

PATHOGENESIS

In ruminants the glycosides are hydrolyzed in the rumen to NPOH and NPA. Both are absorbed from the rumen. NPOH is converted in the liver to NPA. NPA may be metabolized to nitrite, and acute poisoning is characterized by signs and necropsy lesions of nitrite poisoning.

Chronic poisoning is associated with the accumulation of NPA and a resulting syndrome, characterized principally by nervous signs and the development of degenerative lesions in the central nervous system. In experimental animals the dose rate and length of exposure to the toxin determine whether the acute or chronic disease occurs.

CLINICAL FINDINGS

Acute poisoning

The syndrome of dyspnea, tremor, and sudden death is characteristic of nitrite poisoning. Death may occur as soon as 3 hours after the commencement of signs but the course is more commonly about 24 hours.

Chronic poisoning

Affected animals lose weight, and develop a poor hair coat, nasal discharge, and poor exercise tolerance. Respiratory distress, with loud stertor (roaring), is more marked in sheep than in cattle and knuckling of the fetlocks and incoordination, followed in some by paraplegia, is more common in cattle. Temporary blindness and drooling of saliva may also be evident. The mortality rate is very high, the course lasting over several months. Animals that recover have a long convalescence. Death may occur suddenly if affected animals are stressed.

*Indigofera linnaei* poisoning in horses (synonym Birdsville horse disease) is associated with weight loss, gait incoordination, easy falling, toe dragging, dyspnea, and convulsions. The plant is equally poisonous when dry or green, although most cases occur in the spring when the plant is succulent. Horses need to graze the plant for about 10 days before signs appear. Characteristic signs include segregation and somnolence, the animal often standing out in the open in the hot sun, apparently asleep, when unaffected horses are frantically but stay in the one place.

PATHOGENESIS

In ruminants the glycosides are hydrolyzed in the rumen to NPOH and NPA. Both are absorbed from the rumen. NPOH is converted in the liver to NPA. NPA may be metabolized to nitrite, and acute poisoning is characterized by signs and necropsy lesions of nitrite poisoning.

Chronic poisoning is associated with the accumulation of NPA and a resulting syndrome, characterized principally by nervous signs and the development of degenerative lesions in the central nervous system. In experimental animals the dose rate and length of exposure to the toxin determine whether the acute or chronic disease occurs.
A chronic syndrome may develop in some horses subsequent to an acute attack. Affected animals can move about but there is incoordination and dragging of the hind feet with wearing of the toe and inspiratory dyspnea (roaring) may also occur. No lesions have been described in the nervous system of affected animals. L. limnaei contains the toxic amino acid, indospicine, an analog of arginine, but poisoned horses do not develop the liver damage typical of intoxication by indospicine. However, supplementation of the diet with arginine-rich protein feeds prevents development of the disease. Peanut meal (0.5-1 kg/day) and gelatin provide readily available and cheap sources of arginine.

CLINICAL PATHOLOGY
Laboratory findings related to the methemoglobinemia of nitrite poisoning are discussed under nitrite poisoning. Laboratory procedures for the determination of blood levels of miserotoxin and NPOH and NPA are available.

NECROPSY FINDINGS
Brown discoloration of the blood, and extensive petechiation in tissues, are common findings in the acute form of the disease. In the chronic disease there are degenerative changes in the spinal cord and peripheral nerves, especially the sciatic nerve. Gross lesions include pulmonary edema and pneumonia.

DIFFERENTIAL DIAGNOSIS
The differentiation of association with nitrite poisoning is discussed under that heading. The syndrome of a chronic course, dyspnea, and incoordination, with or without paraplegia, is also common. Diagnosis confirmation depends on the identification of the poisonous plants in the environment and the toxins in the plants and animal tissues.

Differential diagnosis list (chronic form)
- Phalaris staggers
- Ryegrass staggers
- Paspalum staggers
- Chronic cyanide poisoning

TREATMENT
Primary treatment for acute poisoning is described under nitrite poisoning. There is no treatment for the chronic form of the disease, although some cases may recover spontaneously after a recovery period of several months.

CONTROL
Control of the growth of the plants by stimulating growth of competitive grasses, or the widespread use of selective herbicides, is recommended but unlikely to be a practicable procedure in many of the situations in which the plants occur. Experimentally, the use of some herbicides significantly reduces the content of miserotoxin in A. miser var. oblongifolia in pasture. Variations between species of Astragalus spp. in their capacity to produce miserotoxin and store selenocompounds (some of them, e.g. A. tomas, do both) provides opportunities to manipulate the grazing of particular fields to best advantage.

REFERENCES

EPIDEMIOLOGY
Occurrence
Animals at pasture are at the greatest risk but poisoning can also occur on diets containing prepared feeds such as soybean (Glycine max) meal, or moldy feed containing Fusarium roseum.

Risk factors
Plant factors
The estrogenic activity of pastures depends on the degree of domination of the pasture by the toxic plants, the variety of the plant species, and the duration of the animal's exposure to them. Newly sown pastures are usually most toxic because of domination by the sown legume. Pastures deficient in phosphorus are also likely to be clover-dominant. High nitrogen fertilizer applications reduce phytoestrogen content. Varieties of Trifolium subterraneum, e.g. Yarloop, Dwalganup, Dinninup and Geraldton, are more toxic than Bacchus Marsh and Dallak. Pastures containing more than 30% of the first four varieties are likely to be unsafe. In some clodgers, e.g. red clover, the estrogen content varies with the season, being high in early spring, low in midsummer, and high again in the autumn, after the hay has been taken off. Insect damage to pasture can increase its estrogen content 10-fold, bacterial infection, e.g. by Pseudepoezia medicaginis, a leaf-spotting organism on alfalfa, and fungal infection can increase it 100-fold. Plants that have matured in the field and set seed have no estrogenic potency, but
the making of potent fodder into hay causes little depression of estrogen content. Clover ensilage can contain high levels of estrogens and the ensiling process is considered to increase the estrogenic effect of clover three- to fivefold.

*Trifolium repens* (white clover, in contradistinction to Ladino clover), does not have a high content of estrogens. However, when heavily infested with fungi it can contain significant amounts. It is believed that the production of estrogens is a by-product of the plant’s mechanism of resistance to the fungal infection. Ladino clover, a large-growing variety of white clover, may contain large quantities of a highly active estrogen (coumestrol), and when it dominates a pasture and is grazed when the pasture is lush, it may be associated with the cornification of vaginal epithelium and functional infertility in ewes. Three estrogenic compounds have been isolated from *T. pratense* (red clover), and where this plant dominates the pasture a clinical syndrome similar to that associated with subterranean clover may be observed. Ewes grazing on red clover pasture, especially a toxic cultivar of the plant, may have their conception rate at the first mating cycle reduced from 75% to as low as 25%.

Animal factors

Sheep eating a lot of estrogenic clover in the spring can become temporarily infertile, but are normally fertile again by the usual breeding season in the autumn. However, ingestion of the plant in several successive years is associated with ‘permanent clover disease’ – infertility from which ewes do not recover. The disease is important only in sheep. Cattle are generally considered to be unaffected but the subject is still a controversial one with the weight of evidence against cattle being affected. For example, cows can ingest large amounts of estrogens (over 40 g/day/cow) in red clover without showing any reduction in reproductive efficiency. Horses usually graze the toxic pasture without ill-effects.

Importance

Massive reproductive wastage has been experienced in sheep on pastures dominated by such plants as *Trifolium subterraneum*, and the death rate due to dystocia and prolapse of the uterus can also be high. The most commonly observed abnormality is a failure to conceive, even with multiple matings, and the flock breeding status worsens progressively, with the lambing percentage falling from a normal 80% down to 30%. Under these conditions sheep farming becomes unprofitable and large areas of country have been made unsuitable for sheep-raising by this disease.

**PATHOGENESIS**

Much of the metabolism of phytoestrogens in ruminants occurs in the rumen, as well as in the liver. The differences between sheep and cattle in the ruminal metabolism of these compounds are thought to be the reason for the comparative freedom of cattle from the clinical disease.

The amount of phytoestrogen ingested by a ewe on a highly poisonous pasture may equal her daily estrogen secretion at the peak of her estrus cycle. The effect of the phytoestrogens is exerted mainly on the uterus and ovaries. Structurally, there is hyperplasia and hypertrophy of the epithelium of the uterus, vagina, and cervix, and dysplasia of the granulosa cells of the ovary, with a consequent reduction in secretion of estradiol. Increases in test size and milk secretion are additional, secondary effects.

The functional abnormality is not one of estrus, in sheep the demonstration and duration of estrus may be normal or depressed, and the defect is one of sperm transport due to changes in the composition of cervical mucus, and the structure of cervical glands. The change is to more watery mucus and this is the basis of a test in affected sheep in which the watery mucus is more readily absorbed by a cottonwood plug inserted in the vagina. The increased weight of the plug is a positive test.

It is possible that a good deal of the infertility seen in ewes on improved clover pasture may be associated with its high estrogen content, in spite of the absence of the more dramatic evidence of hyperestrogenism described above. Because of the necessity to utilize this pasture, a great deal more needs to be known about the seasonal occurrence of the estrogenic substances and the management of sheep grazing the pasture so that the effects of the disease can be minimized.

Another syndrome associated with subterranean clover and unrelated to the infertility syndrome is that of obstructive urolithiasis in sheep, discussed under that heading. This disease occurs in outbreaks in spring in Merino wethers grazing estrogenic strains of the clover. As the isoflavone concentrations in the plants rise, the daily excretion of phenols and acid-precipitable material in the urine increases, so does the occurrence of obstruction by the characteristic soft yellow calculi containing benzocoumarins.

**CLINICAL FINDINGS**

Ewes

**Clover disease**, the severe clinical manifestation of the poisoning, and rarely seen today, includes dystocia, prolapse of the uterus or vagina, and severe infertility in ewes. Wethers show teat elongation, mammary gland and bulbourethral gland enlargement. Deaths occur in both groups. The more common, and less severe, field expression of phytoestrogen poisoning is a significant fall in fertility rate. The infertility may be temporary, normal reproductive efficiency returning soon after the ewes are moved to clover-free pasture.

In ewes exposed to a low level intake of estrogens over a long period, e.g. in excess of two grazing seasons, a process of irreversible ‘deformation’ may occur. This is a state of permanent subfertility. The estrus cycle is normal, the main problem being the failure of an abnormally large number of ewes to conceive.

In affected flocks there may also be a high incidence of maternal dystocia due to uterine inertia, or failure of the cervix or vagina to dilate. Affected ewes show little evidence of impending parturition and many full-term fetses are born dead.

Because of the similarity between this form of the disease and the disease ‘ringwomb’ in ewes in the UK, it has been suggested that the latter may be associated with an excessive intake of phytoestrogens. The mortality rate in lambs may be as high as 40%, and 15–20% of ewes may die of metritis and toxemia. Uterine prolapse may also occur in unbred and virgin ewes and immature ewes some months after lambing. The incidence of prolapse is usually 1–2% but may be as high as 12%. There is marked udder development and copious milk secretion in the ewes.

**Male castrates**

Wethers may also secrete milk, and metaplasia of the prostate and bulbourethral glands is evident. These can be detected at an early stage of development by digital rectal palpation. Continuing hyperplasia and cystic dilatation of these glands is associated with their prolapse in a subanal position, followed by rapid weight loss and fatal rupture of the bladder. Rams usually show no clinical abnormality and their fertility is not impaired.

Neither clover disease nor permanent subfertility occurs in cows. Temporary infertility, discharge of cervical mucus, and swelling of the mammary gland, the vulva, and uterus, have been recorded. Obstructive urolithiasis is described in Chapter 11.

**CLINICAL PATHOLOGY**

Laboratory assays of endocrine are available and essential to diagnosis and monitoring of feed contents of phytoestrogens. Chemical assays are not as sensitive as biological assessments based on increased size of genitalia in subject animals.

**NECROPSY FINDINGS**

In the worst cases there is severe cystic degeneration of the endometrium. Similar
clinical and histopathological changes have been produced by the daily injection of 0.03 mg of diethylstilbestrol per ewe for a period of 6 months. There is also a long-term change in the cervix with an increased incidence of cervicitis and a histologically observable transformation to a uterine-like appearance. In ewes on a long-term intake of toxic pasture, the lesions include elevation of the tail head, partial fusion of the vulvar labia, and iliotral hypertrophy.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation of phytoestrogen poisoning requires laboratory assay of feed, blood, and tissue, and the appearance of genital pathology at necropsy or via peritoneoscopy or uterine biopsy. Differential diagnosis list – the only other diagnoses of the distinctive hyperestrogenism syndrome of phytoestrogen poisoning are:

- Overdosing with a pharmaceutical preparation as part of a program to improve fertility in a herd
- Overdosing by implant or feed additive with a growth stimulant which has estrogenic capability.

TREATMENT
Administration of testosterone is a logical response to poisoning but appears to be an unlikely commercial proposition.

CONTROL
Avoidance of high estrogenic activity strains of the respective plants, grazing management to avoid dangerous pasture at the most toxic part of the season, dilution of the estrogen intake by providing additional, alternative feeds, are all used. Prevention of clover disease can only be achieved by proper management of sheep and pasture to avoid ingestion of excessive amounts of estrogens. Vaccination with a phytoestrogen-immunogenic protein conjugate has produced good levels of antibodies, but has not been successful in preventing the problem. Careful management of flocks on estrogenic pasture can significantly improve reproductive output.

PTAQUISOLID POISONING
Ptaquiloside is a carcinogen, found in the ferns Pteridium spp. (bracken), Cheilanthes sieberi and Onychium contiguum (fuh); the former two also contain thiaminas. In ruminants, two principal syndromes occur. Ingestion of the plants for 2–4 weeks is associated with hemorrhagic disease known widely as bracken poisoning, here referred to as osteomyelotoxic ptaquiloside poisoning to differentiate its bone marrow-damaging effects from its carcinogenic effects and to avoid the use of acute' ptaquiloside poisoning which is a misnomer. Ingestion of much smaller amounts of the ferns over a period of years is associated with bovine enzootic hematuria, the carcinogenic manifestation of ptaquiloside poisoning. Other well-known diseases associated with ptaquiloside are intestinal carcinomas of sheep and cattle, and bright blindness of sheep.

OSTEOMYELOTOXIC PTAQUISOLID POISONING (POISONING BY BRACKEN (PTERIDIUM SPP) AND MULGA OR ROCK FERN (CHEILANTHES SIEBERI))

Synopsis
Etiology Pteridium spp. (bracken), Cheilanthes sieberi (rock fern).
Epidemiology Most common in cattle grazing young fronds. Signs appear after 2 weeks on affected pasture.
Clinical findings High fever, severe diarrhoea, dysentery. Ecchymotic hemorrhages in mucosa.
Clinical pathology Depression of bone marrow activity with pancytopenia.
Necropsy findings Multiple hemorrhages plus bacterial invasion in all tissues.
Diagnostic confirmation Laboratory identification of ptaquiloside not generally available. Clinical signs and exposure to plant plus pancytopenia, low platelet count, abnormal bone marrow.
Treatment Blood transfusion.
Control Bracken eradication.

ETIOLOGY
Ptaquiloside (PT) is a norsesquiaperene glucoside of the illudane type found in some ferns and used to reproduce depression of the bone marrow, hematuria, bladder and bowel neoplasia, and retinal degeneration in experimental animals. Ferns known to contain ptaquiloside are Pteridium spp. (the bracken ferns), Cheilanthes sieberi (mulga fern or rock fern),1 possibly other Cheilanthes spp., and Onychium contiguum (fuh). The fern commonly called bracken is in fact several different species of Pteridium in various parts of the world, known toxic species of which are P. aquilinum in northern temperate countries, P. esculentum in Australia and New Zealand, and P. renulatum in northern Australia and Asia. All species should be regarded as toxic. Large amounts of the plants must be eaten before poisoning occurs. Other cytotoxins in bracken are queccretin, shikimate and cyclolhexanecarboxylate, but no relationship between them and animal disease has been established.2

EPIDEMIOLOGY
Occurrence
Bracken fern poisoning occurs in most countries as a sporadic disease. Although the losses are usually small because of the high intake of the fern required to produce illness, heavy mortalities have been observed in some outbreaks. Cheilanthes sieberi (mulga fern or rock fern) poisoning is confined to Australia.

Risk factors
Plant factors
The toxicity of bracken varies significantly with its geographical distribution within countries, e.g. plants from southern Australia may contain twice the concentration of ptaquiloside than those from the north, suggesting genetic variation.3 Toxicity also varies with the stage of growth and time of the year, younger plants being more toxic. The underground stems (rhizomes) and the curled new fronds (crosiers) of the fern also contain the toxic principle in approximately five times the concentration of that found in mature fronds, and have been used to produce the disease experimentally in cattle. In most outbreaks, cattle have had access to the plants in their grazing for 2–4 weeks. Bracken is most prolific and most dangerous on light sandy soil where its wide climatic and soil type tolerance quickly leads to its domination of the pasture. In these circumstances it is very difficult to control or eradicate.

C. sieberi grows in close association with pasture grasses or in large numbers in mulga (Acacia aneura) communities in eastern Australia, and infrequently is associated with disease in livestock. They are most hazardous after drought-breaking rain.

Animal factors
The disease is most common in, and highly fatal to, cattle. Sheep are very rarely affected by bracken poisoning but natural outbreaks have been recorded and it has been produced experimentally in them by feeding the fern over a very long period. Cattle allowed access to recently plowed fields of bracken eat the rhizomes avidly and may suffer heavy mortalities.

Meadow hay may contain toxic amounts of bracken, and animals at pasture may eat large quantities, especially when young, green fronds appear after drought or burning off or when forage is sparse. Bracken used as bedding may also be ingested in dangerous amounts by animals with a poor nutritive status.
Importance
The toxin is excreted in the milk in significant quantity, and has been associated with neoplasia in the offspring of experimental animals drinking it. The toxin is thought to have health significance for humans drinking milk from their own bracken-grazing cows, or water which has percolated through fields containing bracken populations. Dilution of the toxin in metropolitan pasteurized milk supplies probably eliminates any significant human health risk from that source.

PATHOGENESIS
Bracken fern poisoning in ruminants is manifested by the depression of bone marrow activity, prolonged bleeding time, and defective clot retraction but with normal prothrombin times.

In the bone marrow there is depression of granulopoiesis and thrombopoiesis. The myeloid cells are particularly affected, leading to a severe reduction in circulating platelets and granular leukocytes. The erythrocyte series in bone marrow is affected, but only in the terminal stages.

Bacteremia is a significant part of the pathogenesis in osteomyelotoxic ptaquiloside poisoning. The suggested pathogenesis is that hemorrhage into the alimentary mucosa or submucosa occurs as a result of the thrombocytopenia, and ulcers develop at these hemorrhage sites. Bacterial invasion is facilitated by the neutropenia, and the resulting bacteremia may be associated with infarction in the liver if small vessels are blocked by clumps of bacteria, or the organisms may be carried into the systemic circulation and be associated with infarction in other organs, including the kidneys, lungs, and heart.

The capillary fragility, intestinal ulceration, and laryngeal edema that occur in some cases are thought to be due to damage to tissue mast cells and the liberation of histamine.

CLINICAL FINDINGS
Initially, there is loss of condition and dryness and slackness of the skin. Clinical signs occur suddenly and include high fever (40.5–43°C, 105–109°F), severe diarrhea with dysentery or melena in most cases, bleeding from the nose, eyes and, vagina, and drooling of saliva. Nasolabial ulcers and hematuria may be observed. Petechial and ecchymotic hemorrhages may be visible under mucosa or submucosa occurs as a result of the hemorrhages. Areas of edema are also common in the gut wall, and particularly around the pharynx in calves. The bone marrow is paler than normal. Multiple small, pale, or red areas representing infarcts and areas of necrosis are present in the liver, kidney, and lungs.

Necropsy picture as adult animals, except that marked bradycardia and death from heart failure occur, and a laryngitic form, with marked dyspnea due to laryngeal edema, is not uncommon. Although only a few animals in a group are affected, most of those showing clinical signs die.

Sheep grazing dense stands of young bracken for periods of 2 or more months may develop a less severe form of the hemorrhagic disease. The sheep lose weight, are depressed, lethargic and exercise-intolerant, anorexic, and anemic. The anemia is normocytic and hypochromic, and is accompanied by a leukopenia (lymphopenia and granulocytopenia) and, at necropsy, a gross deficiency of bone marrow, and widespread petechial and ecchymotic hemorrhages.

CLINICAL PATHOLOGY
Estimations of the occurrence of platelets in blood smears appear to be the most valuable laboratory test in diagnosis and prognosis of the disease. Platelet counts fall gradually from normal levels of about 500,000/µL to about 40,000/µL just before death. Total leukocyte levels fall gradually at first and then precipitously to about 1000/µL in the terminal stages. Polymorphonuclear leukocytes are the most profoundly depressed and often none are visible in a smear.

Bone-marrow biopsy is valuable as an indication of the status of the platelet and granulocyte series. Increase in capillary fragility is detectable, and defective clot retraction is also a feature of this disease. A fall in erythrocyte count and hemoglobin content may be detectable in the late stages. Depression of erythropoiesis is more marked in sheep than in cattle. Urine examination may reveal the presence of erythrocytes and many epithelial cells.

Necropsy findings
Death is due to the effects of multiple internal hemorrhages, combined in some cases with bacteremia. The hemorrhages, varying in size from petechiae to large extravasations, occur in all tissues. In some organs, particularly the alimentary tract mucosa, necrosis, and sloughing occur over the hemorrhages. Areas of edema are also common in the gut wall, and particularly around the pharynx in calves. The bone marrow is paler than normal. Multiple small, pale, or red areas representing infarcts and areas of necrosis are present in the liver, kidney, and lungs.

Differential diagnosis
Diagnosis confirmation is by identifying the typical signs and lesions in cattle having access to bracken, plus hematological examination of thin blood smears for platelets in live animals, and bone marrow histopathology from necropsy.

Differential diagnosis list
Osteomyelotoxic ptaquiloside poisoning may be readily confused with many of the acute septicemias and other hemorrhagic diseases of cattle, including:

- Anthrax
- Septicemic pasteurellosis
- Furazolidone poisoning
- Trichloroethylene-extracted soybean meal poisoning
- Sweet clover poisoning
- Pyrexia-pruritis-hemorrhage syndrome
- Radiation injury.

However, bacteriological findings in ptaquiloside poisoning are negative for these specific infections except for the occasional occurrence of a pasteurella septicaemia.

TREATMENT
Supportive treatment may include antibiotics and blood transfusions in those animals in which serious depression of erythrocyte and leukocyte counts have occurred. The transfusions should be large and 4.5 L is considered to be a minimum dose in adult cattle.

CONTROL
Fields containing large quantities of bracken fern should not be harvested for hay, and animals forced to graze affected areas should be supplied with a supplementary diet when the pasture is short.

CARCINOGENIC PTAQUILOSIDE POISONING
The diseases associated with years of ingestion of bracken ferns, Cheilanthes sieberi or Onychium contiguum, are bovine enzootic hematuria and alimentary tract neoplasia.

ETIOLOGY
Chronic ptaquiloside poisoning due to the ingestion of Pteridium spp., Cheilanthes
Nieberi or Onchium contiguum is associated with enzootic hematuria in cattle. A high incidence of vesicular carcinomas, similar to the bladder lesions of enzootic hematuria in cattle, has also been recorded in sheep grazing bracken for long periods.

**Epidemiology**
Enzootic hematuria occurs as an area problem on all continents. The overall incidence is not great, but the disease may be associated with heavy losses in areas where bracken is a common plant. The disease is usually fatal. Cattle over 3 years of age are most commonly affected, and the disease has also been recorded in sheep and water buffalo exposed to infested pastures for periods exceeding 2 years. The disease occurs mainly on poor, neglected or recently opened up land, and tends to disappear as soil fertility and land management improves. It is not closely associated with a particular soil type, although it is recorded most commonly on lighter soils. The ptaquiloside content of bracken varies considerably between geographical locations and there is good correlation between its concentration and neoplasia in rats fed bracken from those areas.

**Pathogenesis**
PTAquiloside converts to an aglycone dienone intermediate at high pH and this substance is the ultimate carcinogen. It has been suggested that the dienone reacts with DNA, particularly with adenosine, to initiate carcinogenesis. Hemorrhage from the bladder wall lesions occurs intermittently and results in ongoing blood loss. Deaths are due to hemorrhagic anemia.

**Clinical Findings**
Severe cases are manifested by the passage of large quantities of blood, often as clots, in the urine. Hemorrhagic anemia develops and the animal becomes weak and recumbent, and may die after an illness lasting 1–2 weeks. Less severe cases are characterized by intermittent, mild clinical hematuria or persistent subclinical hematuria. In these cases there is a gradual loss of condition over several months and eventually clinical evidence of anemia. On rectal examination there may be thickening of the bladder wall. Secondary bacterial infection of the bladder may lead to the development of cystitis and pyelonephritis.

**Clinical Pathology**
In the absence of gross hematuria, a urine sample should be centrifuged and the deposit examined for erythrocytes. Repeated examinations may be necessary. Non-specific anemia is detectable by hematological examination. Granulocyte and thrombocyte numbers are typically normal.

**Necropsy Findings**
All tissues of the carcass are pale and the animal is usually emaciated. The urinary bladder contains blood clots or blood-stained urine. The presence of hemangiomata in the submucosa of the urinary bladder is typical of the disease. A range of other neoplasms may be present, including transitional cell carcinoma, hemangiosarcoma, adenoma, fibroma, and papilloma. The malignant types may have invaded the deeper structures of the bladder and have metastasized to regional lymph nodes or lungs. The neoplastic changes in the bladder are accompanied by inflammatory changes of the mucosa and submucosa, including proliferative changes of mucosal epithelium, lymphocytic infiltrates, congestion, edema, and hemorrhage. In some cases, lesions are seen in the ureters and renal pelvis. The severity of the blood loss is not necessarily related to the size or extent of the lesions, and animals may bleed to death when only small localized lesions are present.

**Differential Diagnosis**
Diagnosis confirmation is by signs in animals grazing fern-infested pasture and preferably by histopathology of bladder lesions. The differential list includes:
- Cystitis
- Pyelonephritis.

Both are usually accompanied by fever, frequent urination, and show poor light and menace reflexes, and on ophthalmoscopic examination there is retinal degeneration. This degeneration may be observable in many more sheep than the clinically blind ones. Leukopenia is a characteristic.

**Treatment**
Primary
No treatment should be attempted and affected animals should be disposed of at the first opportunity.

Supportive
Blood transfusion may be justified in severe cases and hematocrit mixture should be provided in other cases.

**Control**
A general improvement in nutrition is often followed by a decrease in the number of animals affected. A specific recommendation is to apply gyspsum (225–335 kg/hectare) to the pasture as a fertilizer, a measure reputed to delay the onset of the disease. Bracken eradication is difficult and should not be undertaken without the advice of the local weed control officer.

**Alimentary tract neoplasia**
Alimentary tract neoplasia, including the jaws and liver, is recorded in sheep grazing pasture heavily infested with bracken and has been produced experimentally in sheep fed bracken or ptaquiloside. Dairy cattle on farms infested with bracken may have a high prevalence of carcinoma of the intestine and tumors of the urinary bladder. Cancer of the alimentary tract, generally with lesions on the lateral dorsum of the tongue, the soft palate and oropharynx, esophagus, esophageal groove, and the rumen is also common in upland Scotland and northern England. Similar cases are recorded from South America. The epidemiological evidence suggests that papillomas associated with the papilloma virus are transformed into carcinomas by the carcinogenic effect of an environmental agent, probably bracken. Alimentary tract neoplasms in cattle grazing on bracken may be associated in the herd or in the individual with enzootic hematuria, or it may occur on its own. Depending on where the lesions are located, clinical signs may include masti­catory disability, dysphagia, or chronic bloat.

**Bright blindness' of sheep**
A progressive retinal degeneration associated with ptaquiloside observed in sheep kept for more than 3 years in the UK on pastures heavily infested with bracken, the disease has been produced experimentally in sheep fed bracken. Affected sheep are blind, reluctant to move, but bright and alert. The pupils are dilated and show poor light and menace reflexes, and on ophthalmoscopic examination there is retinal degeneration. This degeneration may be observable in many more sheep than the clinically blind ones. Leukopenia is a characteristic.

**Review Literature**
PYRROLIZIDINE ALKALOID POISONING

Synopsis

Etiology Pyrrolizidine alkaloids in Crotalaria, Echium, Heliotropium, Senecio spp., and other plants.

Epidemiology Outbreaks are in or enzotic to very large areas where toxic plants dominate pasture, mostly in cattle and horses. Pyrrolizidine alkaloid-containing weed seeds in feed grains or dry plants in hay also lead to poisoning. Range of diseases associated with primary cumulative toxicosis and effect of metabolites.

Clinical findings Chronic wasting. Hepatic encephalopathy by blindness, head pressing, bouts of frenzy, jaundice, photosensitization, and intravascular hemolysis.

Clinical pathology Liver function tests and blood levels of hepatic enzymes indicate hepatic inefficiency. In some cases, there is only hypoalbuminemia.

Necropsy lesions Hepatic megalocytosis, fibrosis, and biliary hyperplasia.

Diagnostic confirmation Histopathology of liver. Assay of whole blood or liver for pyrrolic metabolites.

Treatment nil

Control Avoidance of significant exposure to plants. Biological control of plants.

ETIOLOGY

Most hepatotoxic pyrrolizidine alkaloids (PAs) are esters of two amino alcohols, retronecine and heliotridine, and occur in three groups—monoesters, non-cyclic retronecine and heliotridine, and occur pyrrolizidine nucleus and a branch in the may be converted to the toxic free base in

ETIOLOGY

Most hepatotoxic pyrrolizidine alkaloids (PAs) are esters of two amino alcohols, retronecine and heliotridine, and occur in three groups—monoesters, non-cyclic (open) diesters and cyclic diesters—in ascending order of toxicity. To be hepatotoxic, PAs require a 1,2 double bond in the pyrrolizidine nucleus and a branch in the ester group. Non-toxic N-oxides of PAs may be converted to the toxic free base in the alimentary tract. A complete list of known PAs would be too long to be useful; for example, Echium plantingineum contains at least ten of them known to be toxic to grazing animals. Most PA-containing plants are classified in the plant families Boraginaceae, Fabaceae (Leguminosae), and Asteraceae (Compositae). The recorded plant sources of hepatotoxic PAs include:

C. goreensis – Gambia pea; contains monocrotaline
C. incana – woolly rattlepod; contains fulvine
C. juncea – sunn hemp; contains retusine
C. mauensis – contains junceline
C. mesoponcita
C. mitchelli
C. novae-hollandiae – New Holland rattledop
C. ramosissima – Kimberley horse poison
C. retusa – wedge-leaved rattlepod; contains monocrotaline, retusine
C. spectabilis – showy rattlepod; contains monocrotaline, spectabiline
Cynoglossum officinale – hound’s tongue; contains heliotridine, heliosupine, echinatine
Echium plantingineum (E. lycopsamine) – Patterson’s curse, Salvation Jane; contains echinatine, echimidine
E. vulgare – viper’s bugloss; contains echimidine
Heliotropium europaeum – common heliotrope, potato weed; contains indicine, heliotrine, lasiocarpane, europine, supinine, heleurine
H. amplexicaule – blue heliotrope; contains lasiocarpine, echinatine
H. ovatifolium
Ligularia amplexicaulis – dola
L. mertonii – bong dok pu
Lithospermum arvense (Buglossoides arvensis) – corn gromwell
Senecio abbyssicus
S. alpinus
S. aquaticus – marsh ragwort
S. brasiliensis
S. bucheilii – geelgibbossie
S. cineraria – dusty miller
S. cissifolius
S. cunninghamii
S. erraticus
S. glabellus
S. harveyanus
S. heterotrichus
S. integerrimus
S. isatoides – Dan’s cabbage, inkanga
S. jacobea – ragwort; contains senechophylline, senecionine, jacobine, jaconine, jacinole, jacholine, jaozone
S. latifolius – Dan’s cabbage, dusnietkabossie
S. brigaloides – fireweed
S. linearifolius – fireweed
S. longifolius – thread-leaf groundsel; contains retrorsine, riddelline, senechophylline
S. madagascariensis – Madagascar fireweed; contains senecionine
S. magnificus – tall yellowtop; contains senechophylline
S. moorei
S. oxyphyllus
S. platensis
S. pterophorus – African daisy
S. quadridenatus – cotton fireweed
S. retorsus – staggers bush, dusnietkabossie
S. riddeltii – Riddell’s groundsel
S. ruwenzorienis
S. scelatus
S. selii
S. spartooides – broom groundsel
S. spathulatus
S. squillatus – Oxford ragwort
S. tweedidei
S. verrinis
S. vulgaris – common groundsel; contains senechophylline, senechophylline, retrorsine
Symphytum officinale – comfrey; contains echinatine, lycopsamine, symphytine
Trichodesma incanum – contains trichodesmine
T. ehrenbergii – contains senkirkine
T. zeylanicum – camel bush; contains supinine.

Some pyrrolizidine alkaloids have their most significant effect on the lungs. Plants containing these include: Crotalaria dura, C. globifera, C. juncea, C. mitchelli, C. spartooides.

One effect on the lungs is produced by C. ramosissima/C. crispa. As well as its dominant hepatotoxic effect, C. retusa is associated with nephrosis in affected pigs.

EPIDEMIOLOGY

Occurrence Diseases associated with PAs occur in most animal species in most countries, causing syndromes such as ‘Molteno strainig disease’ of cattle, ‘walking disease’, ‘Winton disease’ of horses and cattle, and ‘Kimberley horse disease’ (Walkabout disease), ‘dunsiekte’ (panning disease), and ‘dunsiekte’ (thin disease), or ‘Kimbervliy disease’ of cattle: ‘walking disease’, ‘Winton disease’ of horses and cattle, and ‘Kimberley horse disease’ (Walkabout disease), ‘dunsiekte’ (panning disease), and ‘dunsiekte’ (thin disease), or

Risk factors Plant factors

The plants are not very palatable and are usually eaten in sufficient quantity to be associated with illness only when other feed is short, or when they are included accidentally in conserved fodder such as hay or when their seeds contaminate feed grains. The toxicity of plants containing PAs is not significantly reduced by conversion of the plants to hay or ensilage or by pelleting, but hot air drying of the
Plants considerably reduce their toxicity. Flowers are more toxic than herbage. Mature plants avoided, largest intake by animals being when the plants are sending out new shoots. With Senecio spp, it is the foliage that is the source of the poisoning. With Crotalaria, Heliotropium, and Amsinckia spp, the seeds are a common source, either as contaminants of grain crops harvested for animal feed, or in cakes made from the seeds after extraction of oils. This is usually the way in which pigs are poisoned.

Environmental stress, including drought and high temperatures and especially spraying with herbicide, appears to increase the plants' content of PAs. The differences in PA concentration in different samples of the same plant species, invalidates the evaluation of the toxicity of the plant on the basis of intake by the animal.

Animal factors
Species
Cattle and horses are very susceptible to PA poisoning, being 30–40 times as susceptible as sheep and goats. The difference appears to be related to the animal's ability to detoxify the pyrrolizidine alkaloids in the liver, probably related to the diet consumed before domestication. Small herbivores are more likely to be browsers and to develop resistance to the toxins. It is possible that detoxification of the PAs may occur in the rumen as a result of microbial activity but there are opposing opinions about this.11

Stored feeds
Although most field cases of poisoning occur in animals grazing pasture infested with the toxic plants, the disease may result from feeding of contaminated, stored feeds, especially hay, or the use of the plants in bedding. The effects of the intoxication are cumulative and fatal intoxication may develop over a period of years.

Importance
PAs and their metabolites are excreted in cows' milk but are thought not to represent a health threat to humans. Experimental feeding of goats' milk containing PA metabolites has produced hepatic lesions in rats. Concentrations of these substances in the meat of animals eating the plants are similarly not thought to be dangerous to humans. Mass mortalities are possible among intensively housed livestock such as pigs, poultry, and feedlot cattle.13

PATHOGENESIS
Hepatic injury
PAs themselves are not poisonous but their pyrrolic metabolites, produced in the liver, are serious, cumulative hepatotoxins which combine with pyrrol groups to form pyrrolic thiocarboxylic that damage liver cells by inhibiting mitosis leading to loss of hepatocyte numbers and megalocytosis, and thus causing the clinical signs and death due to hepatic dysfunction.15 The relative resistance of sheep to PA toxicity may be related to the relatively low capacity of the sheep's liver to produce pyrroles. In cattle, as well as the megalocytosis, there is damage to the centrilobular and hepatic veins leading to occlusion of the vessels.

The progress of the disease in ponies may be in one of two patterns. In the chronic disease there is a gradual worsening of signs until death at 6–22 weeks. In the chronic-delayed form the lesion progresses, as measured by biopsy, but there are no clinical signs until a sudden onset of illness at 38–58 weeks.16 Similarly, the signs of the disease may not occur until several months after the last ingestion of the toxic material, with death occurring soon afterwards.17

Hepatic encephalopathy
One of the consequences of liver insufficiency is the systemic accumulation of metabolites such as ammonia, which is associated with cerebral edema. This results in the nervous signs of depression, aimless walking, and head-pressing. The spongy degeneration (status spongiosis) produced in the CNS is characteristic of hyperammonemia. Other metabolites may also be significantly involved, but ammonia is best studied.

Toxic jaundice
Liver damage due to ingestion of PAs, commonly Heliotropium europaeum, results in the accumulation of copper in the liver, but only if the copper intake in the diet is above normal,18 and may be associated with clinical cases of chronic copper poisoning in sheep, leading to the development of one of the forms of 'toxic jaundice'. Echium plantagineum has the double disadvantage of containing PAs and a high copper-molybdenum ratio so that copper accumulation occurs readily in the plant.19 Similar accumulations of zinc and iron also occur. There is some evidence for an impairment of storage of vitamins A and E by PAs, but there are no field occurrences of resulting wastage.

The reactive metabolites of hepatic pyrrolizidines produced during their toxic attack on the liver escape into the general circulation and are associated with damage to other tissues, and are also associated with the nephrosis and interstitial pneumonia that occur in some poisonings and in some incidents are associated with poisoning by known hepatotoxins. They also react with erythrocytes and the pyrrolic esters formed there are bound to hemoglobin so that they could be used as markers of past intake of the PAs.14 The usefulness of the technique is limited by the short life span of erythrocytes. Besides the incidental escape of toxic metabolites into the circulation and the subsequent escape to pulmonary tissue, the PAs from some plants, e.g. some southern African Crotalaria spp, exert their major effect on lung tissue and produce pulmonary as well as hepatic signs.20

An unusual outcome to pyrrolizidine toxicity of horses is the development of gastric impaction with the dried stalks of the plant, causing colic with nasal regurgitation and, in some cases, a fatal gastric rupture.21

CLINICAL SIGNS
Although the causative lesions develop slowly in most cases, the onset of clinical signs is usually sudden. The prominent signs are hypsensitivity to external stimuli, anorexia, precipitate drop in milk yield and, in cases surviving for more than 2 days, there is often jaundice and photosensitive dermatitis. The onset of illness may occur many months after the animals have been removed from the toxic pasture. Sheep may have serious liver damage but the effects may be limited to loss of body weight and reduction in wool yield.22 Most animals poisoned with PAs develop the hepatic syndrome detailed below. However, some cases will have signs of uremia or interstitial pneumonia, described elsewhere in this book. For example, horses fed large amounts of Crotalaria juncea seeds in their feed develop severe dyspnea associated with massive consolidation of lungs.23

Cattle
In poisoning due to Senecio spp, there is a sudden onset of depression and poor sensitivity to external stimuli. This hyposensitivity is sometimes punctuated by short outbursts of excitability and frenzy, and often by aggressive behavior. During these episodes there is usually severe diarrhea and straining to defecate. This may result in a high incidence of rectal prolapse. Other signs include abdominal pain, staggery gait, with dragging of the hooves, walking in circles, and partial blindness. Such cases usually die within 2–3 days of the onset of signs.

Some cases may linger on for several weeks. There are no excitable episodes, the animal remains hyposensitive, loses weight and becomes anorexic, is afflicted with diarrhea and tenesmus, and usually develops jaundice, mucosal pallor and, rarely, photosensitive dermatitis.

Horses
Horses poisoned by Senecio jacobaea or Crotalaria crispata/C. ramosissima lose much weight, are mildly jaundiced, and profoundly hyposensitive to external
stimuli, often standing with the head held down and stopping eating halfway through a mouthful of hay or grass. There is muscle tremor, especially of the head and neck, frequent yawning, and difficulty in swallowing. The latter may be sufficiently severe to cause aspiration of food into the lungs or its regurgitation through the nasal cavity. Affected horses appear to be blind. They walk in circles or straight ahead, bumping into objects and becoming wedged in places from which they cannot back out; they also walk into streams, houses, or outbuildings. Death due to misadventure is a frequent outcome. Head-pressing is common and there may be attacks of frenzy and violent, uncontrollable galloping. Multiple skin abrasions of the head and chest are indicators of this deranged behavior. The disease is usually fatal, the course lasting from a week to several months. Poisoning of horses by *Echium plantagineum* is associated with weight loss, severe hyposensitivity, and jaundice. Paralysis of the pharynx and larynx are thought to be associated with an unusual occurrence of severe inspiratory dyspnea in ponies with severe pyrrolizidine toxicosis. A further unusual effect in horses may be intravascular hemolysis, manifested as hemoglobinuria. Pseudo-neoplastic proliferation of bronchiolar epithelium is the basis of jaunsekte of horses manifest as progressive severe dyspnea associated with pneumotoxic pyrrolizidine alkaloids such as dicrotaline, monocrotaline, fulvine, and crispatine in some *Crotalaria* spp., including *C. dura*, *C. globifera*, *C. juncea*, *C. sartorii* in southern Africa and *C. ramosissima*. *C. crispati* and *C. Mitchellii* in Australia.

**CLINICAL PATHOLOGY**

Direct diagnosis of a patient's exposure to pyrrolizidines is possible by the detection of pyrrolic metabolites bound to haemoglobin. Contributory evidence is the presence of hyperammonemia, hyperbilirubinemia, and hypoalbuminemia. The bromsulphalein (BSP) clearance rate and the mortality rate is high.

**Necropsy findings**

Hepatic megalocytosis, fibrosis, which may be veno-occlusive, and biliary hyperplasia are the common histopathological findings. In cases of sufficient duration there is jaundice, general edema, and ascites. Secondary histopathological changes occur in intestinal mucosal cells and may be responsible for impaired absorption of nutrients. In some cases, and in some poisonings associated with PA-bearing plants, necropsy findings will be dominated by lesions of nephrosis, particularly in pigs, or interstitial pneumonia, particularly in horses.

**DIFFERENTIAL DIAGNOSIS**

Diag nostic confirmation depends on positive identification of pyrrolic metabolites in blood or liver. Presumptive diagnosis is provided by hepatic histopathology detecting megalocytosis, which needs to be differentiated from that seen in aflatoxicosis. Cases in which exposure to toxic plants occurred some time ago can only be diagnosed presumptively.

**Differential diagnosis lists**

Cattle, hepato pathies due to:
- Phytotoxins, e.g. in *Lantana* spp.
- Mycoporum
- Mycotoxins as in *Asperillus* spp., *Phomopsia*, *Diaporthe toxica*, *Myrothecium* spp.
- Tunicammylurilc poisoning as in *Clawbat toxin*.
- Cyanobacterial toxins
- Zootoxins as in *Lophyrotoma*, *Arepp*.

Encephalopathies such as:
- Rabies
- Lead poisoning
- Polioencephalomalacia.
- Other causes of jaundice also need to be taken into account. Special attention needs to be given to chronic copper poisoning in sheep because sheep poisoned by PAs are much more inclined to develop high levels of copper in the liver than are other sheep.  

Horses:
- Equine viral encephalomyelitis
- Nigropallidal encephalomalacia
- Leukoencephalomalacia.

**TREATMENT**

Primary treatment of the hepatic lesion is unlikely to be attempted. Supportive treatment requires provision of a high nutrient diet during the convalescent period plus symptomatic treatment for photosensitization and dehydration. Horses that have recovered clinically may never regain their former physical fitness and any exertion will lead to rapid exhaustion.

**CONTROL**

Populations of these plants undergo cyclic changes and the diseases associated with them tend to wax and wane. Artificial reduction of plant numbers using herbicides is attempted. Because of the comparative resistance of sheep to PA poisoning they may also be used to keep infested pasture under control by having them graze it only intermittently, for example for a 1-month period once a year, or for only one season during their lifetime. Biological control, using insects such as the cinnamon moth (*Tyria jacobean*), which feeds only on plants that contain PAs, may be an effective control procedure for their specific host plants. A concerted effort at biological control of *Heliotropium europaeum* and *Echium plantagineum* is currently underway in Australia using several insect herbivores and fungal pathogens in combination. Attempts to control *H. europaeum* poisoning by administration of cobalt or an antimethanogen have been unsuccessful.

**REFERENCES**

S-METHYL-L-CYSTEINE-SULFOXIDE (SMCO) AND DIPROPYL/DIPROPENYL DISULFIDE POISONING

Synopsis

Etiology Brassica spp. contain SMCO. Allium spp. contain N-propyl disulfide.
Epidemiology Outbreaks when mature plants grazed. Heavy morbidity and case fatality rates.
Clinical findings Acute onset, pallor, hemoglobinuria, jaundice if the patient survives long enough.
Clinical pathology Low blood levels of hemoglobin, erythrocytes. Hemoglobinuria.
Necropsy findings Pallor, jaundice, hemoglobinuria.
Diagnosis confirmation High blood levels of dimethyl disulfide in SMCO poisoning. The test is not generally available.
Treatment No primary treatment; supportive treatment is blood transfusion.
Control Dilute toxic feed with, e.g. pasture hay.

ETIOLOGY

Plants of all the Brassica species are associated with several syndromes, including hemolytic anemia due to SMCO poisoning recorded here; blindness, pulmonary emphysema, and digestive disturbances, dealt with under glucosinolate poisoning, and photosensitization. These syndromes may occur separately or in combination.

S-methyl-l-cysteine sulfoxide (SMCO) is a rare sulfur-containing α amino acid which occurs in some genera of plants in the family Brassicaceae (e.g. Brassica, Raphanus). Its metabolic products in ruminants are associated with serious hemolysis and anemia. The plants known to contain SMCO are Brassica campestris (turnip rape, cole), B. napobrassica (swede, rutabaga), B. napus (rape = canola), and B. oleracea (kale, kohlrabi, chou moeller, cabbage, cauliflower, broccoli, Brussels sprouts, calabrese), Raphanus raphanistrum (wild radish), and possibly T. arvense (fanweed) and Berteroa incana (hoary alysum). The green parts of the plants are usual material involved in outbreaks.

The anemia-producing agent in poisonings by these plants is dimethyl disulfide, produced by ruminal bacteria from SMCO. The SMCO content of forage brassicas increases as the plant matures. The toxic dose of SMCO is 15 g/100 kg BW daily to produce severe, fatal anemia. Intakes of 10 g/100 kg BW are associated with a subacute, low-grade anemia.

Culinary vegetables

Particular note should be taken of the occurrence of SMCO in cabbages, swedes, and stubble turnips. The level may be insufficiently high to be associated with anemia, but may be associated with failure to gain weight satisfactorily, or clinically evident ill-thrift. Allium spp. (family Liliaceae), e.g. Allium canadense (wild onion, Canadian garlic), A. cepa (commercial onion), A. sativum (garlic), A. schoenopraum (chives), A. triquetrum (three-cornered garlic), A. ursinum (ramps), and A. validum (wild onions), the plants responsible for onion-induced anemia, are usually bracketed with this group of plants because the hemolytic agents, propyl disulfide, 1-propenyl and 2-propenyl disulfides, are chemically similar to, and their effects are the same as, those of the SMCO-induced anemia.

Hypophosphorosis

Although there may be no etiological relationship, it is not uncommon for the hemolytic disease to occur in the presence of hypophosphorosis, and therefore at the same time as postparturient hemoglobinuria.

The seeds and leaves of these plants also contain another glucosinolate, sinigrin, and its breakdown products, allyl cyanide and allyl isothiocyanate, which may depress food intake but appear to exert no hemolytic activity. The plants may also contain significant quantities of cyanogenetic glycosides but rarely are associated with cyanide poisoning. Nitrate and nitrite poisoning have also been recorded on kale feeding.

EPIDEMIOLOGY

Occurrence

Rape and kale poisoning are well known where these plants are grown for fodder and in some areas they are no longer used because of the danger. The overall prevalence of poisoning is probably not great but on individual farms the number affected is usually significant, and the mortality rate is high.

Risk factors

Plant factors

The plants are more toxic as they mature and when secondary growth begins; the flowers and seeds are particularly poisonous. The toxicity of the plants varies from year to year, and on rape grazing most outbreaks occur in wet years when early frosts occur and the leaves turn a purple color. The toxicity of kale also varies significantly between varieties of the plant but the important factors in most outbreaks are the maturity of the crop and the amount eaten. The toxic principle in kale is destroyed in heat-dried or ensiled material but is still present in frozen and dried material. Onions fed at greater than 25% of the ration for cattle can be associated with hemolytic disease.

Animal factors

Only ruminants are affected by the poisoning, and the hemolytic effect is produced only when the diet consists largely of the plants and when the animals are on the feed for at least 1 and usually 3 weeks. Sheep are less susceptible to onion poisoning than cattle.

PATHOGENESIS

Dimethyl disulfide and the propyl disulfides are agents that oxidize hemoglobin, lead to Heinz–Ehrlich body formation from denatured hemoglobin in erythrocytes, and ultimately to hemolysis. The resulting hemolytic anemia affects all classes of ruminants but its effects are most serious in heavily pregnant and recently parturient females. The reasons for the observed tendency for cycles of spontaneous improvement followed by recrudescence of the anemia are not explained. A previous suggestion that they were related to variations in the cellular content of reduced glutathione, which prevents the formation of Heinz–Ehrlich bodies, has been discredited.

CLINICAL FINDINGS

In the anemia syndrome, the onset in severe cases may be so sudden that no signs are observed before the animal collapses and dies. If clinical illness is apparent, hemoglobinuria is observed first and is soon followed by weakness and dejection. Pallor of the mucosae, moderate jaundice, tachycardia, and a slight increase in respiratory rate and depth are also observed. Diarrhea occurs commonly and, although body temperatures are usually normal to low, there may be fever up to 40.5° C (105°F). Death is common unless effective treatment is provided, and surviving animals require a long period of convalescence. A normal hematological status may not be regained for up to 6 weeks. In an affected herd it is common to find a number of animals that...
are not seriously ill, but with a subclinical anemia.

**CLINICAL PATHOLOGY**
The erythrocyte count, hemoglobin concentration, hematocrit, and leukocyte count are reduced, and Heinz–Ehrlich bodies are present in up to 100% of erythrocytes. They are significantly increased in numbers before anemia appears. The anemia is macrocytic and the hemoglobin level falls from 110 g/L to 6 g or less. Hemoglobin is present in the urine. There is often a concurrent hypophosphatemia. The dimethyl disulfide content of the blood, which will be high at the time of occurrence of the poisoning, can be measured chromatographically.

**NECROPSY FINDINGS**
There is pallor, jaundice, hemoglobinuria, thin, watery blood, dark coloration of the kidney, accentuation of the lobular appearance of the liver, and, in peracute cases, swelling of the spleen. Histologically there is moderate pericardiar, hepatocyte necrosis in the liver, compatible with the effects of hypoxia.

**DIFFERENTIAL DIAGNOSIS**
The occurrence of the disease when cattle or sheep are grazing on plants of the family Brassicaceae or consuming Allium spp. suggests the presumptive diagnosis. Diagnostic confirmation is by measurement of dimethyl sulphide levels in the blood. The differential diagnosis list includes:
- Postparturient hemoglobinuria, which is limited to cows that have calved recently
- Leptospirosis in calves
- Bacillary hemoglobinuria
- Babesiosis
- Chronic copper poisoning.

**TREATMENT**
Primary treatment in the form of an antidote to SMOO is unavailable. Supportive treatment includes, in severe cases of anemia, an immediate blood transfusion. Hematinc preparations and the provision of a highly nutritious diet are also used.

**CONTROL**
The provision of ample hay either daily before the animals are pastured on the rape, as a stack in the rape field, or allowing access to a field of rough grass, are recommended to reduce the consumption of rape. Rape showing purple discoloration should be regarded with suspicion and only limited grazing permitted until doubts as to its safety are satisfied. Cattle and sheep grazing on these plants should be kept under close observation so that affected animals can be treated in the early stages of the disease. An adequate phosphorus intake is particularly necessary. If feeding is stopped, the hemoglobin levels return to normal in about 3 weeks. Even if feeding is continued there is a strong tendency for a spontaneous recovery and further similar cycles to occur. Some varieties of kale have lower concentrations of SMCO and a genetic approach to preventing the disease might be worth examining.

The disposal of superfluous onions is a major horticultural problem, best solved by feeding them to animals. This can be done without fear of causing anemia by feeding them mixed into a balanced ration containing less than 25% of onions. Sheep appear to tolerate the toxins in onions more than cattle and have been adapted to a 100% onion diet without ill effect.6

**REVIEW LITERATURE**

**THIAMINE POISONING**

**SYNOPSIS**

**ETIOLOGY**
Thiaminases occur in the Marsilea, Cheilanthes, Pteridium, and Equisetum spp. ferns, and are generated by microbes in the rumen of animals affected by polioencephalomalacia. 

**EPIDEMIOLOGY**
Outbreaks in ruminants with access to ferns, horses fed hay containing bracken, pigs eating bracken, especially rhizomes. 

**CLINICAL SIGNS**
Ruminants - blindness, depression, horses - muscle tremor, cardiac irregularity, crouched posture, incoordination, recumbency, death; pigs - dyspnea, sudden death. 

**CLINICAL PATHOLOGY**
Low blood levels of thiamin, transketolase, high levels of pyruvate.

**NECROPSY FINDINGS**
Polioencephalomalacia in ruminants, not in horses; cardiac lesions in pigs.

**DIAGNOSTIC CONFIRMATION**
Low blood levels of thiamin.

**TREATMENT**
Thiamin injected gives excellent results, provided thiaminase source is withdrawn.

**CONTROL**
Denial of access to toxic plants.

**ETIOLOGY**
The identified thiaminases which are important to animals occur in ferns and catalyze the decomposition of thiamin. The most widespread occurrence of a thiaminase-induced thiamin deficiency is polioencephalomalacia in ruminants.

The ferns which are sources of thiaminase, and the animal species affected are:
- Horses - Pteridium spp., Equisetum arvense, E. fluviatile, E. hyemale, E. palustre, E. ranviosissimum, E. sylvaticum, Marsilea drummondii
- Sheep - Marsilea drummondii, Cheilanthes sieberi
- Cattle - C. sieberi, Dryopteris borreri, D. filix-mas.1 See also Phalaris aquatica sudden death syndromes.

Thiaminases are of two types, methyltransferase, and a hydrolase. The hydrolases are not found in plants but only in the rumen, presumably as metabolites produced by ruminal bacteria from specific precursors in the plants.2 Plants containing thiaminases are usually deficient in thiamin.

**EPIDEMIOLOGY**
Thiaminase poisoning associated with Pteridium spp. and Equisetum spp. occurs almost always in horses fed on hay contaminated by the ferns, and is most toxic if the hay is cut when the fronds are very young. The standing plants are unpalatable and rarely eaten by these animals. Signs of poisoning in grazing horses do not occur until the horses have had access to the fern for 3–4 weeks, but the period is much shorter if they are fed in stables on heavily contaminated hay. The thiaminase content of the ferns varies widely, being highest at a period of rapid growth and after being grazed severely.

Grazing pigs may root out and eat Pteridium rhizomes, which contain a much higher concentration of the thiaminase than the fronds. Sheep grazed on pastures dominated by Marsilea drummondii (nardoo) on floodplains in inland Australia or forced to graze Cheilanthes sieberi are poisoned.

Grazing cattle may be forced to eat the ferns because of lack of other feed and when the fern is at a toxic, rapidly growing stage, but are not affected by a thiamin deficiency. They succumb to a hemorrhagic disease. Thiaminase activity occurs in the fronds of the ferns Marsilea drummondii, Cheilanthes sieberi and Pteridium aquilinum in descending order of magnitude.

**PATHOGENESIS**
A state of thiamin deficiency is created by the destruction of thiamin in the alimentary tract. The activities of enzymes that require thiamin are impaired and there is an accumulation in tissues of pyruvate and lactate. The relationship between the intake of the thiaminase and the nervous signs is not adequately explained. That there is such a relationship is suggested by the development of brain lesions of polioencephalomalacia in sheep poisoned by Marsilea drummondii and in those fed...
Diseases associated with major phytotoxins

**CLINICAL SIGNS**

Affected horses sway from side to side, show gait incoordination, including crossing the forelimbs and a wide action in the hindlimbs. Abnormal postures include a wide stance, arching of the back, and crouching. Muscle tremor, cardiac irregularity, and bradycardia are evident and the appetite and demeanor are normal. Terminally, the animal falls easily, becomes recumbent and hyposensitive to external stimuli, and makes convulsive movements. The heart rate and the temperature become elevated. Additional signs seen in horses poisoned by *Marsilea drummondii* include carrying the head close to the ground, whinnying, partial blindness, nodding of the head, twitching of the ears, and frequent yawning.

The clinical syndrome in pigs fed bracken rhizomes in excess of 25% of their diet includes anorexia, recumbency, dyspnea, and death after a course of about 6 hours.

Sheep poisoned by *Marsilea drummondii* may be affected by an acute or a chronic syndrome. The chronic syndrome is indistinguishable from polioencephalomalacia, and is dealt with under that heading.

The acute form of the disease is characterized by the sudden onset of dyspnea, depression, and recumbency and death in 6–8 hours. Sheep affected by *Chelianthes* spp. poisoning are hyposensitive to external stimuli, including being blind, and walk slowly and with an uncoordinated gait.

Cattle poisoned by *Dryopteris* spp. are also blind and hyposensitive. Many recover but remain blind.

**CLINICAL PATHOLOGY**

The characteristic findings attributable to a nutritional deficiency of thiamine are present. These include depression of blood levels of thiamine and transketolase, and elevation of levels of blood pyruvate.

**NECROPSY FINDINGS**

In naturally occurring cases in horses there are no lesions recorded other than the non-specific ones of acute or congestive heart failure. Polioencephalomalacia has been seen in sheep and, in pigs, an enlarged motiled heart and congestion of the lungs and liver indicate the presence of congestive heart failure.

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation is based on low blood thiamine levels. The differential diagnosis list includes:

- Hepatic encephalopathy is similar but the course is usually much longer. There are also signs of hepatic insufficiency
- Infectious encephalitides
- Toxic encephalomalacias
- Staggers syndromes, e.g. rye-grass staggers, paspalum staggers, phalaris staggers

**TREATMENT**

In the early stages the administration of thiamin and removal of the dietary source of thiaminase are the critical procedures, and recovery is to be expected. In large animals the IV or IM injection of 100 mg of thiamin, twice on day 1, followed by similar daily IM injections for 7 days (with double doses in severe cases) is recommended. The response to treatment is dramatic.

**CONTROL**

Large-scale control of bracken is attempted by a combination of pasture management, application of herbicide and mechanical slashing, but is expensive and subject to error so that professional agrostological advice is desirable.

**REFERENCE**

**ALPHATIC ACETOGENIN (MONOGLYCERIDE)**

The toxin responsible for poisoning by *Persea americana* (avocado, alligator pear) is a biologically active alphatic acetonin, persin, with the form of a monoglyceride. Only varieties of Guatemalan origin are toxic; Mexican varieties are not. All parts of the plants can be toxic. Horses, ruminants, and ostriches have been affected. In lactating females, poisoning...
produces sterile mastitis and agalactia with necrosis of secretory epithelium of mammary glands. Horses are affected by a heart failure syndrome, usually non-fatal, with severe subcutaneous edematous swelling of the head and dyspnea. In some cases, there is ischemic necrosis of masseter and tongue muscles.\textsuperscript{10} Fatal cases have myocardial necrosis. Colic and diarrhea have been reported in foals. Poisoned ostriches have paresis of neck muscles, edema of the neck, pulmonary edema, and necrosis of cardiac muscle.\textsuperscript{11}

**AMINE TOXICITY**

Two toxic amines identified in plants are the teratonigen cyclopamine in *Veratrum californicum* and tyramine (\(N\)-methylphenylethyl-amine) found in *Acacia berlandieri* (guajillo), and two mistletoes *Phoradendron villosum* and *Viscosum album*.

**Tyramine**

Clinical signs in poisoning by the acacia include gait incoordination, limb weakness and recumbency, all exacerbated by exercise or harrassment, and all of which disappear if the patient is removed from contact with the plant. No signs are attributed to poisoning by mistletoe, the only event recorded being the patient being found dead.

**Cyclopamine**

Cyclopamine, the toxic amine found in *Veratrum californicum* (skunk cabbage) is associated with severe congenital cyclopean deformities of the head, absence or displacement of the pituitary gland with prolonged gestation, and giantism in lambs, calves and kids when fed to the dams in early pregnancy (between the 14th and 30th days in ewes). Many other defects, including cleft palate, harelip, syndactyly, various leg deformities, supernumerary claws, tracheal sension, and fetal death and resorption have been induced in neonatal lambs by feeding ewes at specific times in their pregnancies. For example, feeding ewes root material on day 29 is associated with shortening of the metatarsal, metacarpal, and tarsal bones, medial bowing of the forelimbs at the fetlock, and severe articular surface defects and arthropagrosis in some cases.\textsuperscript{12} Dosing ewes at day 31-33 is associated with lateral flattening of the trachea and death due to asphyxia within 5 minutes of birth. Early fetal death, possibly with resorption occurs, after dosing on day 14.\textsuperscript{13}

**AMINO ACID TOXICITY**

The best-known toxic amino acids are:

- Indospicine in *Indigofera spicata* (creeping indigo)
- Indospicine in *Indigofera linnæi* (*I. dominii, I. emeaphylla*, Birdsville indigo)
- Canavanine in *Canavalia spp.*
- Canavanine in *Canavallia linnaei*
- Canavanine in *Leucaena leucocephala* (lead tree) and *Mimosa pudica* (sensitive plant).

**Indospicine**

Poisoning by *Indigofera linnæi* has generally been ascribed to indospicine but is now considered to be associated with a nitro-compound. Indospicine transmitted to dogs fed on meat from poisoned horses is associated with fatal liver damage in the dogs.\textsuperscript{14} *Canavalia* spp. and *I. spicata* in sheep and cattle are associated with a similar syndrome including anorexia, hyposensitivity, gait incoordination, and abortion in some.

**Canavanine**

Canavanine poisoning is also associated with a syndrome including stiff gait, stumbling, recumbency, and diarrhea, with loss of weight and reduction of feed intake. Necropsy findings include gastroenteritis, nephritis, and pulmonary emphysema.

**Mimosine**

The non-protein amino acid mimosine occurs in *Mimosa pudica* (sensitive plant) and *Leucaena leucocephala*, a leguminous fodder shrub. Mimosine plus an enzyme in plant tissue produces 3,4-dihydroxypropyridone (3,4-DHP), a potent goitrogen, which on mastication yields 2,3-DHP through the action of rumen flora. Mimosine, 3,4-DHP and 2,3-DHP are all toxic. Both plants are associated with alopecia but *Leucaena* spp. is associated with the disease known as ‘jumbe’ (Bahamas) or ‘lamtoro’ (Indonesia). Some varieties of the tree contain more mimosine than others. Safe daily intakes of mimosine are 0.18 g/kg BW for cattle, 0.14 g/kg BW for sheep, and 0.18 g/kg BW for goats. There is a great deal of variation in the effects of poisoning with *L. leucocephala*, depending on the variety of the tree, the amount of other fodder available, and the selection of the feed by the animal. Horses, sheep, and cattle are commonly affected, goats not so commonly.

Cattle and goats in Indonesia, Hawaii and the Virgin Islands, where the tree is indigenous, eat very large amounts of the plant without ill-effect. This immunity is due to the adaptation of ruminal microflora to degrade the mimosine, the degree of degradation varying with the diet, being much greater on a concentrate diet than on a roughage one. A transfer of rumen contents from resistant to susceptible cattle is a successful preventive veterinary procedure. The bacterium capable of degrading the toxins is *Synergistés jonesii*.\textsuperscript{15} In some areas, if ruminants are introduced to the plant gradually enough, the ruminal microflora may develop the capacity of metabolizing mimosine so that poisoning is not a problem.

Alopecia (depilation), commencing at the tail switch and the preputial orifice, and nervous signs are constant clinical findings. Inconstant signs are cataract, gingival atrophy, lingual epithelial ulceration, goiter, infertility, and low birth weight. In experimental animals, hepatic injury is one of the most marked effects, but this is not recorded in field cases.

In horses the loss of hair is most marked in the mane and tail, and around the hocks and knees. Ring formation in the hooves and emaciation also occur. In cattle and sheep shedding of hair or wool occurs soon (7–14 days) after the first exposure to the plant, when very large amounts are fed. The alopecia is not necessarily general but is symmetrical. Experimental feeding of large amounts of the plant to steers has been associated with hair loss especially on the tail, pizzle, and escutcheon. Cattle fed on the plant for long periods develop other chronic syndromes including incoordination, temporary blindness, and hyperactivity to the point of severely interfering with normal handling procedures. A secondary phase of poisoning is associated with the formation of DHP is recorded in some countries, but not others. It is characterized by enlarged thyroid glands, poor breeding performance and goitrous, weak calves. The goitrogenic effect is limited to ruminants, is associated with 3,4-DHP, and is not responsive to iodine administration. A further complication, seen in goats on low-level feeding over a long period, is fibrous osteodystrophy of the mandible, causing salivation, slow eating, and weight loss. The long bones are normal.

In pigs, the feeding of diets containing up to 15% of dried *L. leucocephala* to pregnant gilts is associated with a high proportion of fetuses being resorbed and some having limb deformities. Feeding 1% ferrous sulfate in the diet reduces these effects, and supplementation of the diet of ruminants with iron, copper, and zinc is also claimed to reduce the toxic effects. All toxic effects are quickly reversible by removing animals from access to the plants, so the case fatality rate is usually low. Necropsy lesions are limited to alopecia, oral and esophageal ulcers, and thyroid enlargement.

Animals grazing heavily on *L. leucocephala* are likely to have low blood levels of thyroxine, and high blood and urine levels of DHPs.\textsuperscript{16}
Pigs and cattle may be poisoned by *Senema occidentalis* seeds which contain prepared rations. All of these plants are associated with severe gastrointestinal symptoms. The dose is large and takes one at a time. Liver damage is also a common lesion in experimental and field cases and may dominate the necropsy findings. Smaller doses of *Senema* spp. over a period of a week are associated with necrosis of striated muscle fibers characterized by limb weakness, incoordination, dragging the hind toe tips, and eventually paralysis in sternal or lateral recumbency. Necropsy findings are cardiac and skeletal muscle necrosis, but these have not been shown to be direct effects of the anthraquinones.

**ARISTOLOCHINE**

This alkaloid occurs in:

- *Aristolochia bractea*
- *A. clatnitis* – birthwort
- *A. densiflora*
- *A. elegans*.

In goats, poisoning takes the form of diarrhea, dyspepsia, alopecia, and hindlimb weakness. In horses, signs include straining to urinate, passing small amounts of urine frequently, polyuria, and tachycardia.

**CANNABINOIDS**

Cannabinoids are resinoids found in the plant *Cannabis sativa* (marihuana). The toxic principle is the alkaloid tetrahydrocannabinol. Clinical signs of poisoning in horses include restlessness, hypersensitivity, tremor, sweating, salivation, dyspepsia, staggering gait, and death or recovery after a few hours. No significant necropsy lesions are recorded. Toxin is detectable in stomach (rumen) contents.

**COLCHICINE**

The alkaloid colchicine, found in *Colchicum autumnale* (autumn crocus) and *Gloriosa superba* (flame or glory lily), is associated with acute diarrhea, abdominal pain, tenesmus, vomiting, and salivation in sheep, cattle, and pigs. At necropsy, subcapsular hemorrhages and gastroenteritis are evident. Mortalities are likely when cattle graze dense patches of *C. autumnale* in pasture or are fed hay containing the plant. The toxin is excreted in the milk.

**CREPENYNIC ACID**

Necrosis of cardiac and skeletal muscle, manifested clinically by a staggery gait and recumbency, or sudden death during exercise, is the significant lesion in poisoning of sheep by crepennylic acid, which is found in mature seed heads of *Ixolaeena breviscopnta* (button weed).

**CYCAD GLYCOSIDES**

All cycads that have been investigated contain one or more glycosides of methyl-lazoxymethanol (MAM) known as cyscin, macrozamin, and pakoein. These include species of:

- *Bowiea*
- *Cycas*
- *Dioon*
- *Encephalartos*
- *Lepidodzamia*
- *Macrozamia*
- *Stangeria*
- *Zamia* – cycads or zamia palms.

These robust cone-bearing plants grow in greatest numbers in poor soil in hot climates, and their young leaves and seeds are eaten eagerly by ruminants when other feed is short. MAM glycosides are much more concentrated in seeds than in leaves. The MAM glycosides are hydrolyzed in the rumen. MAM is further metabolized to a highly reactive methylating agent in the liver, producing periacinar hepatocyte necrosis and damage to blood vessels leading to hepatic veno-occlusion. Long-term intake results in liver cirrhosis. The liver lesions result in anorexia, weight loss, jaundice, and photosensitization. In addition, acute poisoning is associated with hemorrhagic necrosis of the abomasum and small intestine in sheep and cattle, causing severe diarrhea. Sheep are more likely than cattle to consume seeds and develop hepatogastrointestinal MAM poisoning. Pigs and horses have been experimentally poisoned with seeds. MAM is mutagenic and carcinogenic in laboratory animals, but this effect has not been described under natural conditions.

An unidentified neurotoxin in *Bowiea*, *Cycas*, *Macrozamia*, and *Zamia* produces posterior ataxia in cattle, a syndrome recognized in Australia where it is called zamia staggerers, some Japanese islands, and in the Caribbean region. This is the most likely result of cattle consuming these plants under natural conditions; however, affected cattle often have some degree of chronic liver damage. This ataxia syndrome in sheep has been produced experimentally but is rare under natural conditions. Clinically, the condition is a proprioceptive defect affecting the hindlimbs causing an irregular, stiff, overextension (’goose-stepping’), and knuckling over at the fetlocks. Atrophy of hindlimb muscles and posterior paralysis may follow. There are degenerative lesions of the fasciculus gracilis, dorsal spino-cerebellar tracts, and corticospinal tracts of the spinal cord. Affected cattle do not recover.

**CYNANCHOSIDE**

Cynanchoside is found in *Cynanchum* spp. (monkey rope) and a very similar
toxin is found in *Marsdenia rostrata* (milk vine), *Sarcostemma brevipedicellatum* (= *S. australis* (caustic vine), and *S. stellata* (caustic bush). It is associated with hypersensitivity, restlessness, stumbling gait, tremor, recumbency, tetanic and clonic convulsions, and opisthotonos. Additional signs include teeth grinding, dyspnea, salivation, and vomiting.

**DIANTHRONE DERIVATIVES**

Hypericin is a complex derivative of dianthrone, and is found in *Hypericum perforatum* (St John’s wort or Klamath weed) and *H. triquetrum* is the prototypical primary photosensitizing agent. All parts of these plants are associated with photosensitive dermatitis when ingested by sheep and cattle, but have to be eaten in large quantities. They are not very palatable and most outbreaks occur when they are in the young stage and dominate the pasture. Narrow leaf varieties contain two or three times as much hypericin as broad leaf varieties, and the flowering tops are six to eight times as toxic as other parts.33 Clinical signs may appear within a few days of livestock going onto affected fields and usually disappear within 1–2 weeks after removal from them. Experimental production of poisoning with *H. perforatum* has shown that the plant contains a primary photodynamic agent. There is neither liver damage nor loss of hepatic function.

Fagopyrin, a red helianthrone pigment found in *Fagopyrum sagittatum* (buckwheat), is associated with primary photosensitization in all species.

**DIHYDROXYCOUMARIN GLYCOSIDE**

Toxins in the dihydroxycoumarin glycoside group are daphnetin and daphnin. Plants that contain them are:

- *Daphne* spp.
- *Pimelea* spp. (some only)
- *Gnidia* spp.
- *Wikstroemia indica* – tie-bush.

In some of *Pimelea* spp. the dihydroxy coumarin glycoside has been isolated. In most others its presence is suspected because of the similarity of the signs produced.

Clinical findings include abdominal pain, diarrhea, dysentery, stomatitis and salivation, and vomiting. Some cases have a short course and terminate fatally preceded by convulsions. Necropsy lesions include stomatitis and gastroenteritis. The clinical picture can be confused by the occurrence of simplexin (see under diterpene poisoning) in the same plant, in which case the signs of congestive heart failure are added.

In *Wikstroemia* spp. the alternative signs seen in red deer are those of a hemorrhagic disease, including mucosal pallor, bounding pulse, loud heart sounds, nasal bleeding, dysentery, and low erythrocyte count and hemoglobin level, platelet numbers are normal. Necropsy lesions include widespread hemorrhages and tissue pallor.

**DITERPENOID (KAURENE) GLYCOSIDES (ATRACTYLOSIDE, CARBOXYATRACTYLOSIDE, PARQUIN, CARBOXYPARQUIN, AND WEDELOSIDE)**

Diterpenoid glycoside toxins have been found in species of:

- Atractylis
- Atractylodes
- Callilepis
- Cestrum
- Iphiona
- Wedelia
- Xanthium.

*Xanthium strumarium* (cockleburr, Noogoora burr) includes the taxa *X. canadense, X. italicum, X. orientale, X. pungens, X. chinense,* and is poisonous to pigs and ruminants. *X. spinorum* (Bathurst burr) is also toxic and assumed to contain diterpenoid glycosides. The two cotyledonary leaves, either within the spiny burrs or just after sprouting, contain the largest amount of toxin and are the usual source of poisoning. The cockleburrs occur on most continents. Poisonings are reported from North America, UK, Europe, and Australia. Most deaths occur on flood plains where the weed is allowed to grow in abundance. After heavy rain the seeds in the burrs sprout and are palatable to all species, especially calves and pigs. Mortalities are also recorded in adult cows and sheep. Burrs may contaminate feed grains and poison livestock fed on the compounded ration.

*Centrum* spp., e.g. *C. parqui, C. laevigatum,* are garden plants originating from South and Central America which, except for *C. diurrum,* also contain a carboxyatractyloside toxin.

*Wedelia asperimenta* (yellow daisy), *W. bifiorda,* and *W. glauca* contain wedeloside. Severe hepatic necrosis is the principal necropsy finding, and the clinical syndrome and clinical pathology are characteristic of hepatic encephalopathy.

The disease in pigs and calves is an acute one, manifested by hypereexcitability, so that the entire herd appears restless, followed by severe depression, rigidity of the limbs and ears, weakness and a stumbling gait, falling easily and recumbency, and clonic convulsions with opisthotonos. Calves may be belligerent. Acute cases die during the first convulsive episode.38 The course may be as long as 48 hours and terminate in recovery, but death is the usual outcome. The characteristic lesion is hepatic necrosis.

Treatment is not undertaken. Control depends on keeping livestock away from pasture dominated by these weeds, especially when there are large quantities of sprouted *Xanthium* spp. seeds available.

**IRRITANT DITERPENOIDS**

The two important irritant diterpenoids are simplexin, an irritant diterpenoid daphnane ester found in *Pimelea simplex,* *P. trichochysta,* and others, and 12-deoxyphorbol found in *Euphorbia* spp. (spurges).

Poisoning by 12-deoxyphorbol is associated with a syndrome of stomatitis and enteritis. Cattle generally avoid leafy spurge (*Euphorbia esula*), apparently because they develop a conditioned aversion to it,39 but sheep and goats will graze it.

Simplexin is associated with a syndrome of congestive heart failure with diarrhea and anemia only in cattle in eastern Australia called St. George disease or Marree disease. Sheep and horses are resistant.

The disease in cattle associated with *Pimelea trichochysta,* *P. simplex,* *P. latifolia,* *P. elongata,* *P. neo-anglica* (desert rice flower, flaxweed, wild flax, mustard weed, broom bush) is characterized clinically by massive edema under the jaw and down the brisket, distended jugular veins, persistent diarrhea, anemia, loss of condition, and death. Ingested simplexin is associated with constriction of pulmonary venules, pulmonary venous hypertension, and right heart failure. Diarrhea is caused by direct irritation of the intestinal lining. Inhalation of the powdered plant is associated with the pulmonary-cardiac lesion only. There is also a severe anemia shown to be due to a significant hemolysis of unknown pathogenesis. The usual field picture is that cattle graze looking for feed between old, dry flaxweed plants and inhale it so that the pulmonary cardiac form is the common one and the commonest occurrence is in summer. Experimentally, it has been possible to produce two forms of the disease, the subacute with diarrhea, weakness, and anemia as the predominant signs, and the chronic form characterized by circulatory failure as evidenced by anasarca, hydrothorax, and cardiac dilatation.

Fatal necrotic gastroenteritis is produced by feeding *Pimelea* spp. to sheep and horses, but it is unlikely they would eat the plant in natural circumstances.

**FLUOROCETATE**

Plants containing toxic amounts of fluorocetate include:

- *Acacia georgiana* – Georgina gidgee (Australia)
Dichapetalum spp. (Africa)
Gastrolobium spp. (Australia)
Ozylobium spp. (some only)\footnote{27}
Palicourea spp. (South America)
Mascagnia spp. (possibly) (South America)
Spondianthus preussi (Africa)

The general syndrome appears about 12 hours after the toxic plant is ingested and includes sudden death without other signs, or hypersensitivity, frenzy, dyspnea, cyanosis, tachycardia with rates up to 300/min, cardiac irregularity, ataxia, recumence, and convulsions. Minor signs include moderate bloating, appearance of signs when animals are driven, and frequent micturition. Death may occur in a few minutes to several hours. Necropsy lesions include necrosis of myocardium, pulmonary congestion and edema, and generalized venous congestion.

In northern inland Australia, poisoning by Acacia georginae has been associated with heavy mortalities in cattle and sheep, and seriously reduced the productivity of large areas of grazing land. The fluorocacetate ion is concentrated in the young leaves and seed pods. At necropsy, there is congestion of the alimentary mucosa, flabbiness of the myocardium, and multiple subendocardial and subepicardial hemorrhages. There may be edema and congestion of the lungs. Gastrolobium spp. (42 species known or suspected to be toxic) are also sources of poisoning in Australia, mostly in the southwest, Palicourea and Mascagnia are responsible for many outbreaks in South America. Twelve Dichapetalum spp., e.g. D. cynumsum (Gifblaar), D. ruhlandii, D. barteri, are poisonous shrubs in Africa but also in the tropics generally. Their fresh green leaves contain fluorocacetate. Acetamide (2 g/kg) given experimentally soon after the ingestion of Dichapetalum spp. appears to have helped animals against the poison.

Similar to other organic fluorides, fluorocacetate is known to exert its effect by poisoning the enzyme aconitase leading to the accumulation of significant amounts of citrate in tissues and to irreversible cardiac damage. Native herbivorous mammals in south-western Australia have evolved a high level of genetic tolerance to this toxin and this has been used as a genetic marker to trace the evolutionary history of some of the continent's indigenous marsupials.

**FURANOCOUMARIN (FUROCOUMARIN)**

Plants containing furanocoumarins (including pсорalens) include:

* Ammi majus - bishop's weed, meadow sweet
* A. visnaga - visagna
* Coopersia pedunculata – thunder lily
* Cymopterus longipes
* Cyrtopodium longipes
* C. watsonii – wild or spring parsley
* Heracleum mantegazzianum – giant hogweed
* Petroselinum spp. – parsley
* Thannosma texana – Dutchman's breeches, blister weed.

Similar furanocoumarins, identified as 4,8-trimethylpsoralen, 5-methoxypsoralen, and 8-methoxypsoralen, are also present in *Pastinaca sativa* (parsnip root) infested with the fungus *Cercospora fimbriata*, and *Atripium graveolens* (celery) infested with *Selortina* spp. (pink rot fungus).\footnote{38} These toxins have the particular characteristic of being photosensitizing by contact, without the need for ingestion, and are associated with serious lesions in humans. *Ammi majus* is most poisonous to livestock when there are ripe seeds in the seedheads. Its most serious occurrence is as a contaminant in hay.\footnote{39} *Coopersia pedunculata*, a perennial forb of western range country in the United States occurs at times of high humidity or after rain has wet the foliage, and the live as well as dead leaves are toxic.

The clinical syndrome is associated with plants containing furanocoumarins is one of photosensitizing dermatitis. It includes severe cutaneous dermatitis, sometimes as severe as cutaneous gangrene, on the white parts of the skin on the dorsal and lateral sides of the body, edema of the head and ears, and the lateral aspects of the teats, the unpigmented conjunctivae, muzzle and the oral mucosa inside the lower lip, and the underside of the tip of the tongue. Photosensitive dermatitis in pigs may be associated with distinctive vesicles on the snout and raise a false alarm of viral vesicular disease. One serious international incident arose out of a feeding of moldy parsnips.

**GALEGINE**

Galegue, an isoprenoid guanidine, is found in:

* Galega officinalis – French honeysuckle
* Schoenus asperocarpus – poison sedge (Australia)
* S. rigens (Australia)
* Verbesina encelioides – crown beard (North America and Australia)

It is associated with a syndrome of severe dyspnea, frothing from the nose, convulsions, and sudden death in ruminants due to pulmonary edema with large fluid accumulations in the thoracic cavity, the result of a direct effect on pulmonary vascular permeability.\footnote{40} Sheep may find access via these plants being mixed in with hay or amongst a standing crop.\footnote{41}

**IFORESTINE**

Iforestine, a heterocyclic nephrotoxin in six *Isotropis* spp. lamb poisons, e.g. *I. forrestii*, *I. atropurpurea*, and *I. cuneifolia* is associated with severe renal damage and uremia in cattle and sheep.\footnote{42} Clinical signs include anorexia, depression, diarrhea, oliguria, anuria, recumbency, and death. Proteinuria and glycosuria are constant and there is severe renal tubular necrosis.

**ISOQUINOLINE ALKALOID**

**Berberine**

A pyridine alkaloid, a subgroup of the isoquinoline alkaloids, occurs in the weeds:

* Argemone mexicana – Mexican poppy
* A. ochroleuca
* A. subfusciformis
* Berberis spp.
* Mahonia spp.

The clinical syndrome in cattle and pigs includes weight loss, dyspnea, and subcutaneous edema. Diarrhea, abdominal pain, and recumbency are also recorded. At necropsy the principal lesion is cardiomyopathy accompanied by fluid in body cavities and pulmonary edema, and gastroenteritis in some cases. The toxic effect of *A. mexicana* seeds may be due to their total content of isoquinoline alkaloids rather than to their berberine content.\footnote{43}

**Bulbocapnine**

An isoquinoline alkaloid found in *Corydalis flavula* (fitweed, fumatory) and *Dicentra spectabilis* (bleeding heart) and is associated with a transient syndrome of tremor, tetanic convulsions, frenzy, including biting at surrounding objects, opisthotonos, drooling of saliva, and vomiting in grazing ruminants. Some patients die during the first episode.

**Chelidonine**

A toxic isoquinoline alkaloid found in *Chelidonium majus* (greater celandine or celandine poppy) is associated with a syndrome of gait incoordination, dribbling urine, drooling saliva, and convulsions in cattle, especially if they are harassed.

**Corydaline**

An isoquinoline alkaloid found in *Corydalis caseana* (fitweed) and is associated with acute diarrhea, frenzy and excitement exacerbated by harassment, clonic convulsions, and a quick death in grazing animals. The same toxin in *Dicentra cucullaria* is associated with a similar syndrome except that vomiting occurs and diarrhea is not recorded but gastroenteritis at necropsy is.

**Unspecified isoquinolines**

Found in *Eschscholtzia californica* may be associated with poisoning.

**JUGLONE**

A poisonous resinoid found in the shavings of *Juglans nigra* (black walnut tree) has been suspected as being associated with lameness and edema of the
lower limbs in horses bedded on the shavings, but jugleone is present in the bark and leaves, not the heart wood from which the shavings are made. The lesions are produced by an increase in local capillary blood pressure.

A similar syndrome is associated with Berteroa incana (hoary alyssum). Signs appear 18–36 hours after ingestion of the plant, and disappear 2–4 days after the plant is removed. Fever and red urine are additional signs seen in some cases. An alternative syndrome of severe gastroenteritis plus intravascular hemolysis is also recorded in horses fed hay contaminated by Berteroa incana.

JUNIPERINE
An alkaloid, juniperine, occurs in Juniperus spp. trees and is reputed to be associated with nephrosis, cystitis, and rumenitis when eaten. Signs include abdominal pain, diarrhea, proteinuria, elevation of blood urea nitrogen (BUN) levels, and abortion.

LECTINS (TOXALBUMINS)
Lectins are very important glycoproteins in human nutrition because of their occurrence in common foods. They are associated with damage to the gut epithelium, leading to defective digestion and absorption, and to increased permeability of the intestinal mucosa. They are of minor importance in animals. The toxins are present in foliage and seeds but are concentrated in the latter. Recorded occurrences are of nephrosis and hepatitis in ruminants. The clinical syndrome includes inappetence, vomiting, diarrhea, and sometimes dysentery, dyspnea, dehydration, rapid weight loss, recumbency, and death in most cases. Serum liver enzymes and BUN and creatinine levels are elevated. Necropsy lesions include abomasal, intestinal erosions, hepatocyte necrosis, and renal tubular injury, pulmonary edema, degenerative changes in myocardium and other organs and in some cases in the brain. Pyridoxine is a satisfactory antidote even if signs have already appeared.

IRRITANT OILS
Irritant oils in plants are associated with gastroenteritis, with salivation, oral mucosal lesions, abdominal pain, diarrhea, and sometimes dysentery. Plants known to contain these oils include:

- Actaea spicata – baneberry
- Artemisia filifolia
- Barbarea vulgaris – yellow rocket
- Bryonia dioica – white bryony
- Croton spp. – croton
- Cryptocarya pleurosperma
- Dittidichrom graevens – (stinkwort)
- Imda conya – ploughman's spikenard
- Sambucus spp. – elders, elderberry.

Bryonin is an irritant oil found in the roots and seeds of Bryonia dioica (white bryony or British mandrake) and is associated with a syndrome of depression, dyspnea, diarrhea, polyuria, stumbling gait, tremor, recumbency, and convulsions. Sweating, agalactia, and sudden death are also recorded.

PLANT PHENOLS (POLYPHENOLS, CALLED ALSO PHENOLICS)
Two groups of plant phenols (hydroxyl containing materials): one, lignins, are important in human nutrition because of their absorption, and to increased permeability of the intestinal mucosa. They are of minor importance in animals. The toxins are present in foliage and seeds but are concentrated in the latter. Recorded occurrences are of nephrosis and hepatitis in ruminants. The clinical syndrome includes inappetence, vomiting, diarrhea, and sometimes dysentery, dyspnea, dehydration, rapid weight loss, recumbency, and death in most cases. Serum liver enzymes and BUN and creatinine levels are elevated. Necropsy lesions include abomasal, intestinal erosions, hepatocyte necrosis, and renal tubular injury, pulmonary edema, degenerative changes in myocardium and other organs and in some cases in the brain. Pyridoxine is a satisfactory antidote even if signs have already appeared.

LYCORINE
Lycorine, an alkaloid found in the bulbs or roots of many garden plants, e.g. Amaryllis, Clivia, Lycoris, Narcissus, and Nerine spp., is associated with salivation, vomiting, and diarrhea when eaten.

4-METHOXYPYRIDONE
4-Methoxypyridone, a pyridoxine analog found in Albizia spp. (A. versicolor, fever tree), Albizia tanguyensis (paperbark albizia), especially in the dried pods is a cardioton. Clinical signs in cattle include hypersensitivity, hyperthermia, dyspnea, ataxia, and tetanic convulsions with rapid blinking and nystagmus. Most cases recover spontaneously. Cardiomyopathy is the diagnostic necropsy finding. Lesions also include petechiation in many tissues, pulmonary edema, degenerative changes in myocardium and other organs and in some cases in the brain. Pyridoxine is a satisfactory antidote even if signs have already appeared.

Gossypol ETIOLOGY
Gossypol, a poisonous phenolic substance present in variable amounts in cottonseed cake made from the seeds of Gossypium spp. and hybrids (commercial cotton), and in the seeds and their hulls, is associated with damage to the myocardium and liver. Toxic meal usually contains 300–400 ppm but may contain as much as 18,000 ppm of free gossypol in a 17% protein ration.

CLINICAL PATHOLOGY
Elevation of serum sorbitol levels is the best laboratory indicator of gossypol poisoning; levels of 18 units/L in normal calves are elevated to 34 units/L in poisoned ones. Thoracic radiographs will demonstrate the presence of fluid, which can be examined for protein content after collection via paracentesis.

CONTROL
Cottonseed cake may be fed with safety to adult cattle provided the daily intake of meal containing = 1000 ppm of gossypol is less than 10–12 kg, and to pigs provided it constitutes less than 10% of the ration, or in large quantities if the material is detoxified. Cooking of the cake or the addition of 1% calcium hydroxide or 0.1% ferrous sulfate to it are efficient methods
of detoxification. In experimental trials the addition of iron in equal proportions to gossypol up to 600 mg/kg of the ration will protect pigs. Significant quantities of cations (particularly calcium and iron) in water supplies or rations appear to be protective. Providing calcium carbonate at a rate of 12 g/kg of whole cotton seed (WCS) for every 0.5% of free gossypol in the WCS prevents reproductive effects in cattle.60

Tannins

These include the condensed tannins (protoanthocyanidins), which are insoluble and non-toxic, except that they may be associated with oral mucosal lesions, and the hydrolyzable tannins, which are soluble and potentially toxic; pyrogallol, a degradation product of hydrolyzable tannins is hepatotoxic and nephrotoxic. Oaks (Quercus spp.) and yellow-wood tree (Terminalia oblongata ssp. oblongata) are important in this group. Miscellaneous other toxic plants in this group include:

- Acacia melanoxylon - black wattle
- A. salicina - black sally wattle
- Cidemia hirtia - harendong
- Elephantorrhiza elephantiina
- Stryphnodendron spp.
- Thilosa glaucocarpa - sipauba, vaqueta
- Ventilago viminalis - supple jack.

Oak (Quercus spp.)

The leaves and windfall acorns61 of many varieties of oak trees, including Q. robur (synonym Q. pedunculata, European oak) Q. havardii (sand shin oak), Q. marilandica (blackjack oak), and Q. garryna, are browsed by animals and are associated with no illness when they form only a small part of the diet. The toxic principles are hydrolyzable tannins and simple phenols in the leaves, especially the young buds. All species of animals are affected, losses in sheep and cattle being reported most commonly, with occasional cases occurring in horses. Goats are thought to be capable of surviving much greater intakes of tannin than cattle because of greater concentrations of tannase enzymes in their ruminal mucosa. Experimental administration of tannic acids to goats has produced anemia, but there is no record of the natural occurrence of the disease.

If little else is eaten, oak foliage and acorns may be associated with nephrosis manifested by polyuria, ventral edema, abdominal pain, and constipation followed by the passage of feces containing mucus and blood. Blood urea nitrogen (BUN) levels are elevated, the specific gravity of the urine is low and there is proteinuria. At necropsy there is edema of the gastrointestinal wall and mesentery, a characteristic nephrosis and hepatic damage.61 There may also be ulcerations of gut wall consistent with the presence of uremia. Survivors of an initial attack of nephrosis make compensatory weight gains and perform well in situations like feedlots.62

Extensive areas of oak-brush range in the United States can be utilized for cattle grazing, but require careful management if losses are to be avoided. The phenol content varies between species so that stands of Q. alba can be much less toxic than those of Q. rubra or Q. velutina. Calcium hydroxide (15% of the ration) is an effective preventive under experimental conditions.

Yellow-wood tree (Terminalia oblongata ssp.)

The foliage contains a hepatotoxic tannin punicalagin63 and an unidentified nephrotoxin, and is associated with losses in cattle. Acute poisoning of cattle is manifested by a sudden onset of hepatopathy/jaundice/photosensitization with some nephrosis and signs of abdominal pain and dehydration. Necropsy reveals a swollen congested liver, swollen gray-green kidneys and gray-green pigmentation of the gastrointestinal mucosa with multiple small hemorrhagic erosions of the abomasal mucosa. Chronic poisoning of cattle is dominated by severe nephrosis with pigment accumulation and fibrosis in the kidney cortex, polyuria, and wasting of the body. Yellow-wood poisoning of sheep is a nervous derangement, manifested by seizures if sheep are excited by handling, and from which they recover spontaneously.

Piperidine alkaloids

ETIOLOGY

The important, identified piperidine alkaloids include coniine, cyanopine, nicotine, and lobeline. The diseases they produce are set down below.

Conium

Conium maculatum (poison hemlock) contains five major acetate-based piperidine alkaloids - conine, N-methylconine, conhydrine, pseudoconhydrine, and γ-coniceine - and a number of other, lesser, alkaloids. γ-Coniceine is probably a precursor of the others, and is much more toxic. The concentration of each of the alkaloids in different parts of the plant, in different climates, and at different times of the year is very variable. For example, at the dormant stage the concentration of the γ-coniceine is high in the fruits when they are formed, but there is no significant content in the roots. In the dormant stage the toxicity of the roots is very high.

EPIDEMIOLOGY

The weed occurs in most parts of the world. All animal species are affected, with cattle, sheep, goats, horses, and pigs showing the nervous form of the disease. Poisoned cattle, pigs, and sheep also produce deformed offspring, with ewes being much less susceptible than cows and sows. Grazing animals are poisoned by eating the standing plant, the seeds or roots at the appropriate time of their development. The plant may also be fed in hay or green feed or the seeds may contaminate harvested grain. Milking cows secrete the alkaloids in their milk.

PATHOGENESIS

The alkaloids are associated with two modes of poisoning, paralysis of skeletal muscle by blocking transmission at neuromuscular junctions and by acting as teratogens. All of the major alkaloids are associated with the acute disease. Only conine and γ-coniceine are known to be teratogenic. Teratogenesis is effected through reduced fetal movements in utero.64

CLINICAL FINDINGS

In the acute, nervous form of the disease signs include tremor, staggery gait, knuckling of fetlocks, frequent belching, sometimes with vomiting, frequent urination and defecation, drooling of saliva, tachycardia, and pupillary dilation. In cows and sows there is also prolapse of the nictitating membrane, and in cows there is a characteristic mousy odor of the milk and urine of affected animals. The course in cattle, goats, and horses is a few hours only and terminates in recumbency and death by respiratory paralysis, without convulsions. Sheep are least affected and recovery is common.65

Serious congenital deformities, including carpal flexure, limb malalignments, scoliosis, and torticollis, occur in piglets and calves. Lambs have similar, but lesser, defects and in many cases they are temporary, disappearing in the first few weeks after birth. By ultrasound scanning the fetal movements of lambs in ewes treated with C. maculatum can be seen to reduce significantly for a short period. At birth some of the lambs will have limb deformities and kinked tails, all of which recover spontaneously.66 Cleft palate, sometimes with hare lip, is also a common accompaniment in calves and piglets but not in lambs or foals. The sensitive period of the pregnancy, during which the fetus is susceptible to the teratogen, is day 55–75 for calves, day 30–53 for sows, and day 30–60 for lambs.

The piperidine alkaloids of C. maculatum, Nicotiana lunare and the quinolizidine alkaloids of Lupinus spp. are all teratogenic to goat does in the 30–60-day period of pregnancy. The carpal, tarsal, and fetlock joints are fixed in flexion or extension and the spinal column is deformed with scoliosis, lordosis, or torticollis, and there are deformities of the rib cage.67
NECROPSY LESIONS
Other than the fetal abnormalities, neither significant necropsy nor clinico-pathological findings are recorded.

Cynapine
Cynapine, a piperidine alkaloid found in Aethusa cynapium (fool’s parsley, lesser hemlock) is associated with dyspnea and gait incoordination in cattle, goats, and pigs.

Nicotiana
The commonly poisonous members of the tobacco family of plants are:
- *Nicotiana tabacum* – commercial tobacco
- *N. attenuata* – wild tobacco
- *N. exigua*
- *N. glauca* – tree tobacco
- *N. megalosiphon*
- *N. trigonophylla* – wild tobacco
- *N. velatina*.

The principal toxins include nicotine, anabasine, and anagyrine. Other alkaloids occurring in *Nicotiana* spp., but which are not recorded as having poisoned animals, are nomicotine and anatabine. Other plants containing these alkaloids include *Duboisia hopwoodii* (pitiuri). Several alkaloids may be present in the one plant but most plant species have a particular alkaloid that predominates. The concentration of the alkaloid varies between parts of the plant, and between different stages of growth. There are two forms of intoxication. Anabasine is a teratogen and the feeding of stalks of *Nicotiana tabacum* to pregnant sows, 10–48 days pregnant and *N. glauca* to cows, 40–75 days pregnant, is associated with the congenital defects of the nervous system. The leaves and bark of *N. glauca* contain more teratogen than the woody parts. The feeding of *N. glauca* to sows also is associated with cleft palate in their offspring. Fed to pregnant ewes this plant is associated with lambs being born with cleft palates, flexed limb joints, rotation of limb joints, and lordosis. The ewes show hypersalivation, ataxia, recumbency, and death. Acute poisoning of livestock ingesting *Nicotiana* spp. or *Duboisia hopwoodii* is associated with muscle tremor, weakness, incoordination, pupil dilation, recumbency, with limb paddling progressing to paralysis. There may be diarrhea.

**POISONING**
Poisoning by *Trachymene* spp. (wild parsnip) in ruminants is thought to be associated with a conium piperidine alkaloid. The syndrome includes sudden death, gait incoordination stimulated by harassment, acute diarrhea in some cases, and congenital limb deformity. Limb deformities also occur after birth in lambs 8–16 weeks old grazing on *T. glauca* (wild parsnip), *T. ochracea* (white parsnip), and *T. cyanantha*. Heifers and calves are not affected. There is outward bowing of all four limbs, most obvious in the pectoral limbs. Ewes preferentially graze the plant when it is in flower and their fetuses will be deformed. The deformity is reversible in milder cases.

**CLINICAL FINDINGS**
In the nervous disease, affected animals may develop dyspnea and depression, followed by coma and death without a struggle. More acute cases have convulsive episodes in which they are dyspneic and staggery, and show frothing at the mouth, clonic convulsions, and grinding of the teeth. A more prolonged disease is reported in cattle poisoned experimentally with *T. montana*. There is anorexia, depression, edematous swelling of the eyelids, tremor, a stilted gait, arching of the back and a tucked-up abdomen, rough hair coat, and prolonged recumbency.

**PATHOLOGY**
High blood levels of serum glutamic-oxaloacetic transaminase (SGOT), creatinine phosphokinase (CPK) and lactic acid dehydrogenase (LDH) are accompanied by a severe myopathy. The possibility of a myopathy being associated with lupins has been raised because the prevalence of enzootic muscular dystrophy appears to be much higher on lupin than on other pasture. Lupins are low in selenium and vitamin E content, and classical white muscle disease may also occur. Histological and biochemical examination of affected calves discount myopathy as the primary lesion. In poisoning by *Cytisus* spp., both
C. laburnum (laburnum) and C. scoparius (broom) are associated with fatalities.

**Teratogenic quinolizidine alkaloids**

The best known congenital defect is crooked calf disease, recorded only in the western United States, Kodiak Island, Alaska, and Canada in cows grazing *Lupinus sericeus* or *L. caudatus* in the 40th–120th day of pregnancy. The cause is the neurogenic quinolizidine alkaloid anagyrine, which has been identified in potentially teratogenic concentrations in *L. formosus* and *L. arboresus*, and are toxic when levels in the feed exceed 1.44 g/kg dry matter. In some cases the alkaloid may be contained in an aphid, *Aphis oracuvovis*, infesting the plant. Teratogenesis is effected by reduction of fetal movement in utero. Only cattle are affected.

**CLINICAL SIGNS**

Affected calves have arthrogryposis, with excessive flexure, malpositioning, malalignment, and rotation of limbs, principally the forelimbs at the elbows and carpal joints, or scoliosis and torticollis, or both. Clef palate is an occasional occurrence. The flexion of the joints is severe and may be associated with difficulty at calving. Surviving calves cannot stand to suckle, do not improve after birth, and have to be killed.

**DIFFERENTIAL DIAGNOSIS**

The defects are similar to those recorded in calves after poisoning of cows by *Nicotiana spp.* or *Conium maculatum*, or a nutritional deficiency of manganese. Similar defects occur after poisoning with the lathyrogen, aminoacetonitrile. Although the classical deformities are associated with anagyrine are not recorded in lambs, hemmelia has been recorded in lambs from ewes fed on *L. cosentini*.

**CONTROL**

This can only be achieved by arranging calving to occur when the lupins are not in a heavy growth stage at the same time as the cows in the herd are in the dangerous phase of 40–120 days pregnant.

**RHODEADINE**

Rhodeadine is an alkaloid found in the seed capsules of *Papaver rheas* (field poppy), and probably *P. nudicaule* and *P. sommerfurus*, which is associated with restlessness, hypersensitivity, ataxia, ruminal stasis, dyspnea, and convulsions, but no significant necropsy lesions.

**SAPONIN POISONING**

Saponins are naturally occurring glycosides with the physical properties of soaps; that is they produce a stable froth in water. They have a bitter taste. They also lyse erythrocytes in vitro. There are two classes of saponins, those with a triterpene aglycone radical and those in which the non-sugar radical is a steroid.

**Triterpene saponins**

In plants, almost all saponins are concentrated in the rapidly growing shoots, the bark and the roots, and are thought to have an insect-repellent role in these sensitive areas of the plant. They are absorbed very slowly, if at all, from the alimentary tract and it seems unlikely that they will exert any systemic effect unless there is pre-existing damage to the intestinal mucosa. Notwithstanding this, a great deal of research has been done on the systemic pharmacological effects in humans of plant pharmacologics such as ginseng.

Knowledge of the toxicity of triterpene saponins for animals is scappy. The principal pathogenic effect is enteritis and gastroenteritis, manifested by diarrhea and dysentery. Other less common signs include abdominal pain, vomiting, and salivation. Plants known to have this effect are:

- *Agrostemma githago*
- *Aleurites fordii*
- *Dialypsis africana*
- *Guttierrezia microcephala*
- *Hedera helix*
- *Jatropha curcas*
- *J. hyssopifolia*
- *Phytolacca americana*
- *P. dioica – pakalacaca*²¹
- *P. dodecantha*
- *Saponaria officinalis*
- *Sesbania spp.*
- *Bubuessa sarmentitii* (Palas santo tree) seed pods and foliage contain an unspecified toxic saponin that is associated with convulsions, licking of forelimbs, geophagia, chewing movements, ruminal atony, bradycardia and frequent urination, and defecation. The bitter taste of saponins may result in a decrease in feed intake and a reduction in growth rate in monogastric animals.

**Steroidal saponins**

These are associated with Scandinavian photosensitization disease (alveld) and occasionally nephrosis in ruminants²²,²³; they occur in:

- *Agave lechequilla*²⁴
- *Brachiharta decumbens grass*²⁵,²⁶
- *Kochia scoparia* – summer cypress
- *Narthecium ossifragum* – also associated with alveld
- *Panicum* spp. grasses
- *P. schinzi*²⁷
- *P. miilageum* – French millet
- *P. coloratum* – kleingrass²⁸
- *P. dichotomiflorum* – smooth witch grass²⁹
- *Tribulus terrestris*.

Other *Panicum* spp. grasses which should now be on the suspicious list for this kind of poisoning are:

- *P. decompositum*
- *P. efferuum*
- *P. maximum*
- *P. queenslandicum*
- *P. whitei*.

Birefringent crystals composed of the glucuronides of epimulagenin and epi­sarsasapogenin formed from an ingested saponin accumulate in the biliary system, blocking it and causing damage to it and surrounding hepatocytes. Jaundice, photosensitization, and hepatitis result.³⁰ Blockage of the bile canaliculi and bile ducts, and cramping of hepatocytes, Kupffer and renal tubules cells by acicular crystals and cloths are characteristic. Necrosis of the distal renal tubules, papillary muscles of the heart, and the adrenal cortex are accompanying lesions.³¹ Other steroidal saponins are present in *Tribulus terrestris*, but appear to be non-lithogenic.

**SELENOCOMPOUNDS**

Organic selenocompounds occur in two classes of plants which preferentially accumulate selenium, primary converter or indicator plants that grow only in soils with abnormally high selenium content, and secondary converters that grow anywhere but accumulate selenium if it is available. Primary converters are more toxic, attaining levels of greater than 1000, and up to 10 000 ppm. Secondary converters reach levels of about 1000 ppm.

Primary converters include:

- *Astragalus spp.* – milk vetch
- *A. bisulcatus*
- *A. pattersonii*
- *A. proelenges*
- *A. pectinatus*
- *A. racemosus*
- *Oenopis condensata* – goldenweed
- *Stanleya pinna* – prince’s plume
- *Xylorhiza* spp. – woody aster.

Secondary selenium indicators include:

- *Acacia cana*
- *Aster spp.* – woody aster
- *Astragalus spp.* – poison vetch
- *Atriplex canescens* – saltbush
- *Castilleja spp.*
- *Comandra pallida*
- *Grindelia squarrosai*
- *Machaeranthera ramosai*
- *Morinda reticulata*
- *Neptunia amplexicaulis*
- *Penstemon spp.*
- *Sideranthus spp.* – ironweed.
Clinical findings include the common, acute form with signs of aimless wandering, circling, apparent blindness, headpressing, dyspnea, lameness and recumbency, teeth grinding and salivation. The chronic form is characterized by alopecia, weight loss, coronitis, hoof deformity, and hoof shedding in all species, including pigs. Assay of selenium in the feed is usually necessary to confirm the diagnosis. Daily intakes of more than 30 ppm are usual in the subacute form. In chronic cases the intake is usually below this level and has been maintained for some months.

Necropsy findings are non-specific and include hepatic, myocardial and renal injury, and erosion of joint cartilages.

**SESQUITERPENES**

Sesquiterpenes are common plant poisons. Subgroups of them are listed elsewhere in this chapter, are:
- furanoid sesquiterpenes
- ipomeanols
- ngaiones
- sesquiterpene lactones
- sporidesmins.

Unspecified sesquiterpenes are also listed as being associated with other poisonings. For example, *Flourensia cernua* and *Vernonia* spp. is associated with heavy losses in South America and Africa due to hepatic necrosis in grazing ruminants. Affected animals show non-specific signs of anorexia, ruminal atony, hypothermia, staggering gait, recumbency, and convulsions. Serum levels of liver enzymes are elevated, accompanying a massive liver necrosis.

**Furanoid sesquiterpenes (furanosesquiterpenoids) poisoning**

Furanosesquiterpenoids, including ngaione and myodesmone, are essential oils in:
- *Losospernum bipinnatum* – ganskweed
- *Myoporum* spp. – boobirola
- Ellangowan poison bush, etc.

Ingestion of these plants usually is associated with jaundice, photosensitization, ruminal stasis, constipation, tenesmus, and abdominal pain. Necropsy findings are limited to hepatic necrosis, jaundice, and photosensitive dermatitis. Ingestion of *L. bipinnatum* by lambs also is associated with the same hepatic insufficiency syndrome, but the same plant from a different part of a farm may be associated with pulmonary and mediastinal emphysema and interstitial pneumonia reminiscent of the ipomeanols. The fungi *Ceratoxystis* spp. is associated with the same problems as *L. bipinnatum*. The following are associated with acute hepatic injury and deaths in ruminants:

- *Myoporum laetum* – ngaio tree
- *Eremophila deserti* (= *M. deserti*) – Ellangowan poison bush
- *M. tetrandrum* – Australian boobirola
- *M. sp. aff. insulare.*

**Ipomeanol**

Ipomeanols are produced in sweet potatoes in response to infection by the fungi *Fusarium solani*, *F. oxysporum*, *F. javanicum*, and *Ceratostomella fimbriata* and are associated with pulmonary emphysema and edema and interstitial pneumonia when fed to animals. Ipomeanols are also suspected of being associated with the poisoning of *Perilla frutescens* (purple mint weed) and *Zieria arborescens* (stinkwood tree). *P. frutescens* is toxic only after the plant has flowered and then loses its toxicity once it has been wilted by frost. Cases appear in calves 3–12 days after they begin eating the plant. Pulmonary edema develops because of damage to endothelial cells and young pneumocytes.*Z. arborescens*, a small tree in Tasmania and eastern Australia, is associated with interstitial pneumonia in cattle, and the disease is reproducible by feeding the foliage. Clinical signs appear as tachypnea, abdominal, grunting respiration with extension of the head, mouth breathing, and a nasal discharge. In bad cases the temperature and pulse are elevated. Most cases die after an illness of 1–21 days. Necropsy lesions include massive pulmonary edema and emphysema.

**Sesquiterpene lactones**

There are very many plant lactones suspected of being poisonous. Plant genera known to owe their toxicity to their content of sesquiterpene lactones include *Centarea* spp., (especially *C. repens*, *C. solstitialis*), *Chrysanthemum* spp., which are associated with contact dermatitis, *Geigeria* spp., *Helenium* spp., *Hymenoxys* spp., *Iphona acheri* and *Parthenium hysterophorus* (parthenium weed).

**Vomiting syndrome**

*Geigeria*, *Helium*) and *Hymenoxys* spp. poisonings in cattle are associated with a syndrome of regurgitation (swallowing sickness, vermeersiakte), salivation, dysphagia, and coughing. An ELISA is available for the quantitative detection of the sesquiterpene lactone dihydrogriesenin in *Geigeria* spp. Contrast radiography of the esophagus, and biopsy of skeletal and esophageal muscle are helpful in diagnosis. Dietary supplements used to prevent poisoning by sesquiterpene lactones, including a soybean meal–sodium sulfate combination, are useful provided they add thiol groups to the ration. Urea potentiates the poisoning.

**Encephalomala cia syndrome**

*Centarea solstitialis* (yellow star thistle) and *C. repens* (Russian knapweed) poisoning in horses is associated with a well-known syndrome of severe depression, constant chewing movements, salivation, tongue flicking, dysphagia, intestinal bloating, paralysis, recumbency, and death. Yawning and somnolence are evident but the horse is easily aroused. Some horses show aimless, slow walking and, in the early stages, transient circling. The gait is not grossly abnormal, a slight stiffness at the walk being the only abnormality except for weakness in the terminal stages. A fixed facial expression is common, the mouth being held half-open or the lips drawn into a straight line. Wrinkling of the skin of the lips and muzzle and protrusion of the tongue are present in many cases. Signs fluctuate in severity for 2–3 days and then remain static until the animal dies or is destroyed. Nigropallidal encephalomala cia and fluid accumulations in body cavities are characteristic necropsy lesions. Areas of necrosis or softening are visible macroscopically in the brain, in the globus pallidus and substantia nigra. The lesions are bilateral in most cases.

The plants do not appear to be toxic to ruminants, rodents, or monkeys and sheep do well on sole diets of the plants.

**STERoidal (SOLANUM SPP.) ALKALOIDS**

*Solanum* spp. plants contain many poisonous glycosidic steroidal alkaloids including solanidine, soladulidine, solasodine, tomatidine, etc. The best known plants in the group include:

- *Solanum bonariensis*
- *S. dulcamara*
- *S. elaeagnifolium*  
- *S. esuriale*
- *S. fastigiatum*
- *S. kwebense*
- *S. pseudocapsicum* (nightshades)
- *S. tuberosum* (potato – sprouted).

The other important member of the genus is *S. malacoxylon* the principal association in enzootic calcinosis. *Lycium halimifolium* and *Lycopersicum esculentum* (tomato) are also listed as containing these alkaloids.

Acute poisoning with steroidal alkaloids, associated with large doses, appears in experimental animals as a syndrome of gastroenteritis, with diarrhea and necropsy lesions of mucosal necrosis in the stomach and intestines. Subacute poisoning with smaller doses, which are not associated with an enteric lesion but are absorbed, is associated with nervous signs of exercise induced gait incoordination, easy falling, a straddled gait, nystagmus and convulsions with opisthotonos, complemented in some...
cases by cardiac irregularity, hemolysis, and sometimes diarrhea. Records of necropsy lesions include only occasional references to the presence of encephalomalacia and cerebellar gangliosidoses associated with the incoordination syndromes. Solanum escuriale has been suggested as being associated with humpy back, a common disease in sheep in Australia, but the association is unproven.\(^9\) On forced exercise affected sheep show gait stiffness in the hindlimbs with shortness of steps. This is followed by an inability to keep walking and the adoption of a peculiar hump-backed stance. The disease occurs only in summer in full-wooled sheep. At necropsy, there is degeneration of spinal cord tracts. In the United States \(S.\) diminutum is associated with a 'crazy cow syndrome' of staggering and incoordination, with a selective loss of Purkinje cells from the cerebellum. A similar syndrome is associated with \(S.\) kewense in South Africa, one by Brunsfelsia pauciflora,\(^9\) one by \(S.\) cinereum in goats in Australia,\(^9\) and one by \(S.\) fastigiatum var. fastigiatum in Brazil.\(^9\) The latter appears to be an acquired gangliosidosis. It is characterized by cytoplasmic membranous bodies in the Purkinje cells and a syndrome identical to that described above for subacute poisoning with steroidal \((Solanum\) spp.) alkaloids. After an attack lasting up to 60 seconds, the animal returns to normal. Affected animals do not recover but do not die unless by misadventure. The animals can be provoked to have an attack by raising their heads, or by holding them in lateral recumbency and then letting go. It is probable that these are not true 'convulsive' diseases but cerebellar incoordinations in which frantic efforts by a seriously ataxic animal give a superficial resemblance to convulsive episodes. It is also probable that the lesions in this disease are not associated with steroidal alkaloids but with \(\beta\)-carbolines. Other plants, e.g. \(S.\) fastigiatum var. acicularium and \(S.\) bonariensis, also appear to be associated with this disease.

Potatoes are toxic only if they are green and sprouted and the toxic alkaloid solanine is concentrated in those parts; potatoes must constitute more than 50% of the diet before toxicity occurs. Pigs are most commonly affected but all species are susceptible. In pigs there is dullness, copious diarrhea, anorexia, hypothermia, and coma in the terminal stages. The mortality rate may be high. In horses the signs include depression and prostration but usually there are no signs of alimentary tract irritation. In cattle dermatitis, comprising vesicles and scabs on the legs, is a more common syndrome. At necropsy in all species there is a moderate hyperemia of the alimentary mucosa. Sprouted or diseased potatoes can be fed safely if they are boiled and the amount fed restricted to less than 25% of the diet.

Some of these plants also contain specific teratogenic steroidal alkaloids which contain \(\alpha\)-piperidine moiety. The plants, in decreasing order of toxicity in terms of producing craniofacial deformities in laboratory animals\(^9\) are:

- \(S.\) elaeagnifolium
- \(S.\) saccharoides
- \(S.\) dulcanara
- \(S.\) melongena
- \(S.\) tuberosum.

### STRYCHNINE

Strychnine poisoning is an uncommon occurrence in farm animals and is usually associated with accidental overdosing with strychnine preparations, or accidental access to grain treated with strychnine and used to be provided for rodent control. Cattle are particularly susceptible to parenteral administration (30–60 mg of strychnine hydrochloride may be fatal) but less susceptible to oral administration because of destruction of the drug in the rumen. Lethal doses by parenteral injection are 200–250 mg in horses, 300–400 mg in cattle, and 15–50 mg in pigs.

In strychnine poisoning there is greatly increased reflex excitability and, after an initial period of muscle stiffness and tetan, toxic convulsions occur. These can be provoked by the application of minor external stimuli. In these convulsive episodes there are extension of the limbs, minor external stimuli. In these convulsive episodes there is extension of the limbs, and the animal returns to normal. Tannic acid preparations administered orally precipitate the alkaloid in the intestinal mucosa, pulmonary congestion and edema, and hepatic congestion in some cases. Seeds of the plant are conspicuous in the ruminal contents of goats via a rumenotomy has been followed by recovery.

### TRITERPENES

Toxic triterpenes include:

- Cucurbitacins, tetracyclic triterpenes found in *Cucumis africanus* and *C. myricarpus,\(^9\)* *Stemodia kingii* and *S. floridana*\(^9\) and, in *Echium elatum*
- Lantadeses A and B, and triterpene acids found in *Lantana* spp.
- Ictericogenis A, B, and C in *Lippia* spp.
- Meliotoxins A and B, tetrnortriterpenes, derived from the berries of *Melia azedarach* var. *australsaisica* (white cedar)
- Colocynthin, a glucoside found in the fruit of the vine *Citrullus colocynthis* (synonym *Colocynthis vulgaris*)

Cucurbitacins are a group of tetracyclic triterpenes found in the fruits of the vines *Cucumis africanus*, *C. melo var. agrestis* (*Uclaro melon*)\(^10\) *C. myricarpus* ( prickly paddy/on), and *Echium elatum* (squirming cucumber). The ripe fruits are most toxic, and in cattle, sheep, and horses are associated with a syndrome of lethargy, dehydration, abdominal pain, diarrhea, dyspnea, and death in a matter of a few hours. Necropsy findings include edema and necrosis of the ruminal epithelium, intense congestion and hemorrhage in the intestinal mucosa, pulmonary congestion and edema, and hepatic congestion in some cases. Seeds of the plant are conspicuous in the ruminal contents.
Icterogenins and lantadene are associated with liver damage and nephrosis, neither of which is specific, but the lantadenes cause damage to bile canaliculi, gallbladder, pancreas, and intrahepatic cholestasis. Jaundice, photosensitization, and ruminal stasis result. *Lantana* is a very pungent plant and cattle will eat it only if other feed is scarce. *Bos taurus* cattle are more susceptible to lantadene poisoning than *Bos indicus* cattle. Treatment with activated charcoal is effective. So is treatment with bentonite, which is recommended as a cheaper alternative to the charcoal. The dosage of either is 5 g/kg BW as a single dose.

Melatoxin administered to pigs also is associated with a syndrome of gastrointestinal manifestations by diarrhea, melena, and vomiting, plus dyspnea due to pulmonary edema.

**TROPANE ALKALOIDS**

Tropane alkaloids include atropine, hyoscyamine, hyoscine, and scopolamine, found in:

- *Atropa belladonna* – deadly nightshade
- *Datura* spp. – thornapple
- *Dobusia leichhardtii*
- *D. myoporoides* – corkwoods
- *Hyoscyamus niger* – henbane.

Ingestion of these plants in sufficient quantity is associated with a syndrome of restlessness, tremor, pupil dilation, blindness, frenzied actions, convulsions, and recumbency. There are no significant necropsy lesions. *Datura stramonium* grows universally but cases of poisoning are few, possibly due to its unpalatability, its high toxic dose, and because it produces ruminal atony in cattle. The seeds of the plant are likely to contaminate grain supplies and may be associated with poisoning.

**TUTIN**

Tutin is a poisonous constituent of the *Coriaria* spp. (tutu trees) in New Zealand. It is associated with hypersensitivity, restlessness, convulsions, a short course and death, without any lesions visible at necropsy.

**VELLEIN**

The toxin vellein, found in the plant *Velleia discophora*, is associated with hypersensitivity, dyspnea, tachycardia, and recumbency but no specific necropsy lesions.

**VERATRINE**

The mixture of alkaloids found in *Veratrum californicum* is associated with a syndrome of salivation, dyspnea, vomiting, diarrhea, frequent urination, cardiac irregularity, and convulsions. The plant also contains the teratogen cyclopamine.

**ZIGADINE (ZIGADENINE)**

The phytotoxin zigadine occurs in the plants *Zigadenus* spp. (death camas), especially the bulb, and is associated with a syndrome of salivation, vomiting, tremor, ataxia, and dyspnea. The toxin has been identified in the rumen of dead cattle by electron impact mass spectrometry, avoiding the necessity of identifying the plant botanically.

**REFERENCES**

PLANT MATERIALS CAUSING PHYSICAL DAMAGE

Ingestion of indigestible fiber is associated with colic in horses due to:
- Gastric impaction – Senecio jacobea
- Impaction of the ileocecal valve – Sorghum spp.
- Ruminal impaction in cattle – loppings of:
  - Frazinus excelsior – ash tree
  - Chrysocoma tenuifolia – bitter weed
  - Eriocephalus spp.
  - Pinus taeda –lobbly pine
  - Prosopis juliflora – mesquite
  - Eremercus setigerus – turkey mullein
- Gastric impaction in pigs – Nicotiana spp. stalks.

Tough fiber in Romulea rosea (onion weed) is associated with an enzootic problem of bovine intestinal and abomasal impaction by phytobezoar in parts of Australia. Phytobezoars can be a problem wherever indigestible fiber is available to ruminants. Cocoon silk of Gonomea spp. (Molo moth) can be associated with ruminal impaction in cattle that eat foliage of Acacia erioboa or A. mellefors trees, the preferred habitat for the moth larvae.

Other physical injuries associated with plant material include persistent cornal ulcers from the bristles of Arctium lappa (burdock seeds); ulcers in the mouth from the spines of Setaria lutescens (yellow bristle grass), and the awns of Triticescale (= triticae). S. lutescens carries heavy bristles which are associated with mechanical stomatitis in cattle and horses. Triticae is a hybrid between wheat and rice used mainly for grain production. If it is harvested green as a crop and made into hay the dried awns are prohibitively irritating to the pharynx and mouth of cattle and horses. Affected horses are slow eaters, refuse to eat hay, and show excess salivation. The clinical signs that result in about a week include cough, mucoid nasal discharge, foul breath, hypersalivation, quidding, and loss of body weight. Some horses develop submandibular edema and there are severe ulcerations at the gum-tooth margins, with many awns embedded in the ulcers. The ulcers are very painful, up to 5 cm in diameter at the labial–gingival junction, the lingual frenulum, the base of the lingual dorsum, soft palate, and the sides of the tongue. After careful cleaning up, the lesions heal slowly over about 3 weeks.

Grass seed abscesses are frequent when there is a large population of Stipa and Stpagrostis spp. (spear grass), Tagetes spp., Aristida arenaria (silver or kerosene grasses), Opuntia spp. (prickly pear), and Hordeum jubatum (barley grass) in the pasture. The hairs on the plant Ditrichia (= Inula) graveolens (stinkwort) are thought to be associated with the fatal enteritis which occurs in sheep eating the plant.

PLANT POISONINGS DUE TO UNIDENTIFIED TOXINS

In many plant poisonings the identity of the toxin is unknown. The more common of these plants are listed below in categories according to the principal sign of the syndrome they produce. Because the information about most of them is meager, no attempt is made to provide a complete picture of each of them. There will be other plants in the main section of the chapter which also are associated with diseases similar to those outlined.

ABORTION
- Fum angustifolia – narrow-leafed sunn hemp
- Salvia coccinea – red salvia
- Tanacetum vulgare – tansy
- Verbena bonariensis – purple top.

CONGENITAL DEFECT
- Lysichiton americanus – skunk cabbage; is associated mostly with cranio-facial deformity.

CYSTITIS
- Gyrostemum (= Didymotheca) cupressiformis – double-seeded emu bush.

DERMATITIS
- Entandrophragma cylindricum – redwood, shavings as bedding are associated with balanoposthitis in rams
- Exococcia spp.
- Heracleum mantegazzianum – cow parsnip
- Vicia benghalensis – popany vetch; is associated with dermatitis, conjunctivitis, rhinitis, fever, and multiple eosinophilic granulomas in many organs
- V. dasyarpa – woolly pod vetch; same symptoms as V. benghalensis
- V. villosa – hairy vetch; same signs as V. benghalensis.

DIARRHEA – WITHOUT GASTROENTERITIS AS A LESION
- Ancredera cordifolia – lamb's tail
- Blechnum spp. – bungwall fern
- Bulbine bulbosa – native leek
- Cadaba rotundifolia
- Centaurium spp.
- Chaerophyllum sylvestre
- Cichorium intybus – chicory
- Chloropophora spp.
- Datisca glomerata – Durango root
- Dichocephalia chrysanthemifolia
- Juncus inflexus – blue rush
- Linum catharticum – purging flax
- Mentha australis – native mint
- Pipturus argenteus
- Phylldium lanuginosum – woolly water lily
- Polygon klotzchii
- Salvia coccinea – red salvia
- Synadenium arborescens – African milk bush.

DIARRHEA – WITH GASTROENTERITIS AS A LESION, OFTEN WITH ABDOMINAL PAIN AND INCOORDINATION, SOMETIMES WITH DYSENTERY AND VOMITING
- Azadirachta indica – neem
- Brunsfelsia australis (= B. bonodora) – yesterday, today, and tomorrow
- Buxus sempervirens – common box
- Centaurium brychii – rock centaur
- Chrysocoma tenuifolia – bitter bush
- Cissus quadrangularis
- Cuscuta spp. – dodder
- Datisca glomerata – durango root
- Dichocephalia chrysanthemifolia
- Dipedal glaucom – poison onion
- Diplcyclos palmaus.
HEMOLYTIC DISEASE – WITH SIGNS OF HEMOGLOBINURIA, ANEMIA, AND JAUNDICE

- Acacia nilotica subsp. kraussiana – scented thorn
- Acer rubrum – red maple; wilted leaves, only to horses
- Mercurialis spp. – mercury
- Secale cereale – cereal rye.

HEPATIC INJURY – WITH DUMMIES

SYNDROME OF CIRCLING, HEAD PRESSING, COMPULSIVE WALKING, BLINDNESS

In many cases, an expression of hepatic encephalopathy with hepatic necrosis and status spongiosus in the brain, e.g., Helichrysum argyrophyllum which is associated with blindness, paresis, and spongy degeneration of the brain in sheep and cattle; H. chrysanthemum (woolly daisy) has caused death and similar brain lesions in cattle. Oxytina acerosa (cowpea), Phyllanthus spp. (spurge), and Riedelia graciliflora, are associated with hepatic injury. Trema tomentosa (synonym T. aspera) is associated with acute hepatic necrosis in cattle and horses. In Matricaria gigelifolia poisoning, affected cattle become clumsy and docile, and tend to push against fixed objects, hence the common name ‘pushing disease’. Sheep are not affected.

HEPATIC INJURY – WITH JAUNDICE

AND/OR PHOTOSENSITIZATION

Acanthospermum hispidum – star burr
- Alnus fruticosa
- Callicarpa dichotoma
- Capparis tomentosa
- Chlorostaphis plicata – terba
- Enterolobium spp.
- Ficalia convolvulus – black bindweed
- Ficus isis – fig tree
- Galeopsis spp. – hedge nettle
- Hertia palens – springbokbush
- Heterophila paulaustula – egcadera
- Kochia scoparia – summer cypress
- Lythrum hyssopifolia
- Nidorella foetida
- Nolina texana – sacahuiste
- Persicaria lapathifolia (synonym Polygonum lapathifolium) – pale willow weed
- Pongamia glabra – Indian beech
- Psathyrotes annua
- Pteronia pallens – Scholtz bush
- Sartuellia faverea – sartwell
- Sesamne brasiliensis
- Strychnodendron coriaceum
- TetradyCMP lycenes – spineless horsebrush
- Trifolium hybridum – alsike clover.

The following are associated with photosensitization:

- Paspalum vulgare
- Phalaris coerulescens
- P. tayloriana
- Solidago chinensis
- Stephania spp.
- Trachymandra spp.
- T. laxa
- T. divaricata.

Many of the findings about these plants are equivocal:

- P. convolvulus
- P. orientale – smartweeds
- P. sagittatum.

INCOORDINATION OF GAIT, WITHOUT OR WITHOUT RECUMBENCY, CONVULSIONS, OR LESIONS OF NERVOUS SYSTEM

Ageratina altissima
- Anemone hortorum – cruel vine
- Berula erecta
- Brachychiton populneus – currajong tree
- Brachyglottis repanda – rangiura
- Catharanthus spp.
- Centella uniflora
- Combretum platyphyllem
- Craspedia chrysanthemum
- Doronicum hungaricum – wild sunflower
- Echinopogon spp. – roughbanded grass
- Eruca spp.
- Eruphoria mauritanica
- Gomphrena celosioidea – soft khaki weed
- Hoya spp. – wax flower
- Idiospermum australiense
- Melanthium hybridum
- Melastoma a suffruticosum
- Melia (synonym Ficus) – kikuyu grass
- Rhodomyrtus macrocarpa – finger cherry; also is associated with blindness.

The following are associated with paralysis in ewes and horses, with lesions of a lysosomal storage disease and include prominent neuronal pigmentation in the brain and spinal cord:

- Romulea spp. – onion weed
- Solidago chinenis
- Stachys arvensis – stagger weed
- Stephania spp.
- Trachymandra spp.
- T. laxa
- T. divaricata.

Romalea bulbocodium is associated with a high incidence of phytobezoars, a level of fertility in ewes as low as 20%, and a severe gait incoordination when stimulated to move. Affected sheep walk with their heads held high, fall easily, struggle momentarily, then relax and get up and walk normally. If they are left on the same pasture for 3 or 4 weeks they become permanently recumbent.

Gomphrena celosioidea is associated with outbreaks of incoordination in horses in northern Australia. Spontaneous recovery follows removal from the pasture.

Echinopogon mauritanicus is associated with hypersensitivity, stiffness, tremor, incoordination, recumbency, and convul-
with skeletal muscle myopathy and paralysis, or a combination of the two syndromes can occur. For example, in *Senma occidentalis* poisoning in horses and goats, the early signs are anorexia and diarrhea and these are followed by hyperpnea, tachycardia, ataxia, staggering, and recumbency. At autopsy there is a fatal cardiomyopathy. The muscle lesion is accompanied by marked elevations of SGOT and CPK levels. Similarly, in pigs, early diarrhea may be followed by lateral recumbency and skeletal muscle myopathy.

**PHOTOSENSITIZATION – PRIMARY; WITHOUT HEPATIC LESION**

Echinodictyon utiliss – Japanese millet
Holocaulx gazozii
Lachnanthes tinctoria
Menlha saturoeoides
Sphenocladium capitellatum
Medicago polymorpha – burr trefoil
Verbara spp.

Dermatitis associated with *M. polymorpha* occurs in all animal species on pasture dominated by the plant, usually in the spring. Lesions on the unpigmented parts of the skin disappear quickly when animals are taken off the pasture; there is no liver damage or permanent after-effect. Aphids, which commonly infest the plant in very large numbers, contain large amounts of a photodynamic agent and may be important in some outbreaks of the disease.

**POLYDIPSIA, POLYURIA**

Orobanche minor – broom rape.

**PULMONARY DISEASE – WITH DYSPNEA AND PULMONARY EDEMA ETC.**

Glehena hederacea (= Nupeta hederacea – golden ivy)
Gystromen spp. – camel poison.

The following are associated with pulmonary consolidation and fibrosis, characterized by dyspnea and cough, in horses:

*Eupatorium (= Ageratina) adenophorum* – croton weed
_E. riparium _– mist flower
Lactuca scarota _– prickly lettuce._

**RED URINE – DUE TO A PIGMENTED SUBSTANCE FROM THE PLANT**

Haloragis antotocarpa _– raspwort
Swartziad madagascariensis
Trifolium pratense _– red clover; in deer
Xanthorhoxoea minor; in cattle; probably associated with plant resins.

**SALIVATION WITH OR WITHOUT STOMATITIS**

Arenaria serpyllifolia _– thyme-leaved sandwort

Puccinia graminis
Scabiosa succisa _– devil’s bit._

**SUDDEN DEATH – WITHOUT CARDIOMYOPATHY**

Arrabida biablaista
Bartlita prunioide
Eupatorium wrightii
Lamium amplexicaule _– dead nettle
Laurelia novae-zelandiae _– pukatea
Nicandra physalides _– apple of Peru
Viguria annua _– annual goldene.

**UREMIA, NEPHROSIS – WITH high bun**

Amaranthus spp.
Anagallis arvensis
Azadirachta indica
Cassine buchanani
Catha edulis _– ghat
Dimorphandra gardneriana
Lythrum hyssopifolia
Petiveria allicacea _– anamu
Pilosotrophe spp. _– paperflowers
Sapupium sebiferum _– Chinese tallow tree
Sarcostolbus globosus
Sartellavia flavifera.

**VOMITING**

Cephaleis ipomoea
Tanus communis _– black broyly, plus colic, paralysis, and death._

**REFERENCES**

**POISONING BY MYCOTOXINS**

Recognition of the importance of mycotoxoses has developed only in recent...
Identification of the fungus by culture of suspect feed requires special laboratory services. It is very important to realize that isolation of a known toxigenic fungus does not provide a diagnosis of mycotoxicosis of itself. Growth conditions in the substrate may not have suited mycotoxin production. For a diagnosis to be made it is essential to identify and quantify the mycotoxin itself in the feed or the animal. Knowledge of the identity of the fungus is essential if control of its growth is contemplated, e.g. by spraying fungistatic material on pasture, or prediction of outbreaks is to be undertaken. The difficulty is compounded by the common occurrence of mixed infections, and the often fleeting period of growth of the fungus. Fungi have very exact requirements of moisture and temperature, in particular, for optimum growth, and when these are achieved the fungus can multiply very rapidly and produce large amounts of toxin in a matter of hours.

Prediction of environmental conditions conducive to outbreaks of mycotoxicosis, especially on pasture, is possible only with an exact knowledge of the growth requirements of the particular fungus, requiring expensive monitoring of pastoral microclimate. A common compromise is to monitor fungal growth by counting the yield of spores obtained from a given area or volume of the substrate. However, this does not provide information on the growth requirements of the fungus if any attempt is to be made to restrain its growth in agricultural materials.

CONTROL MEASURES
Most of the measures identified below are at a trial level and have not been used widely in a range of climatic and industrial environments:

- Spraying of pasture with a fungistat, e.g. thiabendazole for *Pithomyces chartarum* control.
- Adding adsorbents, e.g. hydrated sodium calcium aluminosilicate, activated charcoal, a range of clays (bentonite, zeolite), and synthetic ion-exchange resins.
- Immunizing animals against some mycotoxins, e.g. phomopsin.

Much of the feed fed to animals is contaminated by fungi, the harvesting techniques used and the variability of the weather predicate it, and animals can tolerate even heavy contaminations. To reject all feed showing contamination would result in unnecessary financial loss. Standard management procedures used widely and traditionally to deal with a flawed feed system and limit losses due to mycotoxicoses include:

- Limitation of the use of high moisture grain as feed. Any grain containing more than 20% moisture is liable to some degree of fungal spoilage.
- Avoidance of grazing mature pasture or field crop in which molds grow commonly on seed heads, e.g. *Claviceps* spp. on rye and paspalum, *Diaporthe toxica* on lupins, and *Corallopytstroma ornicipreoue* on Mitchell grass.
- Avoidance of very close grazing of pasture because herbivores can ingest toxic amounts of soil fungi, e.g. *Penicillium* spp.
- Feeding of obviously moldy hay to a small group of test animals because many of the molds on feeds do not produce toxic metabolites, many do but only at certain times, and many have an as yet undetermined status. This procedure has the disadvantage that certain modes of loss may go unrecognized. For example, reduction in feed consumption, and a resulting loss of productivity, is becoming increasingly recognized as a subclinical mode of loss in mycotoxicoses.
- Small amounts of feed can be used as feed by diluting it to, at the most, 10% with undamaged feeds, and preferably fed to a sample, pilot group of animals. Lactating, pregnant, and growing animals are most likely to be seriously affected and should not be put at risk.

The known syndromes are summarized in Table 33.2. A list of the mycotoxicoses in which the toxin has not been identified is included at the end of the section. The invasion of tissues by fungi is dealt with in Chapter 24.

Only the common mycotoxicoses are listed. Many minor ones are listed in the text.

**POISONING BY AFLATOXINS (AFLATOXINOSIS)**

**Synopsis**

- **Etiology**: Aflatoxins produced by *Aspergillus* spp. growing on stored feed.
- **Epidemiology**: All species affected; toxin excreted in milk.
- **Clinical signs**: Blindness, circling, photophobia, depression, tremors, ataxia.
- **Clinical pathology**: Elevated levels of liver enzymes in serum. Assay of aflatoxins in feed and tissues.

**REFERENCES**

**ETIOLOGY**

Aflatoxins (AF) are metabolites produced by fungi growing on spoiled feeds. They include AFB1, B2, G1, G2, and the second...
generation metabolites M₁ and M₂. They are related chemically to, and probably derived from, dicoumarin compounds. Much the most important disease associated with the ingestion of *Aspergillus* spp. is aflatoxicosis, which is associated with the aflatoxins, but other important toxins produced by the fungi are ochratoxin, patulin, and sterigmatocystin.

Levels of AF attained in feed may be as high as 3500 ng/kg for all aflatoxins, 2000 ng/kg for AFB₁, and 1000 for AFB₂. In sheep, a dose rate of 4 mg/kg is associated with death at 15–18 hours due to acute hepatic insufficiency; at dose rates of 2 mg/kg there is increased respiratory rate, a rise in temperature of 1.5°C (34°F) and diarrhea with blood and mucus, at a dose rate of 0.2 mg/kg there is anorexia and diarrhea. Similar dose relationships have been established for calves and for pigs. A great deal of aflatoxin ingested in the feed by cattle is physically bound to ruminal contents, and as little as 2–5% reaches the intestine. Levels of AFB₁ in excess of 100 μg/kg of feed are considered to be poisonous for cattle.

**EPIDEMIOLOGY**

Aflatoxicosis has been reported in most countries and on many spoiled foods, especially harvested peanuts, peanuts-in-shells on hay, cottonseed meal, sorghum grain, corn, moldy bread, green chop sorghum, or rarely on a standing crop, e.g. ears of sweet corn. Common sources are *Aspergillus flavus*, *A. parasiticus*, *Penicillium rubrum*. All animal species are susceptible but outbreaks occur mostly in pigs, sheep, and cattle. The mycotoxin is not destroyed by milling of the grain.

Because the toxin is excreted in cows' milk the disease has public health importance. Aflatoxin is now an important consideration in the etiology of human hepatocellular carcinoma. The concentration of AF in cows' milk may be as high as 0.33 μg/L and may continue to be as high for 3–4 days after ingestion of the feed. Aflatoxins can also be present in the meat from animals eating contaminated feed, but the risks to humans eating the meat are thought to be small.

**PATHOGENESIS**

Hepatopathy and hepatic insufficiency are the principal effects, but mutagenic and teratogenic effects are recorded in laboratory animals and suspected in humans on epidemiological grounds.

**CLINICAL FINDINGS**

Cattle

Clinical signs include blindness, walking in circles, ear twitching, teeth grinding, frothing at the mouth, photosensitive dermatitis and keratoconjunctivitis, diarrhea, severe tenesmus, abortion, and anal prolapse. Terminal recumbency is followed by convulsions. The appetite is normal. Affected animals usually die within 48 hours, calves in the 3–6 month group being most susceptible. Aflatoxicosis is also reputed to interfere with clotting of the blood in cattle, leading to the development of hematomas. Amounts of toxin insufficient to overt disease in cows may be sufficient to reduce food intake, weight gains, and milk production, and to be associated with diarrhea.

**Pigs**

In pigs, the period between when the toxin is ingested and when signs appear is thought to be quite long, at least 6 weeks, and varies with the toxicity of the batch of feed. The mortality rate is often 20%, but may be as high, including euthanasias, as 90%. Feeder pigs are more susceptible than adults. The clinical syndrome includes rough coat, depression, anorexia, weight loss, muscle tremor, staggery gait, walking in a daze, and recumbency. Some have intermittent or hemorrhagic diarrhea, and some have seizures just before death. The course of the disease may be as short as 6–12 hours. Abortion is a commonly reported sequel, but there is doubt about the relationship. At necropsy there is icterus, ascites, swelling of the liver, and mesenteric edema.

**Horses**

Aflatoxicosis in horses is recorded, but is unusual probably because horses are not likely to be fed damaged feeds. No clinical signs are reported but illness, lasting 5 days after a prodromal 3–4-day period of anorexia, begins a few days after access to contaminated feeds. Necropsy lesions include encephalomalacia, hepato toxicity necrosis and hepatic fibrosis, bile duct hyperplasia, hemorrhagic enteritis, and myocardial degeneration. The experimental disease is characterized by depression, inappetence, tremor, and prostration, with death following in 2–6 weeks.

**CLINICAL PATHOLOGY**

Estimation of AFs in feed materials, urine, blood, and tissues is standard practice. Serum hepatic enzyme levels are increased during the acute phase. Laboratory assay methods include chromatography and a quicker and more accurate ELISA.

**NECROPSY FINDINGS**

Necropsy findings in all species are those of hepatopathy, including megalocytosis, multiple foci of necrosis and fibrosis, portal round cell infiltration, and bile duct hyperplasia. Jaundice and serous exudates in body cavities may occur in some animals. A pronounced lesser enteralicosis with diarrhea and dysentery is common, but not constant, in pigs.

**DIFFERENTIAL DIAGNOSIS**

Diagnosis confirmation depends on the detection of aflatoxin in the feed and blood serum, and the characteristic gross and histopathological findings in the liver and nervous tissue.

**Differential diagnosis list:**

- Pyrrolizidine alkaloid poisoning
- Cyanobacterial toxin poisoning
- Phomopsis poisoning
- Sporidesmin poisoning
- Lantadene poisoning
- Steroidal sapogenin poisoning
- Fasciolasis.

Therapeutic administration of *Aspergillus oryzae* to newborn foals as a digestive inoculant to promote fast development of digestion is suspected of producing mycotoxins and being associated with acute hepatic insufficiency, including encephalopathy.

**TREATMENT**

Symptomatic treatment of hepatic insufficiency is all that can be attempted.

**CONTROL**

Since the advent of reliable and accurate methods of assaying AF in feeds there has been a notable tendency for feed to be less contaminated. Supplementation of the diet with zinc, selenium, vitamin E are not effective in preventing aflatoxicosis, and those procedures which have shown promise in experimental trials have not been translated into practicable, cost-effective techniques. Useful, experimental dietary procedures include hydrated sodium calcium aluminosilicate (several formulations of the compound are already used as anti-caking agents in the animal feed industry) and sodium bentonite in the form of clay. Agronomic methods to reduce aflatoxin contamination of peanuts have recently been successful. Ammoniation of feed has been useful in reducing contamination.

**REVIEW LITERATURE**

**REFERENCES**

Citrinin

Citrinin is most widely known as a nephrotoxin produced by the fungi Penicillium citrinum, P. viridicatum, P. patulum, and Aspergillus ochraceus and A. terreus. It is commonly found in combination with Penicillium citrinum, the fungi and the signs and lesions associated with poisoning by the metabolites of all of the fungi are the same. Citrinin plays a different role in the disease pyrexia-pruritis-hemorrhagic diathesis.

Epidemiology

Serious outbreaks of this idiopathic disease have been recorded in the UK since 1977. The epidemiology of a variable number of cows being affected simultaneously in a number of herds in the same locality suggested a chemical intoxicant. Suggested poisons were di-ureidosisobutane (DUIB), the hairy vetch moldy citrus pulp cubes were being fed, when the use of the additive was widespread. The cause is still not certain, but citrinin is now thought to be at least one of the causes.1 A fortuitous outbreak in half a dairy herd in which only one of the causes.1 A fortuitous outbreak in half a dairy herd in which moldy citrus pulp cubes were being fed, while there were no cases in the other half of the herd not fed the cubes, suggested that citrinin, which was present in the cubes (30–40 ppb), was causative.

Clinical Signs

These include pruritus, hair loss, papular dermatitis, variable appetite with roughage being taken but not concentrates, fever (40–41.5°C, 104–106.7°F), petechiation on conjunctiva, and visible mucosae. The dermatitis is widespread, exudative, initially papular, and itching. It occurs principally on the head, neck, perineum, and udder. Pruritus is variable in degree, but is often so marked that rubbing is associated with the affected skin to become raw and bleeding. The dermatitis subsides but the fever persists, and over a period of 4–7 weeks the animal becomes so unthrifty that it is usually sent for slaughter. The morbidity rate is usually 10%, but may be as high as 100%. Seriously affected animals die. A similar but more severe syndrome occurs in which there is petechiation in all tissues, especially subserosally. In these cases there are multiple hemorrhages in all mucosae and free blood at the anus and other orifices.

NECROPSY

Examination shows petechiation in all organs and tissues, although they are absent altogether in some cases. Histological findings include low-grade, longstanding interstitial nephritis, and very little else of significance. Histology, blood chemistry, and serum enzymes are similarly normal. Antibody reactivity to some components of ruminal contents may be elevated, but not apparently significantly.

REFERENCE

Cyclopiazonic Acid

An indoletterol acid, a secondary metabolite produced by Aspergillus and Penicillium spp. growing on stored grain, including sunflower seeds, is associated with feed refusal and conception problems in sows.1 Isolated from A. flavus, cyclopiazonic acid is associated with weakness, anorexia, loss of body weight, and diarrhea in pigs. Necropsy lesions include gastric ulceration and hemorrhages throughout the alimentary tract.

REFERENCE

Ergot Alkaloids

Ergot alkaloids are a subset of indole alkaloids, many of which, like the tryptamines of Phalaris spp., occur naturally in plants and produce similar diseases. The individual toxins, and the plants they parasitize, are only partially identified. A list of the fungi, the toxins they contain and the syndromes attributed to them is as follows:

*Neotyphodium (Acromonium) spp.*

- *Neotyphodium (Acromonium)* coenophialum; contains the ergopeptine alkaloids ergovoline, ergotamine, and is associated with hyperthermia, milk yield drop, peripheral gangrene
- *Neotyphodium (Acromonium)* lolii; contains lolitrem alkaloids and phaseoline, and is associated with gait incoordination (rye-grass staggers)
- *Balansa epichloe*; gait incoordination, peripheral gangrene

*Claviceps africana*—sorghum ergot; contains dihydroergosine; is associated with agalactia, hyperthermia
- *C. cinerea*; gait incoordination
- *C. fusiformis*; agalactia
- *C. paspali*; gait incoordination
- *C. purpurea*; hyperthermia, peripheral gangrene

NEOTYPHODIUM (ACREMONIUM) SPP.

Infestation of the grasses *Achnatherum inebrians* (drunken horse grass) in China1 and *Stipa robusta* (sleepy grass) in North America by endophytes is associated with a syndrome of incoordination in horses and sheep grazing on the grass. Identification of the fungi is not completed but they contain ergovoline and lysergic acid amide. Low levels of pilillene and lolitrem B (indo-terpenoids) are also present.

NEOTYPHODIUM (ACREMONIUM) COENOPHIALUM

There are four diseases associated with this endophytic fungus whose toxic hyphae are present, invisible without microscopy, in the tissues of the grasses *Festuca arundinacea* (tall fescue), and which do not produce fruiting bodies. Spread of the endophyte is via infected seeds. There is no visible effect on the growth of the grass. The fungus produces the ergopeptide alkaloids, principally ergovaline, and many other pharmacologically active compounds including peramine and ergine (lysergic acid amine).

Two major diseases are associated in cattle and sheep, fescue summer toxicosis and fescue foot, and two minor ones, fat necrosis and agalactia in mares. All four syndromes could theoretically occur on the one pasture, but summer toxicosis occurs only in the summer, fescue foot in the winter.

Fescue summer toxicosis (summer slump, epidemic hyperthermia)

Associated with *Neotyphodium (Acromonium)* coenophialum (synonym *Sphaecelum typhina*), this disease has assumed a significant place amongst the loss in dairying in the United States, New Zealand, and Australia because of the high rate of use of tall fescue as a pasture grass.

The syndrome is a period of poor production manifested in cattle at pasture in the summer by a fall in milk production or a failure to grow adequately in fat cattle, both in the presence of what looks like an optimum amount of nutritious pasture. The same poor weight gain is experienced by steers fed on fescue seed, and in sheep. In cattle grazing at pasture the depressing effect on production is made worse by environmental temperatures...
above 31°C (87°F). Affected cattle show hyperthermia with temperatures as high as 40.5°C (104.5°F) dyspnea, hyperalimentation, inappetence, rough coat, and they may compulsively seek out water or tree shade in which to stand. The hyperthermia may not recede until about 6 weeks after the cattle are moved from the pasture.

The mycotoxin responsible is ergovaline, an ergopeptide similar to, but more powerful than, ergotamine.2,3 The lowered milk yield is accompanied by low blood levels of prolactin, resulting in an indifferent prolactin surge when the premilking stimuli are applied.4 Prolactin levels can be significantly increased by the administration of metoclopramide, a dopamine antagonist,5 or phenothiazine or cimetidine.6 The fescue foot is associated with vasoconstriction of sensitive blood vessels, leading to inadequate blood supply to the extremities. Vasodilation is also thought to be associated with the hyperthermia, the diminished cutaneous blood supply reducing heat loss.7

The mode of action of the mycotoxin is unsure but it appears to be mediated via the pineal and pituitary glands, causing an alteration in the metabolism of dopamine and serotonin.8 Thiamin is thought to be involved in the pathogenesis because of the way in which it improves feed intake during periods of hyperthermia.9 There is a great deal of variation in the toxicity of different varieties of the grass: KY-31 is most toxic; Kenhy, Mo-96 and Kenmont are intermediate; and Fawn is least toxic. The disease also occurs in animals fed on hay made from affected pastures.

Control of the disease can be effected by growing endophyte-resistant varieties, by rotating cattle through fescue and other grass and clover varieties. Treatment of parental plants with the fungicide benomyl produces seed, which results in pasture with a reduced infection rate and lower toxicity for cattle grazing it. Oral administration of thiabendazole just before the cattle go onto the toxic pasture prevents the onset of signs. The recommended regimen is a dose rate of 5 g/45.5 kg BW repeated every 7 days. Ammoniation of the affected hay removes its toxicity so that serum prolactin levels return to normal.10 A similar disease is recorded as occurring with poisoning by Claviceps purpurea.

Fescue foot

Fescue foot also occurs in cattle which are grazing pasture dominated by tall fescue, usually within 10–14 days of being turned onto the pasture during cold weather. Cattle permanently pastured on the field do not appear to be affected and horses appear to be able to graze it with impunity. The lesions and clinical signs include severe lameness followed 2 or more weeks later by gangrene and sloughing of the extremities especially the digits and to a less extent the tail. There is a close similarity to the disease associated with the ingestion of Claviceps purpurea and the ergotoxins are also present in fescue (Festuca octoflora) so that identifying the specific cause of gangrene of the extremities may not be possible. The incidence in a herd may be as high as 10%. The lesions are associated with the vasoconstrictive agent ergovaline produced by N. coenophialum. In freezing temperatures, frostbite may be a complicating factor. New cases may continue to appear for up to 1 week after removal from the affected pasture. The grass heads are commonly infested by C. purpurea but the disease occurs in its absence.

Inferitility and poor weight gain in horses

Pregnant mares fed on Neotyphodium (Acremonium) coenophialum-infested pasture can experience a much higher incidence of dystocia, longer gestation, low foal survival, smaller udder development, and poor milk yield, compared with mares on unaffected pastures.11 Prolongation of luteal function, an increase in cycles per pregnancy rate, and early embryonic death significantly reduce reproductive efficiency.12

CLAVICEPS PURPUREA (ERGOTISM)

Etiology

Poisoning associated with the ingestion of large quantities of the naturally occurring ergots of Claviceps purpurea.

Epidemiology

Warm, wet climate; ingestion of pasture or cereal rye or hay made from them.

Clinical signs

Gangrene of the extremities of the limbs, tip of tail and ears, hyperthermia in cattle. Abortion, poor mammary development, early neonatal deaths in mares and sows.

Clinical pathology

Assay of ergot toxins in feed and animal tissues.

Necropsy findings

Gangrene of extremities.

Diagnosis confirmation

Ergot alkaloids in assay.

Treatment

Amputation of gangrenous parts.

Control

Avoid exposure or dilute feed with non-toxic material.

Fescue foot

Claviceps purpurea is a fungus which under natural conditions infects cereal rye and, less commonly, other cereals and many grasses, including the rye-grasses, tall fescue grass, Phleum pratense (timothy, cocksfoot, Yorkshire fog), Cynodon dactylon (Bermuda or couch grass), and Pennisetum typhoides (bulrush millet).13 Ingestion of large quantities of seed heads infested with the sclerotia (ergots) of the fungus is associated with ergotism in cattle, sheep, pigs, horses, dogs, and birds. The ergots contain a number of alkaloids and amines with pharmacological activity and these vary in concentration with the maturity of the ergot. The pharmacologically active compounds in the group, known collectively as ergotoxins, include ergotamine, ergotoxin, and ergometrine, and stimulate the smooth muscle of arterioles, intestines and the uterus.

There is some evidence that corn smut may have pharmacological activity similar to that of C. purpurea. An unidentified ergot Claviceps spp. on Cynodon dactylon (Bermuda or couch grass), may be related to the tremor syndrome which occurs occasionally in cattle grazing this grass.

EPIDEMIOLOGY

Ergot of rye is widespread in its distribution, but it is seldom that sufficient is ingested in its toxic stage to be associated with poisoning. Poisoning is most likely to occur during or after warm, wet seasons which favor the growth of the fungus. Ergotism occurs commonly only in cattle and usually in stall-fed animals feeding on heavily contaminated grain over a considerable period of time. Other species are not usually exposed to the infected grain.

Ergot-infested pasture may be associated with the disease, and the toxicity is preserved through the ensiling process.14 Cows may show early signs of lameness in as short a period as 10 days after going onto an infested pasture, but most animals do not become affected until 2–4 weeks after exposure. Peripheral gangrene occurs in the cooler months, hyperthermia in hot weather.

PATHOGENESIS

The peptide alkaloids of ergot, particularly ergotamine, are associated with arteriolar spasm and capillary endothelial damage, with restriction of the circulation and gangrene of the extremities when small amounts are taken over long periods. In spite of the known abortifacient action of Claviceps purpurea, abortion does not usually occur in poisoned animals.

The experimental feeding of ergots (1–2% of ration) is associated with severe reduction in feed intake and growth rate in young pigs without producing overt signs of ergotism. Experimental feeding of ergot-infested Lolium perenne (perennial ryegrass) seeds to cattle can be associated with hyperthermia, without other lesions.15

CLINICAL FINDINGS

There are three syndromes: classical ergotism characterized by gangrene of
the extremities, a hyperthermia syndrome in cattle, and a reproductive syndrome.

Classical ergotism – peripheral gangrene
The extremities, particularly the lower part of the hindlimbs, the tail, and ears are affected. There are reddening, swelling, coldness, loss of hair or wool, and lack of sensation of the parts initially, followed by the development of a blue-black color, dryness of the skin, and its separation from normal tissues. The gangrene usually affects all local tissues and, after the lapse of some days, the affected part becomes obviously separated and may eventually slough. The lesions are not painful but some lameness is evident even in the early stages and the animal may remain recumbent most of the time. Severe diarrhea is often an accompanying sign. In sheep under experimental conditions there is no gangrene of the limbs, but there is ulceration and necrosis on the tongue, the mucosa of the pharynx, rumen, abomasum, and small intestine.

Hyperthermia form
Affected cows have temperatures of 41–42°C (105–107°F), dyspnea, and hyper-salivation. Milk production and growth rate are depressed and morbidity is about 100%. The syndrome occurs in hot weather conditions when affected animals seek water or shade, but exposure to sunlight under normal conditions of air temperature and humidity can be enough to be associated with clinical signs. Affected animals stressed by exercise in ambient temperatures over 30°C (86°F) commonly die. Long-term low-level feeding of ergot to fattening beef cattle can result in reduced feed intake and weight gain, increased water intake and urination, failure to shed winter coat and increased susceptibility to heat stress.

Reproductive form
This is an uncommon manifestation in cows, but there is one report of a brief exposure to a heavily ergotized pasture causing abortion in late pregnant cows. It also occurs as a single outbreak of agalactia, lack of mammary gland development, abortions, prolonged gestations, and early neonatal deaths in mares fed oats containing Lolium multiflorum seeds heavily infested with C. purpureus. In sheep, the feeding of ergot reduces the chance of fetuses surviving, so that relative infertility occurs, and feeding pregnant ewes on ergotized grain is not recommended.

In pigs, ergotism is manifested by lack of udder development and agalactia in sow, and the birth of small pigs which suffer a heavy neonatal mortality. Some of the piglets survive and subsequently suffer gangrene of the ear edges and tail tip. In sow, the chronic feeding of C. purpureus may not disturb existing pregnancies, but premature births, mummified fetuses, and low litter size are recorded. Levels up to 0.2% in the diet appear to be safe. A specific ergot, Claviceps fusiiformis (bulrush millet), is known to be associated with agalactia in sows in Zimbabwe. Claviceps africana, the ergot of sorghum, has been associated with agalactia in sow and perinatal mortality of piglets in Australia.

Clinical pathology
Samples of fungus-infested material may be submitted for assay or test feeding. Chromatographic and mass spectrometrical techniques can be used to identify the presence of ergot in feed.

Necropsy findings
In cattle, gangrene of the extremities is the principal gross lesion. There may be evidence of congestion, arteriolar spasm, and capillary endothelial degeneration in the vicinity of the gross lesions and in the central nervous system. Uneration and necrosis of the oral, pharyngeal, ruminal, and intestinal mucosae are recorded in sheep.

Differential diagnosis

| Diagnosis confirmation depends on a positive assay of ergot alkaloids in feed or tissues. Differential diagnosis list includes: |
| For classical ergotism: |
| • Poisoning by Neotyphodium coenophialum |
| • Arterial thrombosis and embolism |
| • Trauma causing obstruction of circulation to the part |
| • Bacteremia, e.g. in salmonellosis. |
| For hyperthermic ergotism: |
| • Heat stroke |
| • Water deprivation. |

For reproductive ergotism consult other texts dealing with diseases of the reproductive tract.

Treatment
Treatment is not usually attempted, although vasodilator drugs may have some beneficial effect. The infected fetus should be withdrawn from the ration immediately.

Control
Heavily ergotized grain or pasture fields containing ergotized grasses should not be used for animal feeding. They may be grazed if they are first mowed with the mower blade set high to remove the seed heads. Feed should not contain more than 0.1% of ergot-infested heads. It is probably safest not to feed ergot-infested feed to pregnant females.

Neotyphodium Lolii (Rye-Grass Staggers, Migram)

| Symptoms |
| Etiology | Tremorgers (lolitrem) from Neotyphodium (Acremonium) lolii, an endophytic fungus growing in Lolium perenne. |
| Epidemiology | All species affected, an inconvenient disease associated with almost no fatalities. Outbreaks in late summer when pasture is short. Disappears when rain stimulates pasture growth. |
| Clinical signs | Gross inconveniencing when disturbed; limited not flexed, fall easily, struggling violently attempting to rise. If left alone calm down, rise and graze normally. |
| Clinical pathology | Lolitrem can be assayed in feed and animal tissues. |
| Necropsy findings | No identifying lesions. |
| Diagnosis confirmation | Positive paste or blood assay of lolitrem; >0 endophyte hyphae/mm leaf shear width. |
| Treatment | Nil. Remove animals from affected pasture. |
| Control | Limit access to affected pasture. |
ETIOLOGY

Knowledge about the cause of rye-grass staggers has changed dramatically during the past decade. It is now known to be associated with tremorgenic mycotoxins produced by the endophytic fungus Neotyphodium (Acremonium) lolii in Lolium perenne (perennial ryegrass). The mycotoxins are intensely fluorescent complex indoles called lolitrems. Lolitrem B is the abundant one, and lolitrems A, C, and D are present in only small quantities. N. lolii produces other metabolites including paxilline, a weak tremorgen, and peramine, a pyrrolopyrazine alkaloid which is repellent to insect pests, especially the devastating Argentine stem weevil. N. lolii also has an ameliorating effect on the growth of the plants that it infects, causing increases in dry matter production of 30–40%. This may be due to the deterrent effect of peramine on insect pests.

EPIDEMIOLOGY

Occurrence

Rye-grass staggers occurs chiefly in New Zealand, but also to a limited extent in Australia and Great Britain. The incidence is extremely variable depending on climatic conditions. Rye-grass staggers affects a variable number of animals (5–75%) but is associated with few, if any, deaths. Sheep, cattle, horses, and wapiti deer are all affected.

Risk factors

Plant factors

The endophytes grow in the plant tissues and are also present in the seeds. They are concentrated in the outer, lower leaf sheaths so that the disease is most likely to occur at the end of the summer when the pasture is short, and in animals that graze closest to the ground.1 Different cultivars of perennial ryegrass vary in their degree of contamination by the endophyte; some, such as Nui and Ruana, carry only 30% infection, whereas Yatsyn and Droughtmaster are 100% infected. Lolitrems A and B are present in high concentrations in the seeds of L. perenne, and when seed is fed to sheep is associated with rye-grass staggers syndromes. Rye-grass staggers has also occurred in horses fed on the cleanings of perennial rye-grass seed; heaver cleanings containing more seed are more toxic than the husk-rich cleanings.

Environment factors

Rye-grass staggers occurs most commonly in the autumn, but when the grass is dry and short and making only a small amount of slow growth. A sudden fall of rain and rapid growth of the grass is followed by disappearance of the disease. For this reason facial eczema and rye-grass staggers do not occur together in the same flocks at the same time.

Importance

The disease is an inconvenience because animals cannot be easily moved. A few deaths may occur due to misadventure.

PATHOGENESIS

Because of the transient nature of the disease, the nervous signs in rye-grass staggers are presumed to be associated with a functional derangement of nervous tissue. The disease produced experimentally by the administration to sheep of material containing the tremorgenic mycotoxin penitrem A is very similar to naturally occurring rye-grass staggers. Fine tremor, manifested as muscle fasciculations, is followed by coarse tremor causing movement of the head and body. The tremor is enhanced by movement. There is incoordination with a bounding gait, and abnormal postural reflexes leading to lateral recumbency, or sternal recumbency with the hindlegs stretched out behind. Eating and drinking are unaffected. There are no diagnostic lesions except in prolonged cases and the disease is likely to be a reversible biochemical toxicosis. Bulls grazing toxic rye-grass pastures have lower than normal blood levels of testosterone, and sheep make lower weight gains than normal.

CLINICAL FINDINGS

In sheep, the disease occurs commonly in animals in very good bodily condition. In mild cases, signs are observed only on driving, the limbs being moved without flexion of the joints, so that the gait is bounding. In severe cases, the animal is unable to make any movement without the legs becoming extended and abducted, causing it to fall. Vigorous attempts to rise, which may be interpreted as convulsions, follow. If the sheep are left undisturbed they appear to recover, get up and move off, only to repeat the performance within a few yards or metres. In extreme cases, the sheep are permanently prostrate.

In cattle, the syndrome is similar to that which occurs in sheep. There is some nodding of the head at rest and occasionally head tremor, but the convulsions are more severe and flexion of the limbs is more marked than extension.

In horses, there is tremor, hypersensitivity, and a reeling, drunken gait which may proceed to posterior paralysis. Recovery occurs in a few days when the animals are moved to new pasture. Horses and cattle affected mildly are unable to move quickly because of limb and trunk stiffness and a tendency to fall. Turning is achieved only with difficulty. The signs are not apparent when the animals are grazing, occurring only when they are disturbed.

CLINICAL PATHOLOGY

There are no animal-based tests available to aid in the diagnosis of rye-grass staggers. Heinz-body anemia is common in cattle grazing rye-grass, but its significance in relation to rye-grass staggers is unknown. Toxic pastures are reported to have ~35 hyphal strands/mm of leaf sheath, non-toxic pastures have about 10 strands/mm. An ELISA is available for the detection of the lolitrems.

NECROPSY FINDINGS

The necropsy findings in rye-grass staggers include macroscopic pallor of skeletal muscles and focal areas of haemorrhage on histological examination. Degenerative lesions of Purkinje cell neurons are described in longstanding cases. There are no specific, identifying lesions.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on positive assays for lolitrems in the feed and in animal tissues.

Differential diagnosis list:

- Rye-grass staggers resembles many other functional diseases of the nervous system, especially those associated with poisonous plants
- Nervous syndromes associated with Claviceps paspali, C. cirenea, Balansa ephelche, Phalaris aquatica and Echinopogon ovatus (rough-bearded grass) are very similar to rye-grass staggers

TREATMENT

Livestock should be immediately removed from affected pasture but no treatment is required since spontaneous recovery is rapid. Tranquilizers may be useful in severe cases.

CONTROL

Sheep and cattle should not be allowed to graze potentially toxic pasture for more than 2–3 hours a day unless it is more than 30 cm high. Supplementation of the diet with vitamin E, vitamin A, and minerals has had no effect on the incidence of the disease. Replacing existing toxic L. perenne swards with L. perenne infected with a strain of A. lolii that produces peramine that prevents insect attack while not producing either lolitrem or ergovaline that is associated with livestock disease is an effective control.2,3

REVIEW LITERATURE

REFERENCES

Paspalitrem (Claviceps Paspali-Paspalum Staggers)

Etiology

Claviceps paspali is an ergot-producing fungus which infects the seed heads of:

- Paspalum dilatatum - paspalum or dallas grass
- P. distichum - salt water-couch grass
- P. notatum - Argentine bahia grass
- P. paspalodes - water couch
- P. scrobiculatum (= P. commersonii) - scrobc or ditch millet
- P. wroblei - Vasey grass.

It produces tremorgens called paspalitremes, which are chemically related to the tremorgen of Penicillium cyclopium rather than to the ergot alkaloids. The neurological effect of the Penicillium spp. and Claviceps paspali ergots is almost identical. The ergots are most toxic when they are passing from the sticky 'honeydew' (sphacelial) stage to the hard, black (sclerotial) stage. The 'honeydew' stage itself is comparatively non-toxic. Illness can occur when mature ergots are eaten but the disease is not so severe.

Epidemiology

The degree of infestation of pastures varies widely with climatic conditions, being heaviest after wet, humid summers. Outbreaks of the disease occur in autumn when animals at pasture graze the seed heads because of a shortage of other feed. Cattle are most commonly affected, sheep and horses less so.

Clinical Signs

Signs include manifestations of nervous system derangement. There is hypersensitivity to noise or movement, but not to touch. Muscle tremor is at first only noticeable on exercise but is later continuous, even at rest, and is sufficiently severe to be associated with shaking of the limbs and trunk and nodding or rocking of the head. Involuntary movements may prevent grazing. There is a severe ataxia with gross incoordination of movement, sideways progression and frequent falling into unusual postures. Animals which fall, paddle involuntarily may remain so.

The appetite is always unaffected but may be scoriating, salivation, and some loss of condition. Abortion does not occur. Some deaths are associated with misadventure but recovery occurs quickly in most cases if the animals are removed from affected pastures.

Necropsy Findings

There are no gross changes, except for some increase in cerebrospinal fluid volume, and histological examinations are negative.

Differential Diagnosis

There are many other causes of incoordination in animals at pasture, some of them phytotoxins and mycotoxins. One of the infrequently reported ones is Balanisia epichloe, an ergot-producing fungus found on many pasture plants, especially Cynodon spp. A very similar syndrome is produced by Claviceps cinerea on the seed heads of the grasses Hilaria mutica (tobosa grass) and H. jamesii (galeta grass).

Treatment

Unnecessary for paspalum staggers, but livestock should be removed from the affected pasture, which may, however, be used by permitting only intermittent grazing or after mowing and raking of the seed heads.

Fumonisins

Fumonisins are mycotoxins produced by Fusarium verticillioides (synonyms F. moniliforme, Gibberella fujikuroi) growing on moldy corn (maize) grain. Fourteen other Fusarium species and Alternaria alternata also can produce fumonisins.

They block the synthesis of sphingolipids leading to the intracellular accumulation of sphingosine and sphinganine and coagulation necrosis of cells in sensitive organs, especially the brain, heart, liver, and kidney, in which lesions occur. Horses and pigs are more susceptible to the poisoning than cattle and poultry. Of the known toxic fumonisins, FB1 (fumonisin B1) is the most common cause of animal disease and is a known carcinogen in humans (esophagus) and rats (liver). Sphinganine and sphingosine are excreted in the urine and serum and this is used as a biological marker of exposure to fumonisins.

Fumonisins are not excreted in the milk of cows or sows, ingesting the toxin. Horse and pig feed should contain less than 10 μg fumonisin B1/g. Fumonisin-contaminated feed may be salvaged by feeding it to ruminants.

Equine Duodenitis Proximal-Jejunitis

This idioopathic disease may be confused with colic due to intestinal obstruction. Its characteristic lesions have been produced incidentally, without the clinical signs of the disease, during the experimental production of ELE by poisoning with fumonisin. A link to the mycotoxin was established by the elevated levels of sphingosine in the duodenal lumen.

Porcine Pulmonary Edema/Hepatosis

The fungus F. verticiioides and the fumonisins B1 and B2 are associated with fatal pulmonary edema or hepatosis, the former lesion with higher doses of the toxin. This syndrome results from acute left-sided heart failure and increased pulmonary artery pressure. More chronic cases of the hepatosis syndrome are accompanied by hyperkeratosis and para-keratosis of the distal esophageal mucosa. A reduction in cardiac and vascular efficiency is also part of the chronic intoxication with fumonisins in pigs.

Fusaric acid, a mycotoxin also produced by F. moniliforme, is associated with depression and vomiting in pigs.
**IPOMEANOLS**

4- Ipomeanol is a furanoterpenoid myco-toxin produced by *Fusarium solani* (synonym *F. javanicum*) and *F. semitectum* growing on garden refuse. It has the effect of causing lesions indistinguishable from those of atypical interstitial pneumonia. Other known causes of these lesions are 3-methylindole and the ketone produced by *Perilla frutescens*, *Zizia arborescens*, and one of the fungi *Fusarium solani* or *Oxysporum* spp. on *Ipomoea batatas* (sweet potatoes) tubers. Catabolism by the fungus of phytoalexins induced in the tubers by the fungus produces four closely related ipomeanols. These are not toxic until activated by pulmonary microsomal enzymes. Exper-imental administration of infected potatoes to calves is associated with bronchiolitis and interstitial pneumonia.

**REFERENCES**

**IPOMEANOLS**

- **OCHRATOXIN**
  - **ETIOLOGY**
    - Ochratoxin A is the most potent of isocoumarin derivative mycotoxins. It is a powerful renal toxin which is associated with organellar damage, especially to epithelial cells. It, and ochratoxins B and C, are produced by *Aspergillus alutaceus* (synonym *A. ochraceus*), and other *Aspergillus* and *Penicillium* spp., e.g. *P. viridicatum*. This fungus also produces vomilone and cinerin, both potent nephrotoxins and capable of enhancing the lesion. Modern radioimmunoassay makes chemical identification of the toxin so much easier that identification of the specific fungus is becoming less necessity, and many contemporary accounts of ochratoxin poisoning do not include the identity of the causative fungus.
  
  **EPIDEMIOLOGY**
  - The species most often involved is pigs. They are expected to be affected only at very high dose rates, but goats are rather more susceptible. There is some evidence that chickens and horses can also be affected. The fungus grows on stored barley or corn grain, and nephrosis results when the grain is fed. Affected pigs placed on an ochratoxin-free diet are decontaminated in about 1 month. The ochratoxin residues have been detected as a ‘carryover’ in pigs and poultry meats and have some significance for persons eating contaminated pig meats.
  
  **PATHOGENESIS**
  - A nephrosis occurs naturally, has been widespread in Denmark for many years and has been produced experimentally. The principal lesion is a degenerative change of the renal tubules and there is a consequential impairment of tubular function.
  
  **CLINICAL FINDINGS**
  - The disease is characterized by diarrhea, polyuria, and polydipsia. Blood urea nitrogen levels are elevated and proteinuria is evident.
  
  **NECROPSY FINDINGS**
  - These include dehydration, enteritis, generalized edema, renal enlargement, fibrosis, and necrosis of renal tubular epithelium. Poisoning by ochratoxin in pigs resembles Balkan nephropathy, a naturally occurring disease of humans. Ochratoxin is also an immunosuppressant, is associated with poor sperm quality in boars, and is thought to be associated with fetal death and resorption, and thus abortion.
  
  **CLINICAL PATHOLOGY**
  - Assessment of ochratoxin levels in tissue is now performed with radioimmunoassay techniques.

**PHOMOPSIS**

- **Synopsis**
  - Mycotoxic produced by fungus *Diaportha toxica* growing on dead lupin plants or seeds.
  
  **Etiology**
  - Mycotoxic produced by fungus *Diaportha toxica* growing on dead lupin plants or seeds.
  
  **Epidemiology**
  - Cattle and sheep grazing lupin stubble or fed seeds in ration.
  
  **Clinical findings**
  - Lupinosis is associated with hepatic encephalopathy (blindness, aimless wandering) accompanied by jaundice and photosensitization. Also skeletal myopathy syndrome with stiff gait, difficulty rising.

  **Clinical pathology**
  - Serum levels of liver and muscle-associated enzymes elevated.

  **Neurotoxin findings**
  - Jaundice, swollen liver, diffuse hepatic fibrosis, biliary hyperplasia, myopathy.

  **Diagnosis confirmation**
  - Positive assay for phomopsin.

  **Treatment**
  - Change feed.

  **Control**
  - Do not feed infected lupin stubble. Plant phomopsin-resistant lupins. A vaccine is under development.

**ETIOLOGY**

- *Diaportha toxica* (anamorph *Phomopsis* spp.), a saprophytic fungus, is the source...
of the toxins causing lupinosis of cattle and sheep grazing on the stubble of lupin crops infected with this fungus. Phomopsins A, B, C, D, and E, cyclic hexapeptide mycotoxins, are the specific cause. Diamorpha woodii (anamorph Phomopsis leptostromiformis) was originally, and erroneously, considered to be the source of these toxins. Phomopsis emeics, a saprophyte of Emex australis produces phomopsins in vitro, but is not associated with natural disease incidents.

EPIDEMIOLOGY

Occurrence
The disease is common in Europe, Australia, New Zealand, and South Africa. Cattle, and especially sheep, are most commonly affected, probably because of their greater exposure. Poisoning of pigs and horses occurs, but rarely.

Risk factors
Plant factors
Most occurrences are in animals which graze lupin stubble in which there is dry foliage, seed pods, and seeds. The disease occurs rarely in sheep fed only on the seeds, and has also occurred in pigs fed ground lupin seeds.

Factors increasing the chances of poisoning associated with fungal infection of the senescent plants include summer rain, which is conducive but not essential to fungal growth; the time lapse since rain, toxic lupins remain poisonous for several months; and the provision of alternative feed or the presence of other plants, including weeds, in a crop, both of which may reduce its lupin intake and hence its toxicity. Similarly, if good quantities of lupin seed are available either still in the pods on the standing plant, or spilled onto the ground, there is less chance of poisoning. The mature stalks are the most poisonous so that a heavy stocking rate which encourages the ingestion of all parts of the plants increases its prevalence. Stubble from which lupin seeds have been harvested is the most common cause of lupinosis. Some varieties of lupins are much more susceptible to fungal infections than others.

Animal factors
Naturally occurring cases are more commonly seen in sheep, cattle appearing to be less susceptible to the toxin.

PATHOGENESIS

Phomopsins injected intraruminally have variable effects depending on dose and duration of administration. Subcutaneous dosing results in anorexia, weight loss, lethargy, jaundice, elevation of serum levels of liver enzymes, recumbency, and death in 90% of sheep. Clinical biochemistry findings suggest that the hepatosis is accompanied by injury to muscle, kidney, and adrenal cortex. Necropsy lesions include jaundice and patchy hepatopathy with arrested mitoses.

Affected sheep have a higher hepatic concentration of copper and selenium and a lower concentration of zinc, due to necrosis of liver cells. The affinity for copper may lead to the development of a complicating chronic copper poisoning in affected sheep.

CLINICAL FINDINGS

In sheep, signs include anorexia, constipation, hepatomegaly, stumb lling gait, recumbency, and a variable degree of jaundice and photosensitization. In cattle, three syndromes may be encountered. Most common is ketosis precipitated by inappetence, seen in pregnant or just-calved cows. Less common is hepatic cirrhosis, seen in cattle usually several weeks after they are removed from lupin stubble. The course of the disease is 1–3 days, and signs include anorexia, depression, staggering gait, jaundice, and bleeding from orifices. Photosensitization occurs in cases which survive for more than a few days. Death may occur within a few days of first illness or be delayed for months, affected animals standing immobile for long periods or wandering aimlessly, often dying from misadventure. More chronic cases exhibit ill-thrift and photosensitization. Recovery may occur if animals in the early stages of the disease are taken off the dangerous pasture, but severely affected animals usually die. Animals that recover appetite will completely recover.

A substantial skeletal muscle myopathy has also been observed in sheep poisoned by phomopsins or infected lupin stubble. Affected animals have a stiff gait, walk reluctantly, and stand with their back humped and their feet under the body, and have difficulty getting to their feet.

Experimental phomopsin poisoning at mating time is associated with reduced reproductive efficiency in ewes.

CLINICAL PATHOLOGY

In the early stages of lupinosis, serum enzyme tests are the best aids to diagnosis. The γ-glutamyl transpeptidase test is preferred in the early subacute stages, and aspartate transaminase when the disease is more severe. In the late stages of the disease liver function tests are preferred.

NECROPSY LESIONS

There are jaundice and either a swollen, mottled bright yellow or pale orange, firm, friable liver in acute cases, or a small and fibrotic one in chronic cases, plus extensive hemorrhages under the skin and serous membranes. Spongy transformation of the brain has been recorded in naturally occurring cases and has also been produced experimentally. Histological lesion mitosis figured in many hepatocytes and necrosis of individual hepatocytes, biliary hyperplasia, and diffuse hepatic fibrosis.

DIFFERENTIAL DIAGNOSIS

Diagnosis confirmation depends on liver histopathology and detection of phomopsins in rumen contents and feeds by ELISA. The differential diagnosis list contains many cases of illness in pregnant and recently calved cows in lupin country which are diagnosed as lupinosis but which are actually cases of pregnancy toxemia or fat cow syndrome. Other fungal or plant hepatopathies will need to be differentiated.

TREATMENT AND CONTROL

Lupin crops should be grazed after seed harvest in early summer, not late autumn. Sheep stocking rates should be less than 30 per hectare. It is an advantage to train sheep to eat lupin seed before they are exposed to crops, thus reducing the intake of stubble as the sheep will forage for seed on the ground. Lupins can be managed to reduce their intake during summer grazing by establishing crop mixtures with wheat, oats, or barley. Prevention is assisted by restricting grazing on mature, standing, dry plants during warm, humid weather which favors fungal growth, by avoiding copper supplementation near danger periods and by encouraging the administration of cobalt. Hay made from lupins appears to be free of toxicity and this may be a useful technique in the prevention of the disease. Fungistatic agents, such as benomyl, are also sprayed onto lupins to reduce fungal growth but no specific recommendations have been made. Additional protection may be gained by the oral administration of zinc which has been shown to reduce the severity of liver damage associated with lupins/fungal poisoning, but commercial application of this knowledge is not yet possible, partly because of the toxicity of the administered zinc. It is advisable to be wary at all times when grazing mature lupin crops. If they are used the crops should be inspected regularly for evidence of fungal infection. If this does occur livestock should be permitted to have access for short periods only, and alternate and supplementary feed should be available.

A satisfactory measure of prevention has been achieved by the development of a phomopsin-resistant strain of Lupinus angustifolius, which is capable of reducing the mortality rate from 57 to 8%. A phomopsin-conjugate vaccine has been successfully tested under field conditions, but is not yet commercially available.
POISONING BY RUBRATOXIN

Penicillium rubrum and P. purpurogenum produce rubratoxins suspected of causing hepatic and hemorrhagic diseases, and rubratoxin administered experimentally to calves has produced mild liver damage. Naturally occurring cases of P. purpurogenum poisoning in horses fed cornmeal and cottonseed cake is associated with an acute illness with anorexia, depression, vomiting, profuse bloody diarrhea with foul-smelling feces, recumbency on the day 4 or 5, and convulsions terminally. Necropsy lesions include icterus, liver damage, and severe hemorrhagic enteritis.1

REFERENCE

POISONING BY SLAFRAMINE

Slaframine is an indolizidine alkaloid of the fungus Rhiocreatia leguminicola found on leguminous pasture plants, especially during wet weather, and associated with the disease of pasture known as ‘black patch’.1 Swainsonine, the phytotoxin found in S. argillacea and A. flavescens, is very similar to slaframine and has also been isolated from this fungus. Ingestion of slaframine is associated with a syndrome, identified colloquially as ‘slobberers’, characterized by profuse salivation in cattle, goats, and horses. Excessive lacrimation, stiff gait, tremor, frequent urination, dyspnea, bloat, anorexia, and diarrhea also occur. The salivation is at its peak at 5–6 hours after ingestion and disappears at about 24 hours. No necropsy lesions are recorded. Slaframine is metabolized in the liver to an active metabolite resembling acetylcysteine.

The fungus infects standing alfalfa or red clover plants and clover hay, especially red clover hay. Infested plants carry brown to black spots or rings, and the hay is usually dusty and discolored by black patches on the stems and leaves. Clinical signs usually subside within several days of substituting normal hay. Atropine may be used to control the salivation.

REFERENCE

ETIOLOGY

Sporidesmins are metabolites of the fungus Pithomyces chartarum (Sporidesmium bakeri) infesting dead plant material in standing pasture. The sporidesmins A to H are pyrrolidiones and are associated with facial eczema, a major disease of sheep and cattle. The occurrence of non-toxic strains of P. chartarum probably accounts for the wide variation in disease occurrence between countries.1

EPIDEMIOLOGY

Occurrence

The disease has been recorded most commonly in New Zealand and occurs to a limited extent also in Europe, Australia, and South Africa. The incidence varies widely depending on climatic conditions; in some years the disease does not occur, in others the morbidity rate in affected flocks of sheep may be 70–80% and 5–50% of these may die. Of the survivors, many are unthrifty and make less than normal weight gains. In cattle, the morbidity rate is much lower and rarely exceeds 50%. In spite of the obvious weight loss associated with the non-fatal form of the disease, there is no appreciable effect on the palatability of the carcass meat.

Risk factors

Animal factors

Sheep, cattle, goats, South American camelds, and kangaroos are affected. Experimental production of the disease in Saanen goats requires 2–4 times the sheep dose, and feral goats need 4–8 times the dose.1

Plant factors

The environmental factors which encourage the growth of the fungus and the production of sporidesmin include the type of plants in the pasture, and the climatic conditions. Facial eczema is commonly associated with rye-grass pastures, but the causative fungus is capable of growing on all kinds of dead leaf material, including...
cereal hay, and causing facial eczema. In South Africa the ingestion of *Pithomyces chartarum* is thought to enhance the toxicity of *Tribulus terrestris*.

Facial eczema occurs extensively only when pasture is short and contains abundant dead, recently killed plant material, and during warm, humid weather, which favors growth of the fungus. This is most likely to be a problem in autumn when the summer has been hot and dry, the pasture well eaten back, and good rains fall when the ground is still warm. In such circumstances the grass and the fungus grow rapidly.

**PATHOGENESIS**

Sporidesmin is associated with severe damage to biliary epithelium, leading to acute biliary obstruction and a resulting severe hepatic insufficiency manifested by loss of condition, obstructive jaundice, and photosensitization. Sporidesmin administered by mouth is excreted unchanged in high concentrations in urine and bile, especially the latter where it reaches 100 times the concentration in serum. The resulting inflammation of the bile ducts and progressive oblitative cholangiitis, slow down the rate of bile flow to negligible levels over a period of about 14 days. The photodynamic agent is phylloerythrin, a normal metabolic product of chlorophyll, which is retained in tissues because of failure of its excretion through the damaged liver and bile ducts. The frequent observation that only part of the liver is involved is probably explained by the deposition of toxin in particular parts of the liver, due to portal streaming, on its first passage through hepatic sinusoids. The toxin which reaches the general circulation is probably destroyed.

**CLINICAL FINDINGS**

In cattle and sheep the disease starts suddenly with the appearance of lethargy, dullness, anorexia, jaundice, and photosensitive dermatitis. The skin lesion and jaundice are both variable in occurrence and sheep may die without either having been observed. Many animals die during this acute stage, but some survive and pass into a state of chronic ill-health manifested by poor bodily condition and a susceptibility to minor environmental stresses. Many others show no clinical signs but have significant changes in serum enzyme systems indicative of an acute hepatic injury, and measurable reductions in reproductive efficiency and lamb weights. Occasional animals develop the syndrome of hepatic encephalopathy manifested by dullness, depression, progressing to tremor and lateral recumbency. Spongy vacuolation of brain tissue is observable histologically in these cases. A moderate fall in the plane of nutrition, parasitic infestation, and pregnancy may be associated with further mortalities, and photosensitive dermatitis may recur if the animals are fed on lush green pasture. Cattle are not as commonly affected by the chronic form of the disease as are sheep but dermatitis of the teats may lead to the development of mastitis.

**DIFFERENTIAL DIAGNOSIS**

Diagnosis confirmation depends on a positive assay of sporidesmin in fluids and tissues of affected animals. High spore counts on pasture are circumstantial evidence. Facial eczema must be differentiated from those other diseases in which photosensitization and hepatitis occur.

**Diagnosis confirmation depends on a positive assay of sporidesmin in fluids and tissues of affected animals. High spore counts on pasture are circumstantial evidence. Facial eczema must be differentiated from those other diseases in which photosensitization and hepatitis occur.**

**Differential diagnosis list:**

- Pyrrolizidine alkaloid poisoning
- Aflatoxin poisoning
- Steroidal saponin poisoning
- Lantadene poisoning
- Cyanophyte (cyanobacterial) poisoning
- Fascioliasis
- Phomopsis poisoning
- A disease of cattle in the southern United States believed to be associated with the ingestion of dead forage on which a *Periconia* sp. fungus is growing.

**TREATMENT**

There is no primary treatment, except to change animals to new pasture. Supportive treatment for hepatitis and photosensitization, as outlined under those headings, and the administration of antibiotics and anthistamines to control secondary infection and shock may be applicable in animals of sufficient economic value. The provision of drinking water containing 5 g zinc sulfate per 100 L for 28 days is claimed to hasten recovery of affected cattle.

**CONTROL**

One of the major difficulties in the control of the disease is that of predicting the occurrence of an outbreak so that the flock can be changed to non-dangerous pasture. Meteorological observation can be of value, but the counting of spores by a mobile spore catcher is now routinely used in danger areas.

In bad seasons the incidence of facial eczema can be reduced by alternating grazing between native and improved pastures or by reducing the intake of the fungus in any other way. Because of the proclivity of the fungus for dead grass, two acceptable management procedures for prevention are summer irrigation and hard grazing, both of which reduce the amount of foliar substrate available for fungal growth. Avoidance of sandy soils in bad seasons is also advisable because of the greater tendency for grass death on this kind of soil. Allowing pasture to flower, the sward to grow long, the pasture to be damaged by diseases and pests, and frequent mowing, encourages facial eczema.

In a comparison of fungicides used to control the growth of *P. chartarum*, carbendazim was best (at 0.15 and at 0.30 kg/hectare of active ingredient), while benonl and thiophanate methyl was effective only at 0.30 kg/hectare. The original methods of applying fungicidal agents to pasture included thiabendazole or benomyl (Benlate) sprayed on at the rate of 272 g/hectare in January. The growth of *P. chartarum* was controlled and the development of facial eczema prevented.

The discovery of non-toxic strains of *P. chartarum* in New Zealand and South Africa which sporulate profusely but produce no sporidesmin, and compete aggressively with sporidesmin-producing strains, raises the question of controlling facial eczema by dominating the pastoral fungal population with the sporidesmin-negative strain.

The daily oral administration of zinc (30 mg/kg zinc BW/day) to lactating dairy cows has been shown to reduce the toxic effects of sporidesmin. The zinc salt can be administered by drench as slurry of zinc oxide, by spraying zinc oxide onto pasture, and adding zinc sulfate to the drinking water. Zinc poisoning is reported as a result of overzealous applications of zinc for these purposes. Iron salts, including ferric ammonium citrate, ferric and ferrous sulfates, have the same protective effect but the volume required makes their application impractical.
Attempts vaccination against sporidesmin has so far been unsuccessful in protecting sheep against facial eczema. Resistance to sporidesmin is strongly inherited but flocks containing increased numbers of resistant animals do not have superior productivity. Finnish Landrace sheep are significantly more resistant to P. chartarum poisoning than Romneys, with cross-breds in an intermediate position.

Other soil penicillia produce tremorgens. P. piscarium produces verruculogen and fumitremorgen B. P. esterigenum also produces verruculogen. P. niger is yields penitrem A. P. janninellum and P. cyclopium also produce penitrem A. P. rubrum is associated with frothing at the mouth, champing of the jaws, jaundice, cutaneous erythema, and collapse in goats and pigs. In horses, the clinical signs of intoxication include incoordination, chronic spasm, jaundice, diarrhea, abdominal pain, and vomiting. These fungi are soil-borne and could be accidentally ingested by cattle and sheep while grazing. A. fumigatus in moldy corn silage produces tremorgens and toxins capable of causing enteritis.

The disease 'rye-grass staggers' is now known to be associated with the endophytes Neotyphodium lolii but it is possible that some outbreaks of incoordination in sheep and other species may be contributed to or even associated with other tremorgens such as those listed above. A subsidiary effect of tremorgenic fungi is a depression of testosterone production in rams and bulls. To confirm a diagnosis that fungal intoxication is the cause of cases of staggers depends on the isolation of tremorgenic fungi from the feces of affected animals. The fungal elements survive passage through the ruminant gut and can be cultured from the feces.

Other fungi causing similar incoordination syndromes but in which no toxin has been identified are listed.

**POISONING BY TRICHOTHECENES**

Trichotheccenes are the largest group of mycotoxins, and amongst the most toxic. They are divided into two groups, the macrocyclic and the non-macro cyclic trichotheccenes, on the basis of their molecular structure.

**MACROCYCLIC TRICHOTHECENES (SATRATOXIN, VERRUCARIN, RORIDIN, ETC.)**

The standard nomenclature for the diseases associated with this group of mycotoxins is retained, stachybotryotoxicosis, and myrothecioticosis.

**Stachybotryotoxicosis**

Toxins in the fungus Stachybotrys chartarum (S. atra, S. alternans), which is associated with this disease, are the macrocyclic trichotheccenes, satratoxins G and H, roridin E, and verrucarin J. Horses, cattle, sheep, and pigs may be affected and the disease is characterized by fever, ruminal atony, diarrhea, dysentery, necrotic ulceration, and hemorrhages of the nasal and oral mucosas, causing epistaxis and purulent nasal discharge, and conjunctivitis causing lacrimation. Drying and cracking of the skin are visible, especially periorbitally and on the face. At necropsy there are hemorrhages into all tissue and under all serous membranes.

An important abnormality is the depression of leukocyte formation, causing agranal cytosis, and producing a disease not unlike that associated with bracken poisoning in cattle. Hemorrhages are visible in the mucosae, there is also hemorrhagic enteritis and, in sheep, Pasteurella haemolytica can often be isolated from tissues. The infection is thought to occur as a result of the immunosuppression associated with the toxins. In horses there is also a subacute or acute myositis. The disease resembles alimentary toxic aleukia, associated with the ingestion of toxin from Fusarium poae and F. sporotrichioides, in humans.
tentative. A partial list of fungi includes the following best known ones:

- Cephalosporium spp.
- Fusarium culmorum
- F. graminearum
- F. moniliforme
- F. nivale
- F. poae
- F. roseum
- F. semitectum
- F. sporotrichioides
- F. tricinctum
- Trichoderma spp.
- Trichothecium spp.

The standard syndrome associated with these fungi includes vomiting, feed refusal, anorexia, diarrhea, gait incoordination, mucosal hemorrhages, and ulcerative stomatitis. Necropy lesions consist of generalized hemorrhages and hemorrhagic enteritis.

Any one or combination of them can be implicated in the production of the following diseases if they produce the specified toxin at the specified time. The specific toxins involved, and the syndromes they are associated with include those discussed below.

**T2 toxin**

A sesquiterpene compound, the T2 toxin is produced by *F. tricinctum*, *F. nivale*, and *F. sporotrichioides* growing on grain may be associated with generalized hemorrhages, but experimental administration of the purified toxin parenterally produces a quite different range of signs including emesis, posterior paresis, lethargy, hunger, and frequent defecation of normal stools. Other experimental evidence is that the oral administration of the T2 toxin or cultures containing it to piglets and calves is associated with no hemorrhagic disease.

Field evidence of the relationship between the ingestion of the fungus and the appearance of hemorrhagic disease is strong, but the identity of the specific toxic agent may be in doubt. Confusion about the effects of the toxin may be due to the refusal of pigs to eat contaminated feed, while cattle will eat it. T2 toxin fed to pigs is associated with necrotic, contact lesions on the snout, and commissures of the mouth and the prepuce.1 Topical application of T2 toxin to pig skin is associated with initial swelling and purple discoloration, followed by separation and sloughing by day 14.2 It has also been cited as the probable cause of congenital skin defects about the head and tarsus of pigs. T2 toxin is associated with immunosuppression when fed to laboratory animals, sheep, and pigs. This leads to leukopenia, lymphopenia, and atrophy of lymph nodes, thymus, and spleen, but the immunosuppression is minor. Blood coagulability is reduced due to toxic effects on platelets.3 The toxin also is associated with reproductive ineficiency when given experimen tally to pigs, causing small litters, repeat breeders, and abortion.

**Deoxynivalenol**

Deoxynivalenol ( synonym vomitoxin), is a sesquiterpene compound found in *Fusarium graminearum* (roseum), *F. sporotrichiella*, and *F. culmorum*. It is a potent central emetic, to which pigs are very sensitive; sheep and cattle are quite resistant, and horses much less so.4 The toxin may be associated with acute diarrhea, dysentery, ataxia, mucosal hemorrhages, and sudden death. The commonest field observation about the toxic effect of deoxynivalenol fed to pigs is that it is associated with absolute feed refusal or reduction in weight gain and feed intake.5 This effect is magnified when the toxic feed also contains *fusaric acid*.6 Deoxynivalenol is not excreted in the milk.7

The only effective method of preventing losses due to deoxynivalenol is to dilute affected corn with uncontaminated feed. Mixing the feed with bentonite, sweeteners, or sodium-calcium aluminosilicate is ineffective as a detoxification method,8 but rinsing and removing floating material is recommended.9 Feed toxic to pigs may be utilized by feeding it to ruminants.

**Diacetoxyisocynenol**

The most important disease in those associated with the non-macroyclic trichothecones is the one associated with *F. tricinctum*, a fungus common on ear corn. It produces a potent toxin (diacetoxyscirpenol) which is associated with necrotic lesions and hemorrhages in the skin, mouth, intestine, liver, and kidneys. In cattle, the clinical syndrome includes mucosal hemorrhages and erosions, intermittent salivation, and depression. The stomatitis is characteristic and needs to be differentiated from similar lesions associated with viruses. Continued exposure to the fungus can be associated with heavy mortalities in cattle. In pigs, the experimental disease is manifested by hemorrhagic bowel lesions, but the toxin also produces a syndrome including emesis, lethargy, hunger, frequent defecation of normal stools, and posterior paresis.

**Fusariotoxicosis syndromes without specified toxins**

*F. graminearum* (roseum) produces toxins associated with emesis and refusal of feed and toxins lethal to pigs, as well as estrogenic substances causing infertility in pigs. *F. culmorum* also is associated with inappetence, scouring, ataxia, and a fall in milk yield when fed to cattle. The fungus *F. moniliforme* is associated with food refusal in cattle. Food refusal is also recorded with zearalenone.

**REFERENCES**

**POISONING BY ZEARALENONE**

*Fusarium graminearum*, *F. roseum* (Gibberella zae) growing on moldy maize or barley grain produces estrogenic substances, especially T2, or zearalenone, a non-steroidal estrogenic mycotoxin which acts by depressing serum gonadotropin levels. Swine are most commonly affected but cases occur in cattle and sheep. *F. culmorum* growing on oat herbage also produces much zearalenone but not when growing on perennial rye grass. Zearalenone has been detected in pastures in New Zealand, where it has been associated with infertility in ewes and cows.3

In pigs, vulvovaginitis, including swelling of the vulva to three to four times normal size, enlargement of mammary glands, a thin, catarhal exudate from the vulva, and increased size and weight of the ovaries and uterus is the severest form of the poisoning. Prolapse of the vagina occurs commonly (up to 30% of affected pigs), and prolapse of the rectum in some (5-10%). The toxin does reduce serum progesterone levels in sows but the administration of progesterone to affected gilts does not counteract the estrogenic effects.2 The syndrome is indistinguishable from that produced by long-term overdosing with diethyl stilbestrol. Signs appear 3–6 days after feeding of the moldy grain commences and disappear soon after the feeding stops. Pigs of all ages are affected, including sucklings feeding on sows which themselves show no signs of estrogenism.3 Worst affected are gilts 6–7 months old. The mortality rate is high due to the secondary development of cystitis, uremia, and septicemia.1

The more important manifestation of the poisoning may be infertility, including absence of estrus, high levels of stillbirth, neonatal mortality, and reduced litter size. Small fetal size, fetal malformations, splayleg and hindlimb paresis, pseudo-pregnancy, and constant estrus are also recorded.
Experimental feeding of zearalenone to boars has some depressing effect subsequently on libido but all structural parameters, such as testicular size, are unaffected. There is no effect on the volume or concentration of the ejaculate, 

or the motility of spermatozoa in rams. In small pigs, zearalenone is associated with degenerative changes in seminiferous tissue, but does not delay the onset of puberty or have any subsequent effect on female reproductive efficiency, provided the toxin is withdrawn from the diet at least 2 weeks before mating.

In cattle, the effect is largely on conception rate, and the rate of services per conception may rise but the overall effect is less than in sows. Behavioral estrus occurs at times unrelated to ovarian cycles and in late pregnant cows. There is idiopathic vaginitis. Symmetrical enlargement of the mammary glands is recorded in prepubertal dairy heifers feeding on the feed for estrogenic activity by feeding it to experimental animals may be attempted. Complete recovery follows when the feeding of the affected grain is stopped and no treatment other than surgical repair of the prolapsed organs is attempted.

**REFERENCES**

**MISCELLANEOUS FUNGI LACKING IDENTIFIED TOXINS**

Diseases associated with fungi without the causative toxin having been identified, are arranged in order of the predominant clinical disorder, and are outlined below.

**HEPATIC DAMAGE**

*Helminthosporium ravenelli* growing on esparto grass is credited with producing a syndrome of excitement, dyspnea, tachycardia, hypersalivation, tremor, jaundice, and some deaths in Argentinian cattle. *Drechslera campanulata* (synonym *Helminthosporium* spp.) occurs as brown-red spots on the leaves of cereal oat plant and is associated with diarrhea, milk yield reduction, and death in some cows. Similar syndromes are found in sheep and goats, except that photosensitivity is also apparent in goats. At necropsy there is ulceration of the forestomach mucosae. A fungus, *Periconia* spp., which grows on forage in the field, is also suspected of being associated with hepatic damage and photosensitization in cattle in the southern United States. There is a close resemblance in clinical signs and circumstances of occurrence to facial eczema and myrotheciosis. Sesquiterpenes found in moldy sweet potato tubers are listed under that heading.

**CONGENITAL DEFECTS**

**Congenital spinal stenosis**

In calves whose dams were fed moldy hay during pregnancy, this defect may affect 100% of the calf drop in a particular year. Clinical signs include posterior paralysis or paresis, shortened limbs, arthritic deformity of the front limbs, brachygnathia of the upper jaw, and dome-shaped cranium.

**BLACK SOIL BLINDNESS**

This is a newly-identified mycotoxicosis of grazing cattle, associated with the fungus *Corallorhytis asterophora* growing on Mitchell grass (*Asterlea* spp.) in pastures on heavy basalt (black soil) soil in tropical north-west Australia. The disease has occurred only once, in a year marked by heavy, seasonal rainfall and a longer than usual growing season. Morbidity and mortality were high at the peak of the outbreak. Clinical characteristics include blindness and death within 24 hours. Necropsy lesions include renal tubular nephrosis, rumenorectitis, and moderate liver cell damage.

**NERVOUS SIGNS**

Nervous signs of tremor, gait incoordination, recumbency, and convulsions predominate in the toxic effects ascribed to the ingestion of *Trichothecium roseum* and *Penicillium cyclopium*. *Diapedia maydis* (synonym *D. zea*, *Sclerotinia maydis*) is associated with a severe disease of maize cobs, corn cob rot. Infected cobs fed to cattle, sheep, goats, and horses are associated with diapodiosis, a neurymocytocysis, reported only in South Africa. If the subjects are females in the second and third trimesters of pregnancy, there may be a very high mortality, up to 87%, of stillborn or newborn lambs or calves, many of the dead neonates have widespread degeneration of the central nervous system. The fungus develops its toxin only after a prolonged (more than 6 weeks) period of growth. This may explain frequent reports that the fungus is not poisonous. The same applies to cultured fungus used to produce the disease experimentally; it must be a culture at least 8 weeks old. Affected animals recover if feeding of the infected grain is stopped. Clinical signs in adults include lacrimation, salivation, tremor, ataxia, paresis, and paralysis, but signs disappear when the grain is removed from the diet. A status spongiosus lesion may occur in the brain of affected animals, but in most cases there are no necropsy lesions. Fetuses are much more susceptible and spongiform lesions in the brain are present in most. Their body weights are less than normal and the gestation period is also reduced.

**Aspergillus clavatus poisoning**

Substrates for *A. clavatus* include distillery by-products, sprouted barley grain, sorghum beer residues and sprouted maize. Muscle tremor, frequent falling, ataxia, progressive paresis, knuckling at the fetlocks, especially in the hind limbs, seizures, paralysis, and death occur in cattle and sheep. Degenerative lesions of large neurons have been recorded in the brain stem, the gray matter in the spinal cord, and spinal ganglia in cattle and sheep. Muscle necrosis occurs in some cases.

**REPRODUCTIVE DYSFUNCTION**

*Penicillium roqueforti*, growing on moldy mixed grain and ensilage, is suspected of causing bovine abortion and retained placenta. *Trichothecium roseum* (white clover) does not normally contain estrogens but when heavily infested with fungi it may contain significant amounts. *Ustilago hordei* (barley smut) fungus is thought to be toxic to farm animals; feeding it to experimental animals has been associated with infertility and stillbirths. In southeastern Australia a common infertility syndrome, including abortion and fetal mummification, has been ascribed to an onion-like weed, *Romulea rosea*. There is a suspicion that the disease may be due to a toxin produced by a fungus, *Helminthosporium biseptatum*, growing on the weed.

**UREMIA**

*Tilletia tritici* (wheat smut) fungus should not be included in rations for pigs because it is thought to be associated with glomerulonephritis and failure to gain weight. Estimates of the maximum safe content of infected grain that can be fed in the ration vary from 5% to 30%.

POISONING BY CYANOBACTERIA

CYANOBACTERIA IN FRESH WATER BLOOMS

ETIOLOGY
Toxic cyanobacteria, or blue-green algae, which form dense blooms in fresh water bodies, include:

- Anabaena circinalis
- A. spiralis
- Aphaniizonon spp.
- Coelosphaerium spp.
- Cylindrospermopsis raciborskii
  (containing the hepatotoxin cylindrospermopsin)
- Gloeotrichia spp.
- Gomphosphaeria spp.
- Microcystis aeruginosa (synonym Anacystis cyanea)
- Nodularia spumigena (brackish water)
- Nostoc rutilare
- Oscillatoria spp.

They contain toxins which survive in water when the cells die or are damaged. Toxicity occurs from ingestion of live cyanobacterial cells or their toxins liberated from ruptured cells.

EPIDEMIOLOGY
Occurrence
Cyanobacterial toxins are associated with outbreaks of poisoning in farm animals that drink contaminated water. Lakes, dams, ponds, stagnant rivers, and waterholes are all affected, especially when the organisms are concentrated by onshore winds so that large quantities may be ingested. In small waterholes, dams, and ditches the surface water is often completely covered with a very thick coat of gelatinous organisms (water bloom), and animals are unable to drink without ingesting some of it. The disease has been recorded in most countries, especially the United States, Canada, Scandinavia, Japan, South Africa, Australia, and New Zealand, and affects all animals and birds. The cyanobacteria occur also in brackish and marine waters and are associated with mortalities in fish. Deaths do not necessarily occur, especially if animals are able to avoid large concentrations.

Risk factors
Heavy growth commonly occurs in the late summer to autumn period. Factors promoting growth of the organisms and increasing the chances of animals being poisoned include high water temperature, especially sunny weather when the water is very shallow, high electrolyte concentration as a result of massive water loss by evaporation, and a high concentration of other nutrients such as nitrogen and phosphorus, associated with animals defecating and urinating in the water, by fertilizer run-off or human sewage inflow.

ETIOLOGY
Toxic cyanobacteria, or blue-green algae, which form dense blooms in fresh water bodies, include:

- Anabaena circinalis
- A. spiralis
- Aphaniizonon spp.
- Coelosphaerium spp.
- Cylindrospermopsis raciborskii
  (containing the hepatotoxin cylindrospermopsin)
- Gloeotrichia spp.
- Gomphosphaeria spp.
- Microcystis aeruginosa (synonym Anacystis cyanea)
- Nodularia spumigena (brackish water)
- Nostoc rutilare
- Oscillatoria spp.

They contain toxins which survive in water when the cells die or are damaged. Toxicity occurs from ingestion of live cyanobacterial cells or their toxins liberated from ruptured cells.

EPIDEMIOLOGY
Occurrence
Cyanobacterial toxins are associated with outbreaks of poisoning in farm animals that drink contaminated water. Lakes, dams, ponds, stagnant rivers, and waterholes are all affected, especially when the organisms are concentrated by onshore winds so that large quantities may be ingested. In small waterholes, dams, and dugs the surface water is often completely covered with a very thick coat of gelatinous organisms (water bloom), and animals are unable to drink without ingesting some of it. The disease has been recorded in most countries, especially the United States, Canada, Scandinavia, Japan, South Africa, Australia, and New Zealand, and affects all animals and birds. The cyanobacteria occur also in brackish and marine waters and are associated with mortalities in fish. Deaths do not necessarily occur, especially if animals are able to avoid large concentrations.

Risk factors
Heavy growth commonly occurs in the late summer to autumn period. Factors promoting growth of the organisms and increasing the chances of animals being poisoned include high water temperature, especially sunny weather when the water is very shallow, high electrolyte concentration as a result of massive water loss by evaporation, and a high concentration of other nutrients such as nitrogen and phosphorus, associated with animals defecating and urinating in the water, by fertilizer run-off or human sewage inflow.

PATHOGENESIS
The toxins in a variety of cyanobacteria appear to be the same or similar and fall into two groups: neurotoxic and hepatotoxic. The known neurotoxins are a combination of at least three compounds:

- Anatoxin-a, an alkaloid and a potent postsynaptic depolarizing neuromuscular blocking agent
- Anatoxin-A (s), an organophosphorus compound and potent cholinesterase inhibitor
- Saxitoxin and related paralytic shellfish toxins (sodium channel blockers).

These are known to come from Anabaena spp., most commonly, but also from Oscillatoria and Aphaniizonon spp.

The known hepatotoxins are the cyclic peptides microcystin from Microcystis aeruginosa and other Microcystis spp., Anabaena flos-aquae, Oscillatoria spp., and nodularin from Nodularia spumigena, which prefers brackish water, and the alkaloid cylindrospermopsin from Cylindrospermopsis raciborskii.

The toxic effects of cyanobacteria vary widely depending on the species present and the amounts of toxic material consumed. Many blooms are not toxic, but all should be considered potentially so.

CLINICAL FINDINGS
Affected animals are commonly found dead, particularly so with neurotoxic blooms. Clinical signs may become apparent within 15 minutes after exposure. In acute cases the affected animals have muscle tremor, stupor, increased salivation in some outbreaks in cattle, staggering, recumbency, and in some cases hyperesthesia to touch so that slight stimulation, provokes a convulsion with opisthotonus. Abdominal pain, diarrhea, and dyspnea are additional signs. After experimental dosing, death may occur within a few minutes of the first appearance of clinical signs, but in field cases the course may be prolonged for several hours.

In the less acute hepatotoxic cases there is severe liver damage manifested by anorexia, stupor or hypersensitivity, ruminal atony, dehydration, recumbency, jaundice, and photosensitization in cattle and sheep. Many of the apparently unaffected and recovered animals die in the ensuing 3 months.

Affected pigs are anorexic and show dullness, vomiting, lethargy, tremor, frothing at the mouth, coughing, sneezing, dyspnea, and dysentery.

CLINICAL PATHOLOGY
The toxins may disappear from the water within 2–3 days and samples should be taken as soon as possible after the poisonings occur. Laboratory examination for the presence of high concentrations of known toxic cyanobacteria is required. Not many laboratories are equipped to carry out the examination, and a negative result should be treated with caution, especially as there may be as yet unidentified cyanobacteria. Because there is a great deal of variation in the toxicity of strains of the known toxic species, ELISA and other analytical laboratory tests for the toxins produced by the organisms have been introduced. A specimen of the bloom material should be collected and be immediately preserved for identification, as degeneration of cyanophyte cells is rapid during transport to the laboratory. Add 1 mL of 10% formalin to 20 mL of bloom material. For toxicity testing submit at least 20 mL of bloom material without added preservative (1 L preferred).

Clinical pathological findings rated in order of frequency in sheep exposed to microcystin are high levels of bile acids, glutamate dehydrogenase, γ-glutamyl transferase, and serum bilirubin, and reduced levels of albumin.

 necropsy lesions are usually absent in animals that die suddenly of the neurotoxic syndrome. In cases of the hepatotoxic syndrome, lesions may include massive hepatic necrosis, generalized petechiation, plasma transudates in body cavities, and congestion of most viscera. Severe gastroenteritis with intestinal hemorrhage and
severe bloody diarrhea have also been observed in some outbreaks.

### DIFFERENTIAL DIAGNOSIS

**Diagnosis confirmation** is by positive assay for the algal toxins in water or preferably body tissues or fluids.

**Differential diagnosis list:**
- Neurotoxic (sudden death) syndrome:
  - Electrocution or lightning strike
  - Cyanide poisoning
  - Anthrax
  - Nutritional deficiency of selenium or vitamin E
  - Nutritional deficiency of copper (falling disease)
  - Poisoning by *Phalani* spp.
  - Poisoning by cardiac glycosides in plants
  - Poisoning by fluoroacetate as 1080 compound or in plants
  - Poisoning by a number of miscellaneous plants which are associated with cardiac arrest but in which the cardiox toxin has not been identified
  - Poisoning by monensin or other ionophore, especially in horses.

**Hepatotoxic syndrome:**
- Pyrrolizidine poisoning
- Steroidal saponin poisoning
- Lantadene poisoning
- Phomopsin poisoning
- Sporidesmin poisoning
- Aflatoxin poisoning
- Fascioliasis.

### TREATMENT

There are no specific primary antidotes. **Supportive** treatment includes activated charcoal orally intended to prevent further absorption of toxin.

### CONTROL

The two principles involved are the prevention of ingestion of floating bloom material by animals and preventing the addition of nutrients that promote cyanobacterial growth to the water.

Prevent the ingestion of toxins by:
- Moving livestock to clean water sources, or drawing drinking water from a site away from the bloom
- Keeping bloom away from water intake by a floating boom
- Add precipitants, e.g. lime, ferric alum, gypsum; removes algae without release of toxin; removes phosphates (see below). Alternatively spread straw on top of water and suspend bales of straw in the water.
- Killing cyanobacteria with algicides such as copper sulphate added to the water was a common recommendation, but is no longer advocated. The killed cyanobacteria release toxins into the water, so as it is contaminated it cannot be used for stock drinking water for at least 5 days. The algicides also damage other vegetation and may ultimately promote further cyanobacterial blooms.

Prevention of the addition of nutrients to water by:
- Fencing off water sources from direct livestock access and providing drinking water by piping it to troughs
- Precipitate phosphates with lime, gypsum, ferric alum; useful only for small reservoirs
- Mechanical aeration of bottom layers of water body; useful only for large water reservoirs
- Exert catchment control and minimize use of phosphatic fertilizer, inflow of sewage, filter the inflow by enhancing reed bed and wetland growth, and control overfertilization and vegetation generally along the banks of watercourses
- Remove feral fish, e.g. European carp, which increase the availability of phosphate in the stream by stirring up the sediment on the bottom.

### REVIEW LITERATURE

### REFERENCES

### ALPINE PASTURE CATTLE DEATHS

Cattle grazing high alpine pastures in summer have access to oligotrophic drinking water in ponds and lakes containing the cyanobacteria *Oscillatoria limosa* and *O. tenuis* (synonym *Phormidium konstantinowii*) growing as dense mats on submerged rocks and sediments and producing hepatotoxic microcystin which can be in sufficient quantity to be associated with fatal hepatoxicosis.¹

### RATHAYIBACTER TOXICUS IN NEMATODE GALLS OF PASTURE GRASSES (ANNUAL RYE-GRASS TOXICITY, FLOOD PLAIN STAGGERS, STEWART'S RANGE SYNDROME)

#### Synopsis

**Etiology** Bacteriophage-infected *Rathayibacter toxicus* plus grass nematode *Anguina funesta* infesting grass, e.g. *Lolium rigidum*, *Lachnagrostis filiformis*, *Polypogon monspeliensis* eaten by all species.

**Epidemiology** Outbreaks when grass mature and infected seed head galls ingested.

**Clinical findings** Fall when disturbed, paddling convulsion, hypermetric, stiff gait; death during a convulsion. High morbidity and mortality rates; up to 100% in sheep.

**Clinical pathology** Increased activity of hepatic enzymes in serum.

**Necropsy finding** Diagnostic perivascular edema in meninges and brain.

**Diagnosis confirmation** Tunicamyluracil in pasture seed heads.

**Treatment** Cyclodextrin.

Chlordiazepoxide effective but lacks practicality.

**Control** Close up paddocks when pasture grasses mature.

### ETIOLOGY

Nematode larvae infest and are associated with galls in the seedheads of *Lolium rigidum* (Wimmera or annual rye-grass), *Festuca nigrescens* (Chewing's fescue), *Polypogon monspeliensis* (annual beard grass)³ and *Lachnagrostis filiformis* (formerly *Agrostis avanacea*) (blowaway grass). The nematodes *Anguina funesta*, *Anguina spp.* and *Vulpia myuros* carry *Rathayibacter toxicus* (formerly *Corynebacterium rathayi* or *Clavibacter toxicus*) into the grass seeds attached to their cuticles. Provided these bacteria are infected by a bacteriophage, they produce toxins in the seedhead gall, and the sheep, cattle, and horses grazing the pasture are poisoned, with the development of a characteristic clinical picture.

The ***toxins*** are glycolipid tunicamyluracils (corynetoxins) which originate from galls containing the yellow-pigmented *R. toxicus*. They reach peak concentration when the grass is fully mature.

Lethal oral dose of corynetoxins for sheep is 3-5 mg/kg. The subcutaneous lethal dose is much smaller, 30-40 μg/kg as a single dose or a set of small sequential doses. The toxins are cumulative.
if the intervals between doses are less than weeks.

**Epidemiology**

**Occurrence**

The disease which occurs in livestock pastured on *L. rigidum* (termed annual ryegrass toxicity, or ARGT) or in those grazing *Lachnagrostis filiformis* (*Agrostis avenacea*) (floodplain staggers) has become a very important cause of death losses on farms in western and southern Australia, and is also recorded in South Africa. Toxicity on *Polypogon monspeliensis* (termed Stewart’s Range syndrome) is restricted to a small part of southern Australia. Clinical signs do not occur until the stock has been on the pasture for several days or up to weeks. Forced exercise and high ambient temperatures precipitate or exacerbate clinical signs.

**Plant risk factors**

Pasture improvement based on annually alternating crop-pasture rotations seems to predispose to the disease, with the worst outbreaks occurring after the end of a cropping year. This can be avoided by burning the pasture in the autumn. It is introduced onto farms by the introduction of infested grass seed or agricultural implements contaminated with it. *Lolium rigidum* has become a weed in southern Australia and herbicide-resistant strains have evolved, complicating control measures. The standing grass becomes toxic as soon as the seed head appears, and loses the toxicity as soon as heavy rain falls. Hay made from infested grass remains poisonous for 5–6 years. The disease, associated with *Agrostis avenacea,* has occurred in cattle on extensive pasture recently subjected to severe flooding, hence the name floodplain staggers.

**Pathogenesis**

The causative toxin is similar structurally to the antibiotic tunicamycin, and the diseases associated with each of the two compounds are indistinguishable. The tunicamycin interferes with glycoprotein synthesis and is capable of causing cerebral vascular lesions in experimental animals. Interference with cardiovascular function and vascular integrity leads to interference with oxygenation of tissues, particularly the brain.

**Clinical signs**

Signs appear when the cattle or sheep are disturbed or stressed, especially by driving. The animals fall in a convulsion with paddling of limbs, nystagmus, opisthotonos, jaw champing and salivation, sometimes neck ventroflexion, head nodding, tetanic extension of limbs and, in sheep, posterior extension of the hindlimbs. Death may occur during a convulsion or, if left alone, the animal may recover to the point of being able to stand, but there may be gait incoordination, due to hypermetria, stiff gait, a broad-based stance, head swaying, rocking backwards and forwards, and loss of balance. Intermittent convulsive episodes recur and the patients soon go down again and death occurs in up to 24 hours. Further cases occur for up to 10 days after affected animals are removed from the pasture. Morbidity and mortality rates may reach as high as 100% in sheep flocks.

**Clinical pathology**

Blood levels of liver enzymes, bilirubin and bile acids are elevated.

**Necropsy findings**

Necropsy findings are inconsistent and non-specific. The liver may be enlarged and pale. There may be haemorrhages in a range of tissues. Histologically, there may be perivascular edema in the brain, particularly in cerebellar meninges. Other lesions may include significant liver damage.

**Differential diagnosis**

Staggers/convulsion syndromes associated with a high mortality rate are not uncommon. Diagnosis confirmation depends on:

- combination of a convulsive syndrome with access to mature pasture carrying seed
- detection of severe inhibition of liver microsomal N-acetylglucosamine-1-phosphate transferase activity from liver biopsy or necropsy samples
- histopathology of brain and liver
- identification of bacterial galls in seedhead material
- quantitative detection of *Rathayibacter toxicus* antigens by ELISA on pasture, fodder, rumen contents, faeces
- a positive assay of corynetoxins in pasture or fodder

The differential diagnosis list includes:

- Phalaris staggers
- Perennial ryegrass staggers
- Lead poisoning
- Poisoning by any one of a large number of plants in which the toxic agent has not been identified.

**Treatment**

Affected flocks or herds should be removed from a toxic pasture as slowly and quietly as possible to good-quality feed with shade and water in a place free of disturbance. Pharmacological measures are impractical. An antidote was developed by CSIRO in Australia for use early in outbreaks of poisoning. It is a cycloheximide, a cyclic glucose molecule with a hydrophobic central cavity which sequesters the corynetoxins molecules. It is formulated as a gel for intra-peritoneal injection. Field trials have been disappointing.

**Control**

Pasture management in endemic areas should aim to reduce exposure of livestock to mature pastures with seedheads. This may be achieved by a variety of measures such as heavy stocking during winter and spring, harvesting pasture for silage or hay before seedling followed by heavy grazing to remove ryegrass seedlings, burning crop and pasture residues and herbicide application. Biological control measures being pursued include development of early-flowering *L. rigidum* cultivars that carry fewer bacterial galls and the pasture application of *Dilophospora alopecuri,* a fungal pathogen of *Anguina funesta.* Administration of cobalt orally may have some prophylactic effect against the poisoning. Immunization against the toxin is promising and is being actively researched.

SNAKEBITE

**Synopsis**

**Etiology** Venom injected into victim by a bite with specially adapted fangs.

**Epidemiology** Isolated attacks during summer months. A rare clinical disease in large animals.

**Clinical findings** Muscle weakness, stumbling gait, recumbency, pupillary dilation, swallowing paralysis, salivation, muscle tremor. May be swelling and tissue necrosis at bite site.

**Clinical pathology** Venom detectable in blood, urine, body tissues and fluids generally.

**Necropsy findings** May be local swelling and tissue necrosis.

**Diagnosis confirmation** Based on detection of venom in body tissues or fluids.

**Treatment** Injection of type-specific antivenene.

**ETIOLOGY**

At least four toxic actions can result from snake venoms, and different snakes have varying combinations of toxins in their venoms (Table 33.3). The toxins include necrotizing, anticoagulant, and coagulant fractions as well as neurotoxic, cardiotoxic, and hemolytic fractions. Although there is often insufficient toxin injection to cause death in large animals, a serious secondary bacterial infection may be set up in the local swelling and cause the subsequent death of the animal. The common venomous snakes include *Crotalus* spp. (rattlesnakes and pit vipers of North America), the true vipers, e.g. *Vipera berus* (northern viper, the United Kingdom's only venomous snake), and the elapid snakes including the cobra, mamba, and most of Australia's venomous snakes including *Notechis scutatus* (tiger snake) and *Pseudonaja* (Demansia) *textilis* (common brown snake).

**EPIDEMIOLOGY**

The incidence of snakebite is controlled by the geographical distribution of the snakes and their numbers. Asia, India, Africa, Central and South America, Australia, and the southern United States are areas in which snake populations are large. In general, the morbidity rate in farm animals is low, although a mortality rate of 20% has been recorded in a small group of bitten animals.

Most snakebite accidents occur during the summer months and bites are mainly about the head because of the inquisitive behavior of the bitten animal. Pigs are not highly susceptible but not, as generally believed, because of their extensive subcutaneous fat depots. Sheep may be bitten.

</tbody>
</table>
on the udder but their long wool coat is generally effective as a protective mechanism on other parts of the body. Large animals tend to be resistant because of their large size and the large dose rate required to cause death. However, horses appear to be much more susceptible to venom than any other species.

PATHOGENESIS
The effects of snakebite (envenomation) depend upon the size and species of the snake, the size of the bitten animal and the location of the bite, particularly with reference to the thickness of the hair coat and the quantity of subcutaneous fat. As a general rule the venom is injected by fangs which leave a bite mark comprising a row of small punctures with two large punctures outside them. An exception is the coral snake, which must chew to inoculate the venom. The bites may be visible on hairless and unpigmented skin but can only be seen on reflection of the skin at necropsy in many instances. Non-poisonous snakes may bite animals, but the bite mark is in the form of two rows of small punctures.

The toxins in venom include:
- Neurotoxins, causing flaccid paralysis, pupillary dilatation, and paralytic respiratory failure
- Cytolysins, which are associated with tissue necrosis, including platelets, leading to intravascular coagulation
- Hemolysins, coagulant or thrombolytic, and anticoagulants leading to a hemorrhagic tendency
- Myotoxins, causing muscle necrosis and myoglobinuria.

The overall effect of a bite by a snake depends on the mix of specific venoms in the dose delivered and the actual dose which depends on the size of the snake and the period since the snake last bit. Tiger snake venom contains neurotoxins and coagulants. Death adder venoms contain only neurotoxin, brown snake has coagulant and some neurotoxin. Rattlesnake venom is associated with necrosis of arterioles and arteriolar thrombus formation, and in most species contains an anticoagulant, causing a bleeding diathesis. The Mojave rattlesnake Crotalus scutulatus is an exception.

CLINICAL FINDINGS
Bites by adder-type snakes (crotalids) are associated with a local swelling which develops rapidly and is associated with severe pain, usually sufficient to produce signs of excitement and anxiety. Bites about the head may be followed by swellings of sufficient size to cause dyspnea. If sufficient neurotoxin has been injected a secondary stage of excitement occurs and is followed by marked dilatation of the pupils, salvation, hyperesthesia, tetany, depression, recumbency, and terminal paralysis. In small animals, death may occur due to asphyxia during convulsions in the excitement stage of the disease. In animals that recover there is usually local sloughing at the site of the swelling.

Bites by cobra-type snakes (elapids) are associated with local swelling in animals that survive the effects of the neurotoxin. These commonly develop local swellings due to bacterial infection 3–4 days later. The major effects after bites of cobra-type snakes are excitement with convulsions, and death due to asphyxia. The signs appear quickly and death occurs usually in up to 48 hours in horses. In calves, the effects of the neurotoxin are manifested by marked pupillary dilatation, excitement, incoordination, and later paralysis.

Clinical signs in horses bitten by tiger snakes (Notechis scutatus) in Australia include pronounced pupillary dilatation without pupillary response to light, but the menace reflex is present and the animal can see. Muscle tremor is most obvious in the standing patient and the horse is very fidgety and wants to lie down. The tremor disappears when the animal lies down, but it will not stay down and insists on rising and wandering about in a compulsive way.

Clinical signs in foals bitten by brown snakes (Pseudonaja textilis) in Australia are similar to those associated with tiger snake envenomation. There is drowsiness, drooping of eyelids and lips, partial tongue paralysis, muscle tremor and weakness, leading to recumbency; pupillary dilatation occurs in some. The respiration becomes labored and abdominal. Sweating and inability to suck, swallowing or whinny, occur late in the course. Adults also show inability to swallow, with salivation and accumulation of food in the mouth.

Rattlesnake bite in calves is associated with restlessness, teeth grinding, vomiting, dyspnea, ataxia, and convulsions.

CLINICAL PATHOLOGY
An ELISA for identification of venom in blood, urine or other body tissue or fluid is available. It is highly accurate, suitable for field or office use, immediate but expensive. It is limited to the snake species for which reagents are available.

NECROPSY FINDINGS
Local swellings at the site of the bite are due to exudation of serous fluid, which is often deeply blood-stained. Fang marks are usually visible on the undersurface of the reflected skin.

DISENTIAL DIAGNOSIS

<table>

</table>

Local swelling, consider also a diagnosis of:
- Blackleg
- Anthrax in horses and pigs
- Non-specific phlegmonous infections

TREATMENT
In human medicine the application of a tourniquet proximal to a limb bite site has been replaced: a firm pressure bandage is applied over the bite to restrict the distribution of the venom via the lymphatics and retain it in the site and prevent systemic effects. Excision of the bite site is recommended for the bites of snakes (crotalids) which are associated with a serious local reaction.

Systemic treatment should include antivenin, antibiotics, and antitoxin. Antivenin containing antibodies against the venoms of all the snakes in the area can usually be obtained locally, often in highly purified form. It is expensive to use but highly effective. Speed is essential and the IV route is preferred. A portion of the antivenin should be injected locally around the bite. The dose rate varies widely with the size of the animal, one unit often being sufficient for animals weighing 70 kg or more, but smaller animals of 9–18 kg BW require about 5 units. A broad-spectrum antibiotic should also be administered to control the local infection at the site of the bite. The occurrence of clostridial infections after snakebite suggests the administration of antitoxins against tetanus and gas gangrene. Supportive fluid treatment may be advisable when shock is severe and the administration of a sedative may be necessary to control pain and excitement.

Many other treatments have been used in snakebite, including particularly ACTH, cortisone, and antihistamines. These drugs have been found to be valuable as a protection against possible anaphylaxis after treatment with antivenin, but in cases where local tissue damage is evident they are without value and in many cases exert deleterious effects. Adrenaline or epinephrine have little or no value and calcium salts do not significantly reduce mortality.
The application of chemicals to the incised bite area is also of no value and may exacerbate tissue damage. Attention has been drawn to the need to appreciate the mode of action of one's local snakes before attempting a general program of treatment—or what may be effective in one country may very well be lethal in another.

REVIEW LITERATURE

REFERENCE

BEE STINGS

Multiple stings by bees may be associated with severe local swelling up to 6 cm diameter, similar to those in angioedema but with a stinger in the center. The tips, eyelids, tongue, and vulva are often swollen and painful. Pain may result in pronounced excitement, and in severe cases in horses there may be diarrhea, hemoglobinuria, jaundice, tachycardia, cardiac arrhythmia, rapid breathing, sweating, and prostration. Animals attacked about the head may show dyspnea because of severe local swelling. Horses often show mild-to-moderate colic. In rare cases the attack may be fatal, usually after a course of 4–12 hours. Necropsy lesions include hemorrhages and edema of all connective tissues and the bowel wall. Treatment includes the local application of a weak solution of ammonia or sodium bicarbonate, nervous system stimulants if prostration is severe, and tracheotomy if asphyxia threatens.

REFERENCE

ANT BITES

Bites from the aggressive red imported fire ant (Solenopsis invicta) have been associated with focal necrotic ulcers of the cornea and conjunctiva of newborn calves. Weak calves are most likely to be injured.

REFERENCE

TICK PARALYSIS

Infestations with a variety of species of ticks are associated with paralysis of animals. Dogs are most commonly affected but losses can occur in lambs, calves, goats, foals, and even children. Ixodes holocyclus have been shown to paralyze calves of 25–50 kg BW. Between four and ten adult female ticks are required to produce this effect and paralysis occurs 6–13 days after infestation occurs. The ticks under natural conditions parasitize wild fauna, and infestations of other species occur accidentally. The disease is limited in its distribution by the ecology of the ticks and the natural host fauna. The paralysis characteristic of the disease is associated with a toxin secreted by the salivary glands of female ticks and which is present in much greater concentration in the glands of adults than in other stages. The severity of the paralysis is independent of the number of ticks involved; susceptible animals may be seriously affected by a few ticks.

The toxin of Dermacentor andersoni interferes with liberation or synthesis of acetylcholine at the motor end plates of muscle fibers. The disturbance is functional and paralysis of the peripheral neurons is the basic. Continuous secretion of toxin by a large number (35–150) of partly engorged female ticks which have been attached for 5–8 days is necessary to produce paralysis, complete recovery occurring within 24 hours when the ticks are removed. The disease is confined to calves and yearlings.

Clinically, there is paralysis in dogs, but deep. Ulcers of the gastric squamous mucosa are highly diagnostic but no necropsy findings occur in many cases. Mass spectrometric and gas or liquid chromatographic methods facilitate detection of cantharidin in field specimens of blood, urine, gut contents, and feed.

Treatment is symptomatic. Inspection of hay for the beetles can avoid the problem. Infested fields should not be harvested.

MARE REPRODUCTIVE LOSS SYNDROME (EARLY FETAL LOSS, LATE FETAL LOSS, EPIDEMIC FIBRINOUS PERICARDITIS, EPIDEMIC UNILATERAL ENDOPTHALMITIS)

ETIOLOGY AND EPIDEMIOLOGY

A syndrome of increased incidence of early fetal loss (< 70 days of gestation) and late-term abortion was recognized in north central Kentucky and southern Ohio, Illinois, and Indiana in 2001 and,
Diseases associated with zootoxins (animal bites and stings)

The early fetal loss in mare reproductive loss syndrome is associated with the ingestion of Eastern Tent caterpillars (Malacosoma americanum).1-3 Abortion of mares at 40–80 days of gestation is induced by gavage with starved Eastern Tent caterpillars, feeding of whole caterpillars, or feeding of caterpillar exoskeleton, but not gavage or feeding of caterpillar frass (excreta), autoclaved homogenate of caterpillars, or filtrate of homogenized caterpillars.1-3 Abortion is induced by feeding or intragastric administration of 50 g of caterpillars/day for 10 days.1-3 Mares abort from 8 to 28 days after first ingestion of caterpillars.1-3 The lag time between ingestion of caterpillars and abortion is longer for ingestion of lesser amounts of caterpillars.2 The association between ingestion of Eastern Tent caterpillars and late term abortion, birth of weak or non-viable foals of normal gestational age, pericarditis, and endophthalmitis has not been demonstrated experimentally. However, there is strong epidemiologic and circumstantial evidence to support a role for M. americanum in the etiology of these diseases.

Actinobacillus spp. is often isolated from pericardial fluid of horses with pericarditis during outbreaks of epidemic pericarditis, which has a temporal relationship with early fetal loss and late-term abortion, but is likely not the inciting agent.4

Occurrence
The documented outbreak of the syndrome occurred from April 26 through mid-June of 2001, with a lower incidence of disease during the same months in 2002. The disease has been recorded only in the Ohio River valley and north-central Kentucky. The disease caused early fetal loss in 25–63% of mares on one-third of farms, 14–24% on another third, and 2–13% on the remaining one-third.5 Approximately 21% of mares pregnant at 42 days of gestation were not pregnant when examined at 70–90 days of gestation. 6 The expected pregnancy loss rate between 42 days and parturition is 12%.6 Over 3000 mares aborted during the outbreak.4

Risk factors
Risk factors for the disease are those associated with exposure to Eastern Tent caterpillars and include the presence of large numbers of caterpillars on pasture, pasturing or feeding hay to horses at pasture, and presence of mares with pericarditis on the farm.5,6

For late-term abortion the risk factors include increased amount of time at pasture, less time in stall, feeding concentrates on the ground, increased proportion of feed obtained from pasture, and being fed exclusively in pasture during the final 4 weeks of gestation.7 All of these factors favor exposure to Eastern Tent caterpillars.

Risk factors for pericarditis include presence of mares or foals with mare reproductive loss syndrome on the farm, grazing, and exposure to Eastern Tent caterpillars.7 Risk factors for endophthalmitis have not been defined.

Eastern Tent caterpillars are endemic to the eastern United States including the Ohio River valley.8 Egg masses are laid on many trees in the Rosaceae family including cherry trees, the preferred host.8 Eggs hatch in the early spring at the time that the cherry trees bud. Local populations of the caterpillars fluctuate dramatically from year to year, but mares are likely exposed to small numbers of the caterpillars every spring.8,9 Climatic conditions that favor survival of Eastern Tent caterpillars and synchronize their maturation result in simultaneous hatching of large numbers of eggs. The rapid emergence of large numbers of caterpillars results in abrupt and heavy exposure of horses and consequent development of mare reproductive loss syndrome.4 Weather conditions believed to contribute to the 2001 outbreak include a period of low temperatures in March, above normal temperatures in April, and a frost and freeze in late April immediately followed by several warm days.5

The economic losses incurred because of mare reproductive loss syndrome during 2001 are estimated to be $US330 million.4

PATHOGENESIS
The pathogenesis of the diseases associated with mare reproductive loss syndrome has not been defined.

CLINICAL SIGNS
Early fetal loss
This is detected by per rectum uterine examination, either manual or using ultrasonographic visualization of uterine contents, during early pregnancy. Fetal loss occurs after 35 days, conception not being affected, and affected mares do not come into estrus because of the presence of endometrial cups, which do not regress until 100–150 days after ovulation.10 Mares have no clinically detectable premonitory signs of fetal loss. Ultrasonographic examination of the uterus of pregnant mares reveals that the allantoic fluid of fetuses <80 days of age has increased echogenicity on the day of fetal death.10 Allantoic fluid increases in echogenicity with increasing fetal age and care should be taken when interpreting this observation.

Late fetal loss
This occurs as a late-term abortion (final several weeks of gestation), birth of a stillborn foal at full term, and the birth of a foal that is weak and of reduced viability.10-11 The birth of an affected foal is associated with premature placental separation ('red bag' deliveries), foaling while standing, and explosive expulsion of the fetus and placenta.10,11 Foals born alive are weak, have sunken eyes, progressive neurologic signs consistent with hypoxia, and have a high death rate (50%) despite intensive care.10,11 Severe leukopenia at birth often progresses to leucocytosis at 24–48 hours of age. Serum biochemical abnormalities include elevated serum creatinine concentrations, hypoglycemia, and increased serum creatine kinase activity.10 Bacteria isolated from stillborn foals at necropsy or on culture of blood samples from sick foals are non-specific organisms including non-hemolytic streptococci and Actinobacillus spp.

Fibrinous pericarditis
This manifests as signs of congestive heart failure secondary to cardiac tamponade in adult horses. Horses often have a history of fever but not other clinical abnormalities. There is accumulation of large quantities of pericardial fluid and fibrin deposition on the parietal and visceral pericardial surfaces evident on ultrasonographic examination of the chest.12 The lungs have ultrasonographic evidence of consolidation consistent with pneumonia in approximately 50% of cases. Pericardiocentesis yields abundant fluid that is light yellow and has a low white blood cell count (≤5 x 10^9/L) characterized by well-preserved neutrophils.12 Horses with a prolonged course of the disease (>2 weeks) can have elevated white cell counts in pericardial fluid secondary to opportunistic infection, usually with Actinobacillus spp.13,14 Hematologic abnormalities are minimal and characterized by a slight leucocytosis in approximately 50% of cases.15 Azotemia occurs in horses with severe cardiac tamponade.

Diagnostic confirmation is based on the presence of appropriate clinical signs with a history of exposure of affected horses to Eastern Tent caterpillars.

NECROPSY FINDINGS
Examination of placenta, stillborn foals and foals that die after birth reveals inflammation of the intra-amniotic umbilical cord (funisitis), diffuse alveolitis, and hemorrhage in a variety of organs.16 Horses with pericarditis have impressive accumulation of hairy fibrin in the pericardial space with marked thickening of the visceral and parietal pericardium (a hoary heart).
TREATMENT
Treatment of affected foals is based upon the principles delineated in 'Principles of the care of newborns' and is primarily supportive. Horses with pericarditis should have the fluid drained to relieve or prevent cardiac tamponade and to minimize the accumulation of fibrin. Pericardial fluid might need to be drained on a number of occasions and its accumulation should be monitored ultrasonographically. Administration of broad spectrum antibiotics and dexamethasone phosphate or equivalent (30–40 mg IV or IM once daily for 3–5 days) is successful in approximately 50% of horses with disease of <5 day's duration. Horses with disease of longer duration might require more aggressive therapy including pericardial lavage and pericardiectomy. The prognosis for survival for such horses is grave to hopeless.

CONTROL
This is based on prevention of ingestion of Eastern Tent caterpillars by horses.11,13 The control measures include: removing wild or black cherry trees, the favored host species for Eastern Tent caterpillars, from pastures, hedges, and fence rows; applying pesticides to trees to kill over wintering eggs or, after hatching, caterpillars; installation of barriers to caterpillar migration on to pasture; manual removal of egg masses and restricting access of mares to pasture.11,13 Application of bifenthrin or permethrin, but not 3% horticultural oil, to egg masses (tents) during the winter prevents emergence of caterpillars in the spring.13 Insecticidal soap or oils sprayed on neonatal caterpillars is minimally effective. Bifenthrin or spinosad are effective against all instars for 7 days when sprayed on foliage.13 Injection of trunks of cherry trees with dicofolos or enamecin is effective against all instars but injection with milbemecin or avermectin is not effective.13 A spray of 50 mL of 39% permethrin diluted in 4 L of water and applied to a 2-m wide band of pasture outside the fence line kills migrating caterpillars and prevents them obtaining access to pasture.14 This solution can also be sprayed on the trunks of trees to kill caterpillars as they leave the tree.

Preventing horses ingesting caterpillars by minimizing access to pasture and feeding hay in stalls is likely to be beneficial. Farms that have aggressively implemented measures to prevent horses ingesting Eastern Tent caterpillars have prevented the disease.11

LOPHYROTOMIN AND PERGIDIN
(SAWFLY LARVAE) POISONING

Larvae of the sawflies Lophyrotoma interrupta in Australia, Arge pullata (birch sawfly) in Denmark, and Perreyiea flanipes in South America2 are eaten by cattle, sheep or pigs as they lie on the pasture under the infested trees. The toxins they contain, the peptides lophyrotomin and pergidin, are associated with severe liver necrosis and a syndrome of tremor, dyspnea, recumbency convulsions, and sudden death in acute cases. Less acute cases show hyposensitivity, jaundice, photosensitization, diarrhea, and dysentery. Necropsy lesions include periacinar or panacinar hepatic necrosis, some nephrosis, and extensive hemorrhages in the alimentary tract, and fluid transudates in serous cavities in longer surviving cases.5

Mares may also be exposed by transfusion of incompatible blood. While whole blood transfusions to mares or fillies are unusual, plasma transfusions are increasingly being used to treat failure or partial failure of transfer of passive immunity to foals. Because plasma usually contains some red blood cells, transfusion of plasma from donors possessing blood group antigens that the foal does not could immunize the foal against these factors with the potential for disease when the foal matures and gives birth. However, most commercial plasma products are harvested from donors that do not have the blood group antigens identified as being problematic.

32 blood group antigens are recognized in horses:\3
- A, a, b, c, d, e, f, g
- C, a
- K, a
- U, a
- D, a, b, c, d, e, f, g, h, i, j, k, l, m, n, o, p
- P, a, b, c, d
- Q, a, b, c

Neonatal isoerythrolysis is attributable in over 90% of cases to antibodies directed against either Aa or Qa antigens, although disease due to antibodies against Ab, Dc, Da, Db, Ka, Qb, Qc, Qrs, Pa, and Ua is reported.2,3 The presence in the mare of antibodies against Cb decreases the probability that she will develop anti-Aa antibodies.4

15 blood groups have been identified in pigs and the disease is recorded as occurring spontaneously associated with antibodies to the G group antigens. Historically, the main occurrence of neonatal isoerythrolysis in pigs was manmade and related to repeated vaccination against hog cholera using the pooled blood, inactivated by addition of crystal violet, of affected pigs.

The disease has also occurred in calves whose dams had been vaccinated against babesiosis or anaplasmosis using a vaccine containing bovine blood.5 As a result of vaccination the dam develops lytic antibodies against sire antigens, usually of the

### ALLOIMMUNE HEMOLYTIC ANEMIA OF THE NEWBORN (NEONATAL ISOERYTHROLYSIS, ISOIMMUNE HEMOLYTIC ANEMIA OF THE NEWBORN)

**Synopsis**

**Etiology** Maternal alloantibodies to neonate’s blood group antigens are transferred to the neonate in colostrum and cause lysis of the neonate’s red blood cells.

**Epidemiology** Disease in progeny of multiparous mares or sows. The dam lacks blood group antigens possessed by the sire and inherited by the foal, calf, or piglet. The majority of cases in foals are due to the presence of Aa or Qa antigens and antibodies. Sows vaccinated with crystal violet vaccine or cows with babesia or anaplasmosis vaccines can be associated with disease in their newborns.

**Clinical findings** Lethargy, recumbency, tachycardia, tachypnea, icterus, and hyperbilirubinemia.

**Diagnostic confirmation** Positive antiglobulin (Coombs test) or hemolysis test using mare’s serum or colostrum and foal’s red blood cells.

**Treatment** Transfusion of blood or packed red blood cells from suitable donor, or of mare’s washed red blood cells.

**Control** Identify at-risk mares by blood typing. Examine mare’s serum or colostrum for presence of incompatible antibodies before allowing foal to suckle.

### ETIOLOGY

Hemolytic anemia of newborn horse and mule foals, calves, and piglets occurs because of immune-mediated (antibody-dependent cellular cytotoxicity or type II hypersensitivity) destruction of the neonate’s red blood cells by antibodies acquired from the dam. The specific antibodies are present in the colostrum, absorbed by the neonate, and cause lysis and/or agglutination of red blood cells.

The disease is associated with the natural occurrence of inherited blood groups and only occurs if the dam is exposed to red blood cell antigens that she does not possess. In response to such exposure the dam produces antibodies directed against the foreign red blood cell epitopes. If the neonate possesses a blood type against which the dam has developed antibodies and depending on the red blood cell factor involved, red blood cell destruction can occur. The newborn acquires the red blood cell types that are foreign to the dam through inheritance from the sire. Disease occurs after birth because the fetus is not exposed to the antibodies in utero because of the epitheliochorial placentation in mares and sows and the synedochorial placentation of cattle. Antibodies in serum are secreted into the colostrum in the peripartum period and are subsequently ingested and absorbed by the newborn. Mares that have anti-red blood cell factor antibodies in their serum almost invariably have the same antibody in their colostrum.1 The serum concentration of anti-Aa and Qa antibodies is highest in the last 3 months of gestation and peaks about 1 week after parturition. For neonatal isoerythrolysis to occur:

The fetus must have blood group antigens (factors) that the dam does not. These are inherited from the sire. The dam must be exposed to the foreign blood group antigens that the fetus possesses.

The dam must produce antibodies against the blood group antigens of the fetus. Not all blood group antigens are highly immunogenic or are associated with disease in the neonate.

The newborn must ingest and absorb colostrum that contains antibodies directed against antigens on the newborn’s red blood cells.

The disease occurs naturally in foals and piglets but is usually iatrogenic in calves. Exposure of the dam to foreign red cell epitopes may occur at parturition or during gestation as a result of placental lesions although most incompatible pregnancies do not result in sensitization of the mare.
A and F blood groups, and antibodies in colostrum cause acute hemolytic anemia in the calves.

**EPIDEMIOLOGY**

**Horses and mules**

From 1 to 2% of Thoroughbred and Standardbred mares have antibodies capable of causing neonatal isoerythrolysis. The incidence is partially related to the proportion of the mare population at risk. An at-risk mare is one that lacks either the Aa or Qa blood group factor. The proportion of mares that lack one or both of these factors is breed dependent, with 19% of Thoroughbreds lacking either Aa or Qa antigens and 17% of Standardbred mares lacking Aa antigens. All Standardbred horses lack the Qa factor; neonatal isoerythrolysis in this breed is usually due to antibodies against the Aa factor, with 10% of Standardbred mares having anti-Aa antibodies. Only 2% of Thoroughbred mares lack the Aa antigen but this low proportion is important because approximately 50% of these mares will develop anti-Aa antibodies. Conversely, 16% of Thoroughbred mares lack the Qa antigen, but only 5% of these mares have the anti-Qa antibody. The risk of mares developing antibodies against certain red blood cell types is also related to the prevalence of the antigen in the horse population. For instance, Standardbred mares lack the Qa antigen, but because this antigen is not found in the breed any Standardbred stallion the mare is mated to will not be Qa positive, neither will the foal, and there is no risk of the mare being exposed to the antigen.

The incidence of neonatal isoerythrolysis in mule foals (donkey sire horse dam) can be 10% and is attributable to the universal presence of a unique blood group antigen, 'donkey factor', in jacks and mule foals. Mares do not possess this factor and therefore all donkey sire horse dam pregnancies are incompatible. Progeny of horse sire donkey dam matings are not affected.

A feature of naturally occurring neonatal erythrolysis in foals and piglets is that it rarely if ever occurs in offspring of primiparous dams because the induced anti-red blood cell antibody titer is not sufficiently high to induce the disease. Subsequent exposure during later pregnancies elicits an anamnestic response that results in higher anti-RBC antibodies, and disease in the newborn. However, first pregnancy offspring are often affected after vaccination of the dam with blood products.

**PATHOGENESIS**

The interaction between the antibody and the red cells of the newborn is followed by hemolysis with resultant anemia, hemoglobinuria, and jaundice. Following ingestion and absorption into the systemic circulation, antibodies bind to red blood cell membranes. Parts of the cell membrane of the antibody-coated cells are removed from the circulation, probably by the spleen and associated reticuloendothelial tissues, and affected cells are eventually lysed and release hemoglobin into the circulation. The affected animal develops normovolemic anemia and, if the destruction of red blood cells is sufficient, develops anemic hypoxia and dies. The reaction between red blood cells and antibodies occurs sufficiently quickly that the bone marrow is unable to compensate immediately for the loss of red blood cells. Disseminated intravascular coagulation (DIC) occurs and may contribute to the death.

Permeability of the intestine of the newborn foal to antibody disappears by 36 hours and in most cases much less. Hourly milking of the mare rapidly reduces the antibody content of the colostrum. The duration of the alimentary permeability in piglets has not been determined.

**CLINICAL FINDINGS**

**Horses and mules**

Pregnancy and parturition are uneventful and the foal is normal for some hours after birth. Signs appear only if the foal ingests and absorbs colostrum containing anti-red blood cell factor antibody. The severity of disease ranges from clinically inapparent to fulminating with death ensuing soon after birth.

**Peracute cases** develop within 8–36 hours of birth, and the first indication of the disease may be collapse. Severe hemoglobinuria and pallor are evident but icterus is not apparent initially. The mortality rate is high.

In **acute cases** signs do not develop until 2–4 days after birth and jaundice is marked, with only moderate pallor and hemoglobinuria. **Subacute cases** may not show signs until 4–5 days after birth. Jaundice is marked, but there is no hemoglobinuria and only mild pallor of mucosae. Many subacute cases recover without treatment.

The severity of the disease is related to the type and quantity of antibody ingested. Antibodies against Aa usually produce severe disease apparent within 24 hours of birth, while ingestion of anti-Qa antibodies causes a milder disease apparent at 3–4 days after birth.

General signs include lassitude, weakness, and disinclination to suck. The foal lies down in sternal recumbency for long periods and yawns frequently. There is no febrile reaction but the heart rate is increased up to 120/min. Respiration is normal until severe anemia develops when tachypnea (respiratory rate up to 80/min) and yawning are observed. Terminally, dyspnea and convulsions may develop. Peripheral edema does not occur and there are no signs of involvement of the central nervous system. Bilirubin encephalopathy or kernicterus is a rare complication of neonatal isoerythrolysis. It is apparent as altered mentation and seizures in foals with high serum bilirubin concentration.

**Isoimmune thrombocytopenia** of foals and mules may be evident as ecchymotic hemorrhages and a tendency to bleed from relatively minor wounds. A syndrome in foals characterized by ulcerative dermatitis, neutropenia, and thrombocytopenia appears to be related to ingestion of colostral antibodies. Affected foals have oral and lingual ulcers, and crust and erythema around the eyes, muzzle, perineum, trunk, and neck. There are ecchymotic and petechial hemorrhages in mucus membranes. Treatment with corticosteroids and antibiotics is associated with a good prognosis.

**Pigs**

Piglets show essentially the same syndrome, being normal at birth but developing jaundice at 24 hours and weakness at 48 hours, with most affected pigs dying by the 5th day. Peracute cases occur and piglets may die within 12 hours of birth, showing acute anemia but no jaundice or hemoglobinuria. A proportion of subclinical cases also occurs in which hemolysis can be detected only by hematological examination. **Isoimmune thrombocytopenic purpura** of piglets may manifest as increased bleeding following routine management procedures such as tail docking.

**Cattle**

In calves clinical signs develop within 24–48 hours after birth and the calves die during the first week of life. Surviving calves are returned to normal health in 2–3 weeks. Peracute cases die within 24 hours, and at necropsy examination are characterized by pulmonary edema and splenomegaly.

**CLINICAL PATHOLOGY**

Hematological examination reveals acute anemia; erythrocyte counts, packed cell volumes, and hemoglobin concentrations are low and there is greatly increased erythrocyte fragility and sedimentation rate. Depending on the severity of the disease and its duration, there can be leukocytosis, attributable to neutrophilia and monocytosis, and the presence of nucleated red blood cells (in piglets and calves but rarely in foals). Affected mule foals, but not horse foals, are often thrombocytopenic. Isoimmune thrombocytopenia is characterized by widespread ecchymotic hemorrhages and petechiae, as well as neutropenia.
bocytopenia occurs rarely in foals and is not associated with neonatal isoerythrolysis, as it is in mule foals. In piglets, the erythrocyte count may be as low as 1 million/µL, the hemoglobin level below 2 g/dL, and thombocytopenia is present. Serum biochemical analysis reveals an increased serum concentration of unconjugated bilirubin.

Diagnostic confirmation is achieved by demonstration of the presence of antibodies in the mare's serum or colostrum that cause hemagglutination or lysis of foal red blood cells. Tests to demonstrate hemagglutination or lysis of foal red blood cells exposed to mare serum or colostrum have been developed. Of these, the standard hemolysis test appears to have the greatest utility. However, for practical purposes a positive direct antiglobulin test (direct Coombs' test), confirming the presence of antibodies on the surface of red blood cells in a foal with anemia, provides a diagnosis of neonatal isoerythrolysis. False negative (foal has the disease but the Coombs' test is negative) results occur occasionally because of the hemolytic nature of the antibodies. The same principle is applicable to all species. Detection of antibodies on the surface of the neonate's red blood cells is possible using direct immunofluorescence flow cytometry. The test identifies the presence of antibodies on red cells in some instances when the Coombs' test is negative.

The use of blood typing and other prepartum predictive tests in the prevention of the disease are discussed under control.

DIFFERENTIAL DIAGNOSIS

- There are no diseases of the newborn that present the same clinical picture as that of alloimmune hemolytic anemia.

Differential diagnosis list for unexpected death and/or lethargy of neonates

**Foals and calves**
- Septicemia
- Neonatal maladjustment syndrome
- Uroperitoneum
- Prematurity
- Birth trauma
- Hypoglycemia
- Equine herpesvirus-1 infection

**Piglets**
- Septicemia
- Birth trauma
- Hypoglycemia.

TREATMENT

The aims of treatment are to:
- Prevent the deleterious effects of anemia
- Prevent or treat hemoglobinuric nephrosis
- Prevent ingestion of further colostrum
- Prevent secondary infection in severely ill animals
- Restore normal fluid, electrolyte, and acid-base status
- Provide adequate nutrition
- Minimize stress.

The treatment of choice for neonatal isoerythrolysis depends on the severity of the disease. The choice of treatment should be based first and foremost on the severity of the clinical signs and secondarily on the hematocrit and red blood cell count. Foals or piglets with mild clinical signs (minimal lethargy, mild tachycardia, slight exercise intolerance) need only protection from environmental and nutritional stresses in order to recover. However, such animals should be carefully monitored to insure that their clinical condition does not worsen.

Severely affected animals need a transfusion of compatible blood to alleviate the anemia and intravenous fluids to insure adequate urine flow and minimize the risk of hemoglobin-nephrosis. In general, the younger the animal at the time the disease is evident, the more severe the disease and the more likely the need for intensive treatment. See Chapter 9 for a discussion of ‘transfusion triggers’.

**Foals**

**Transfusion**

Transfusion of an adequate quantity of whole blood or packed red blood cells results in dramatic resolution of clinical signs and anemia. The decision to transfuse blood should be based on the foal's clinical condition, and not solely on the presence of a low hematocrit or red blood cell count (see Blood transfusion, in Chapter 9). In general, foals that are tachycardic, tachypneic, unable or reluctant to suck, have severe exercise intolerance or are unable to stand should receive blood. These foals will usually have a hematocrit less than 15% (0.15 L/L). Recumbent foals usually have a hematocrit less than 10% (0.10 L/L). Foals that are mildly tachycardic and tachypneic but are able to suckle vigorously and keep up with the mare generally have hematocrits above 15% (0.15 L/L) and do not require transfusion of red blood cells. The hemocrit should be monitored and foals in which the hemocrit is declining rapidly will likely require transfusion of blood or packed red cells.

The volume of blood transfused depends on the clinical condition of the foal and the progression of the anemia. Foals often require transfusion of 1–4 L (20–100 mL/kg body weight) of whole blood or 500 mL (approximately 10 mL/kg body weight) of packed red blood cells, and might require more than one transfusion. Blood should be administered slowly, 1 L/hour, and the foal's condition monitored closely during the infusion. Packed red cells are preferred for transfusion because of the small volume administered. Transfusion of large quantities of blood should be performed slowly because of the risk of fluid overload of the circulatory system. The half-life for mare erythrocytes transfused into foals is about 5 days.

The optimal donor is a horse that does not have Aa and Qa blood group factors nor anti-Aa and Qa alloantibodies. The former should not be present as the maternal antibodies against Aa or Qa in the recipient foal's plasma will destroy the transfused cells. Similarly, donor antibodies against Aa or Qa will cause further lysis of foal red blood cells. Such donors must be identified in advance, because of the time required for the blood type testing, and are only likely to be available on large breeding farms or in specialized veterinary hospitals.

An ideal source of red blood cells is the dam because the maternal alloantibodies in the foal's plasma will not react with the mare's red blood cells. However, whole blood transfusions from the dam are contraindicated because of the presence of alloantibodies in the dam's plasma. This problem can be avoided by transfusing only the mare's washed red blood cells. Blood is collected from the mare (up to 25 mL/kg) into acid citrate dextrose or sodium citrate (10 mL of a 3.8% solution per 90 mL of blood). The mare's red cells are then washed by removing the plasma, resuspending the cells in isotonic (0.9%)
saline, thorough mixing, and subsequent removal of the saline. Plasma and red cells can be separated by large volume centrifugation or sedimentation. Adequate separation of red cells and plasma occurs by sedimentation within 1–2 hours if the blood is undisturbed.

If an ideal blood-typed donor is not available and the mare's red cells cannot be washed in time, or are unavailable, then a donor should be chosen based on routine cross-matching. The sire will not be a suitable donor, since the antigens against which the mare's antibodies are directed were inherited from him. A cross-match should match the foal's (or dam's) serum against the donor's red blood cells, and the donor's plasma against the foal's red blood cells. The chance of finding a suitable donor is enhanced by selecting ponies or breeds other than Thoroughbreds, Standardbreds, and Arabians, because of the higher prevalence of Aa and Qa negative animals in these breeds.

Emergency support of severely affected foals can be achieved by administration of a solution containing polymerized bovine hemoglobin. This compound increases the hemoglobin concentration of blood thereby increasing oxygen carrying capacity. It is not a replacement for transfusion of blood or packed red cells, but is a useful bridging procedure while a donor is identified and blood collected. The recommended dose rate is 10–30 mL/kg administered slowly (10 mL/kg/h) intravenously. However, the cost of the compound might necessitate the use of lower doses (3–5 mL/kg).

Nutritional support
The foal should not be permitted to nurse the mare until it is >36 hours old. Therefore, nutritional support should provide approximately 100 kcal/kg per day in the form of mare's milk (10 L per day per 50 kg foal), goat's milk, or commercial mare's milk substitutes. If the foal is more than 36 hours old, then it is highly unlikely that either the mare's milk will still contain a significant quantity of antibodies or that the foal will be able to absorb them, and the foal should be allowed to continue to suckle the mare. In younger foals, an alternative feed should be supplied until the foal is at least 36 hours old. The mare should be milked out every 3–4 hours during this time to remove the colostrum.

The fluid, electrolyte, and acid–base status of moderately to severely ill foals should be assessed and corrected with intravenous administration of balanced polyionic fluids and sodium bicarbonate. Fluid administration should be used to insure an adequate flow of urine to prevent hemoglobinuric nephrosis.

Antibiotics

**Broad-spectrum antibiotics** should be administered to severely ill foals to prevent secondary infection (see Principles of providing care to the critically ill neonate).

**Nursing care** should be provided to minimize stress and prevent the development of complications such as pressure sores in recumbent foals.

**Piglets**

In pigs the prevention of sucking for periods of up to 24 hours does not prevent the disease. The safest procedure is to remove piglets from the sow, feed them artificially for 48 hours, and then return them to the sow. Frozen bovine colostrum collected as soon as possible after calving is a satisfactory substitute for sow colostrum but is improved by the addition of pig serum. When transfusion is necessary the intraperitoneal route is practical and safe.

**CONTROL**

The principles of control are:

- Identification of incompatible matings by blood group typing
- Identification of at-risk foals by testing of mare serum or colostrum for the presence of alloantibodies directed against blood factors possessed by the foal.

**Blood group typing** permits the identification of mares that are at risk of developing antibodies against Aa or Qa antigens. If an Aa or Qa negative mare is mated to a stallion that has Aa or Qa factors then there is the potential for neonatal isoerythysis. If the stallion is Aa and Qa negative, then there is no risk of the disease caused by antibodies to these blood groups.

**Measurement of alloantibodies** in the serum or colostrum of at-risk mares is useful in identifying mares at increased risk of having affected foals. Serum from at-risk mares is collected during the last month (preferably 3–5 weeks before expected parturition) of pregnancy and examined for the presence of antibodies against the blood of the sire or, if a sample of the sire’s blood is not available, a range of blood group factors including Aa and Qa. Mares that have such alloantibodies causing hemolysis at >1:16 are not permitted to suckle at risk newborn foals. If the titer is between 1:2 and 1:16, it is measured again 1–2 weeks before anticipated parturition to determine if the titer is rising, in which case the mare is likely carrying a foal with an incompatible blood group. Equine blood typing and detection of isoantibodies is performed by specialized laboratories in a number of countries:

- Australia – www.aegr.crc.uq.edu.au/services
- New Zealand – www.ivabs.massey.ac.nz/centres/centre_blood.asp
- USA – www.uky.edu/Agriculture/VetScience/textpages/epvrlHTM

The jaundiced foal agglutination test (JFT) is useful in determining the compatibility of mare's colostrum and foal's red blood cells (Table 34.1). In this test foal red blood cells are added to serial dilutions (1:2 through 1:32) of colostrum and the presence of agglutination examined. Agglutination at dilutions of 1:16 in horses and 1:64 in mules are considered significant and the foal should not be permitted to receive the mare's colostrum. The foal should be fed colostrum from another, compatible,mare (Table 34.1).

<tr>
<td>1.</td>
<td>Assemble eight 5–10 mL clean glass tubes. Label one as control (saline), and the others 1:2, 1:14, 1:8, 1:16, 1:32, 1:64, 1:128</td>
</tr>
<tr>
<td>2.</td>
<td>Place 1 mL of 0.9% isotonic sterile saline in each tube</td>
</tr>
<tr>
<td>3.</td>
<td>Add 1 mL of colostrum to the tube labeled 1:2. Mix this tube well and then transfer 1 mL of the contents of this tube to the tube labeled 1:4. Repeat this procedure until all tubes have had colostrums added. This procedure produces serial dilution of the colostrums.</td>
</tr>
<tr>
<td>4.</td>
<td>Add one drop of well mixed, anticoagulated blood (e.g. blood collected into a tube containing EDTA) to each tube.</td>
</tr>
<tr>
<td>5.</td>
<td>Centrifuge the tubes at 300–500 g for 2–3 minutes</td>
</tr>
<tr>
<td>6.</td>
<td>Pour off the supernatant and observe the red cell pellet</td>
</tr>
</tbody>
</table>

**Interpretation**

If no agglutination is present the red cells will flow evenly down the side of the glass tube whereas with complete agglutination (>4+) the cells remain tightly packed at the bottom of the glass tube. Strong agglutination (>3+) causes the cells to form large clumps that are visible to the naked eye. Agglutination of grade 3 or 4 is considered a positive test.
Purpura hemorrhagica

ETIOLOGY
The disease is acute and non-contagious. The cause of the vasculitis that characterizes purpura hemorrhagica is likely the deposition of complexes of antigen and immunoglobulin in the walls of capillaries and small blood vessels. The disease appears to be immune complex-mediated and due to a type III hypersensitivity reaction. The common association of the disease is with *Strep. equi* infection of the upper respiratory tract. The high concentrations of antibodies to *Strep. equi* M protein in affected horses, and the presence of complexes of IgA and streptococcal M protein in sera are evidence that the disease is associated with an immune reaction to streptococcal protein. The immune complexes are not found in the serum of horses recovering from *Strep. equi* infection that do not have purpura hemorrhagica. However, in many instances there is no history of streptococcal infection. There is a suggestion that the disease might be associated with an adverse reaction to therapeutic drugs. Vaccination using modified live *Strep. equi* M protein or killed *Strep. equi* vaccines is strongly suggested for inducing the disease.

EPIDEMIOLOGY
Purpura hemorrhagica is an uncommon, non-contagious, sporadic disease of horses. It has been recorded in pigs and cattle. Estimates of the incidence of the disease are uncommon and imprecise. There was an incidence of 27 cases in 1438 horses housed over a 3-year period in a Swedish Army remount facility. All cases of purpura hemorrhagica followed upper respiratory infections, of which 11 were typical of streptococcal infections. Only a small proportion of horses are affected but the incidence is highest when extensive outbreaks of strangles occur, possibly because of reinfection with streptococci of horses already sensitized by previous infection.

Of 53 horses with purpura hemorrhagica treated at a referral center, 17 had been exposed to or infected with *Streptococcus equi*; 5 had been vaccinated with *Streptococcus equi* M protein; 9 had been infected with *Corynebacterium pseudotuberculosis*; and 5 had a history of apparently infectious respiratory disease of undiagnosed cause. Fifteen of 53 horses had no history of recent infectious disease.

There is a strong suspicion among clinicians of an association between purpura hemorrhagica and vaccination. However, vaccination against *Strep. equi* infection has not been clearly demonstrated to be a risk factor for purpura hemorrhagica. Certainly, cases of purpura do occur in horses that have been vaccinated against strangles, but presumably there was a high probability that such horses were at increased risk of developing strangles. The consensus is that vaccination with vaccines containing M protein or avirulent *Strep. equi* is associated with increased risk of purpura. Edema of the lower limbs does occur after vaccination with streptococcal M protein and may represent a mild form of the disease. It is recommended by some authorities that horses with high serum antibody titers to streptococcal M protein not be vaccinated against strangles, although definitive data to support this recommendation are not available.

There does not appear to be breed, age, or sex predisposition to the disease. Horses as young as 6 months of age, and possibly younger, can be affected.

The case fatality rate with appropriate treatment is approximately 10%. Purpura hemorrhagica accounted for 2 and 8% of 2028 and 1245 deaths among horses shipped from Great Britain and the United States, respectively, to South Africa during the Boer War. This mortality rate was before the advent of antimicrobials or corticosteroids which have presumably decreased the case fatality rates.

PATHOGENESIS
The basis of the disease process is an aseptic vasculitis of capillary walls that is accompanied by extravasation of plasma and blood into the tissues. Thrombocytopenia does not occur, nor is there a defect in coagulation in most cases. Prolonged clotting times (activated clotting time, partial thrombin time, and thromboplastin time) occur in severely affected horses with infarctive purpura hemorrhagica. Skin lesions predominate but other organs, including the kidney, muscles, and gastrointestinal tract, are affected.

CLINICAL FINDINGS
Affected horses are usually depressed and have reduced or absent appetite. The temperature is elevated in approximately 60% of cases, as is the heart rate. Extensive subcutaneous edematous swellings are the characteristic sign of the disease. They occur most commonly about the face and muzzle, but are often present on other parts of the body and are not necessarily symmetrical in distribution. The swellings may appear suddenly or develop gradually over several days. They are cold and painless, pit on pressure, and merge gradually into normal tissue without a definite line of demarcation. There is no discontinuity of the skin, although it may be tightly distended and even ooze red-tinged serum. Swellings about the head may cause pressure on the pharynx with subsequent dyspnea and dysphagia. Lesions in the lungs are usually not clinically apparent without radiographic or ultrasonographic...
Submucous hemorrhages occur in the nasal cavities and mouth, and petechiae may be present under the conjunctiva in over 80% of cases. Hemorrhage and edema of the gut wall may cause colic but in most cases there is no diarrhea or constipation. Severely affected skin, and especially that of the legs, may slough and leave granulating wounds.

Infarctive purpura hemorrhagica is an uncommon manifestation of the disease characterized by infarction of multiple tissues including the gastrointestinal tract and muscle. Affected horses have signs of colic and muscle swelling. The course is usually over 3–5 days and death, which is the most common outcome, is associated with severe colic and rapidly deteriorating metabolic status.

The course of the disease is usually 1–2 weeks and many animals die from blood loss, dyspnea due to laryngeal or pharyngeal swelling, and secondary bacterial infections. Relapses are uncommon among appropriately treated horses.

CLINICAL PATHOLOGY
There are no characteristic abnormalities detected on routine hematological or biochemical examinations of affected animals.

Hematological changes are typically a mild anemia (usually <32 but >20%, <0.32 L/L but >0.20 L/L) with a neutrophilic leukocytosis and hyperfibrinogenemia. The platelet count is normal. Hypergammaglobulinemia can be present.

There is an elevation in serum activity of creatine kinase (CK) and aspartate aminotransferase (AST) in affected horses, likely a result of muscle lesions, in approximately 25–30% of cases. Horses with infarctive purpura have marked elevations in serum activity of creatine kinase and aspartate aminotransferase, neutrophilia, and in severely affected horses, there is evidence of disseminated intravascular coagulation.

Diagnostic confirmation is achieved by skin biopsy, especially of early lesions, and reveals leukocytoclastic vasculitis. Immunofluorescence staining of sections of skin may reveal the presence of antibodies, antigens, or complement in the walls of small blood vessels.

NECROPSY FINDINGS
Ecchymotic and petechial hemorrhages are present generally throughout the body. The subcutaneous swellings contain plasma which may be blood-stained, or sometimes whole blood. The lungs are edematous and congested. Histologically, the changes are also dominated by bland hemorrhage but a leukocytoclastic vasculitis is usually observed in scattered vessels. Sample of lung, muscle, and gastrointestinal tract, in addition to skin, should be examined via light microscopy to check for the presence of vasculitis.

Horses with infarctive purpura have dark red to black, multifocal coalescing hemorrhages in skeletal muscles. Hemorrhages also occur in the lungs and gastrointestinal tract. Histological examination reveals coagulative necrosis of muscle and other tissues. There is inflammation of the blood vessels.

DIFFERENTIAL DIAGNOSIS
Horses
Causes of edematous swelling include:
- Equine viral arteritis and equine herpesvirus 1 or 4 infection, which do not have petechiation and are readily distinguished by their epidemiological characteristics and by serological testing
- Equine granulocytic anaplasmosis (ehrlichiosis) which can be differentiated by the presence of granular inclusions in the cytoplasm of neutrophils
- Congestive heart failure, which should be apparent on clinical examination
- Angioneuritic edema, which is not associated with petechiation
- Stachybotryotoxicosis
Causes of petechial hemorrhages include:
- Equine infectious anemia
- Thrombocytopenic purpura
- Stachybotryotoxicosis

Cattle
Hemorrhagic septicemia, poisoning by bracken fern and sweet clover, thrombocytopenia associated with bovine viral diarrhea, and stachybotryotoxicosis are more likely causes of a hemorrhagic syndrome than purpura hemorrhagica.

TREATMENT
The principles of treatment are to reduce inflammation of the blood vessels, remove the inciting cause, and provide supportive care. Because of the possibility that the disease is due to an adverse drug reaction, administration of any drugs that the horse is receiving at the time the disease develops should be discontinued.

Reduction of inflammation of the blood vessels involves mitigation of the immune response and removal of the source of the antigenic stimulus. The immune response, and its associated inflammatory reaction in blood vessels, should be treated with corticosteroids such as dexamethasone (0.05–0.2 mg/kg, IV or IM every 24 hours) or prednisilone (0.5–1 mg/kg, IM or IV every 24 hours). Prednisilone might not be as effective as dexamethasone. The dose of corticosteroid can be gradually reduced as the clinical signs improve, and the drug can be given orally.

Non-steroidal anti-inflammatory drugs (phenylbutazone 2.2 mg/kg orally or IV every 12 hours, or flunixin meglumine 1.1 mg/kg orally or IV every 12 hours) may reduce inflammation and provide some analgesia.

Removal of the source of the antigenic stimulus of the disease is difficult, especially in cases when an antecedent infection or disease is not readily identified. On the assumption that purpura hemorrhagica is often a sequela to Strept. equi infection, and the suspicion that occult Strept. equi infection is present and the source of antigen associated with the disease; affected horses are usually treated with penicillin (procaine penicillin, 20 000 IU/kg, IM every 12 hours, or potassium penicillin, 20 000 IU/kg, IV every 6 hours) until the clinical signs resolve. Treatment with antibiotics might need to be continued for as long as 20 days.

Supportive care includes bandaging of swollen limbs, care of wounds, hydrotherapy, and intravenous fluid administration. Swelling of the head and pharynx may necessitate placement of a nasogastric feeding tube to permit enteral feeding of dysphagic horses. Respiratory distress can develop very rapidly and emergency tracheotomy may be required to relieve respiratory distress and prevent asphyxiation.

CONTROL
There are no specific preventive measures. However, control and prevention of upper respiratory tract infections in horses should lead to a reduction in the incidence of purpura hemorrhagica. Careful consideration should be given to the use of vaccines containing streptococcal M protein or avirulent Strept. equi in horses at low risk of developing strangles. Although the relationship between M protein containing vaccines and purpura hemorrhagica is not definitive, circumstantial evidence and the opinion of authorities in the field support such an association. Measurement of serum antibodies to M protein might be useful in determining the need for vaccination of horses in endemic areas or at high risk.

Horses with antibody titers >1:3200 should not be vaccinated.

REFERENCES
EQUINE SEASONAL ALLERGIC DERMATITIS (QUEENSLAND ITCH, SWEET ITCH)

This is an intensely pruritic dermatitis of horses caused by hypersensitivity to insect bites.

ETIOLOGY

The disease is caused by type I (immediate) hypersensitivity to salivary antigens introduced into the skin by the bites of sandflies and other insects. There may be a lesser role for type IV (cell-mediated) hypersensitivity in the disease. Culicoides brevitarsus is the cause in Australia, C. pulicaris in the United Kingdom and Europe, and C. obsoletus in Canada. Stomoxys calcitrans, the stable fly, and Simulium spp. have been incriminated in the UK. The distribution of the lesions is related to the feeding habits of the inciting insect. For instance, C. pulicaris has a predilection for landing at the mane and tail, and this is where the lesion is most commonly seen.

EPIDEMIOLOGY

The prevalence of the disease varies depending on environmental factors, and possibly characteristics of the local horse population. Up to 60% of horses are reported affected in areas of Queensland, Australia, 22% in Israel, and 18% of Icelandic horses in Norway. The prevalence in Switzerland is very low in regions above 1000 m and 1.6% in lower areas.

The disease is quite common worldwide in areas where hot and humid summer weather favors the causative insects: Sweden, the United Kingdom, Japan, Israel, Hong Kong, North America, Australia, the Philippines, India, and France. Most cases occur during summer and lesions disappear during cooler weather. Lesions disappear when the horses have been stabled in insect-proof barns for several weeks or are moved outside the geographical range of the inciting insect.

The disease is characteristically sporadic and affects only a few of a group of horses. However, because the predilection to the disease is likely inherited, there may be multiple cases among related animals on a farm. The prevalence of the disease increases with age: 3.4% of Icelandic horses 1–7 years of age compared to 32% of horses older than 14 years were affected.

PATHOGENESIS

Reaginic antibodies (IgE) produced in response to exposure to proteins in insect saliva bind to mast cells in the skin and, when exposed to the antigen, are associated with degranulation of the mast cell. Horses with sweet itch have IgE antibodies that react with constituents of the salivary gland of Culicoides sp., whereas horses that do not have the disease have IgG, but not IgE, antibodies against Culicoides salivary gland antigens. Horses that have not been exposed to Culicoides sp. do not have either antibody to the insect salivary gland antigen. Degrading mast cells and intradermal or subcutaneous lymphocytes release various vasoactive substances and cytokines that cause inflammation and accumulation of eosinophils in the skin affected areas and eosinophilia. The distribution of the lesions on patients reflects the insects’ preferred feeding sites. Ponies with seasonal allergic dermatitis have greater numbers of circulating CD3+ and CD4+ T lymphocytes than do normal animals. Increased numbers of CD3+ T lymphocytes, most of which are CD4+, and eosinophils are present in the skin of affected ponies after injection of Culicoides antigen. Furthermore, eotaxin and monocyte chemoattractant protein (MCP) I, but not MCP-2 or MCP-4, mRNA expression is upregulated in skin biopsies of sweet itch lesions, demonstrating a mechanism for accumulation of eosinophils and T-2 lymphocytes in the lesions.

CLINICAL FINDINGS

Lesions are usually confined to the base of the tail, rump, along the back, withers, crest, poll, ears and, less commonly, ventral midline. In severe cases the lesions may extend down the sides of the body and neck and onto the face and legs.

Pruritis is intense, especially at night, and the horse scratches against any fixed object for hours at a time. In the early stages slight, discrete papules, with the hair standing erect, are observed. Constant scratching may cause self mutilation, severe inflammatory lesions, and loss of hair. Scaliness and loss of hair on the ears and tail-base may be the only lesions in mildly affected horses.

CLINICAL PATHOLOGY

Affected animals have eosinophilia and thrombocytosis.

Diagnosis is facilitated by skin biopsy, fungal culture, and parasitological examination of skin scrapings, and intradermal sensitivity testing. Skin biopsy of early lesions, before trauma masks the true picture, reveals edema, capillary engorgement, and eosinophilic and mononuclear perivascular infiltration. Fungal culture and parasitological examination of skin scrapings are useful only in that they rule out dermatophyosis, onchoceriasis, and strongyloidosis. Intradermal skin testing demonstrates immediate and delayed sensitivity reactions to extracts of Culicoides and Stomoxys spp.

DIFFERENTIAL DIAGNOSIS

Infection with larvae of Onchocerca sp. or Strongyloides sp., or Dermatophilus congolensis can produce similar lesions. Alopecia of the tail head may be caused by Oxyuris equi.

TREATMENT

The principles of treatment are removal of the inciting cause and suppression of the hypersensitivity reaction.

Removal of the inciting cause is achieved by preventing horses from being exposed to the inciting insects. This can be achieved by relocating the horse to a geographical region where the insects do not occur, stabling the horse in an insect-proof stable during the periods of the day (early evening) when the insects are most active, or applying agents that kill the insect or otherwise prevent them from alighting on and biting the horse.

Suppression of the immediate hypersensitivity reaction or its sequelae can be achieved by administration of corticosteroids (prednisolone, 1 mg/kg every 48 hours initially then reducing to as low a maintenance dose as possible). Theoretically, hypo-sensitization may be effective, but the only controlled clinical trial to date did not demonstrate a beneficial effect, although the placebo effect on the owners was impressive.

CONTROL

Prevention of the disease necessitates protection against sandfly bites by stabling in insect-proof quarters. Continuous spraying of the horses with insecticides or repellents may be of some value. A 4% permethrin pour-on gives effective protection. Most horses need only one application a week; others need an application every second day.

REFERENCES

SEASONAL ALLERGIC DERMATITIS

A disease similar to sweet itch of horses occurs in sheep in the UK. The lesions
are similar to those in horses and are located principally on the teats, udder, and ventral midline, but also on the tips of the ears, around the eyes, and on the nose and the lips. Because of their appearance only in summer, and in senior ewes, and at a time when midges are plentiful enough to cause signs of insect worry, a cutaneous sensitivity to *Culicoides* spp., especially *C. obsoletus*, is suspected. Histologically the lesions represent the changes characteristic of immediate hypersensitivity. Cutaneous sensitivity to ground up *Culicoides* spp. was demonstrated. A very similar disease occurs in cattle in Japan. It is thought to be due to an allergy to the bite of an external parasite.2

---

**ETIOLOGY**

Heaves, previously referred to as chronic obstructive pulmonary disease, is caused by inhalation by susceptible horses of dust particles found in barns, bedding, and feed materials such as dusty hay. The inhaled particles include endotoxin, mites, plant debris, inorganic materials, and conidia and fragments of molds. *Paenibacillus rectivirgula* (formerly known as *Micropolyspora faeni*), *Aspergillus fumigatus*, and *Thermoactinomyces vulgaris* are molds commonly associated with respiratory disease in susceptible horses, as evidenced by experimental studies involving inhalation of molds or mold fragments by horses.1 Molds contain a number of inflammatory substances including various allergens, glucans, mycotoxins, and proteases and it is not clear which of these agents are the inciting cause of heaves. Moreover, dust containing mold also contains endotoxin. Endotoxin contamination of molds contributes to the airway response to inhalation of preparations of molds used in experimental studies4 and inhalation of endotoxin alone produces airway inflammation and impaired respiratory function in horses in a dose-dependent manner, with heaves-susceptible horses having an exaggerated response at lower doses.4 However, the response to endotoxin is less than that of susceptible horses exposed to hay dust containing endotoxin indicating that endotoxin alone is not sufficient to cause the clinical signs of heaves. Other compounds in hay dust are integral to the development of heaves.5

It is emphasized that there is not one causative agent acting alone but rather a range of agents that, when inhaled in sufficient concentration by susceptible horses, induce airway disease. It is likely that heaves is associated with the potentiating interactions among several agents present in barn or hay dust and is not simply a response to one agent.3,4 The mechanisms underlying development of airway inflammation and respiratory dysfunction are provided under 'Pathogenesis'. Viral infections and 3-methylindole intoxication are not considered important causes of heaves.7

**EPIDEMIOLOGY**

**Occurrence**

Although heaves is one of the more common diseases of horses, and is a major cause of loss of performance and wastage in European horses,3 there are few reports of its epidemiological characteristics. The disease is common in Europe and North America but is rare in Australia. In Germany, 83% of horses believed to be healthy at an auction were found to have clinical evidence of chronic pulmonary disease.4 Inflammatory airway disease is very common in horses, with 96% of racehorses in Hong Kong examined at necropsy and 12% of horses examined in an abattoir in the northern U.S having histological evidence of bronchitis.4,10 Twenty-seven per cent of healthy racehorses in training had an increased proportion (>20%) of neutrophils in tracheal aspirate, indicating inflammatory airway disease.7 However, the airway inflammation common in young athletic horses is not generally considered to be heaves, or a prodrome of heaves. The prevalence of heaves is not well documented. The case-fatality rate for moderately to severely affected horses is approximately 20% over a 2-4 year period.11 Most mildly to moderately affected horses respond well to treatment and continue to perform at a satisfactory level.12

**Risk factors**

**Animal risk factors**

The disease occurs in adult horses and ponies, and animals >7 years of age are 6 to 7 times more likely to be examined because of the disease than are horses <4 years of age.13 There is no apparent breed or sex predisposition with the exception that Thoroughbreds are 3 times more likely to be examined for the disease than are ponies,13 although this could represent a sampling bias in that owners of Thoroughbreds might be more likely to seek veterinary attention than owners of ponies. The finding of increased likelihood of Thoroughbred horses having the disease is not consistent among studies. Horses are approximately 2 times more likely to be examined by a veterinarian because of the disease in winter or spring compared to summer, suggesting a seasonality to the occurrence of the disease perhaps as a result of increased stabling during winter. There are horses that develop the disease and other horses, maintained in an identical situation, that do not. Development of disease is dependent upon the horse being susceptible to the inflammatory effect of inhaled dust but the reasons for this individual susceptibility are poorly understood. A familial predisposition has been suggested based on the observation that...
Lipizaners and German and Swiss Warmbloods are 3.2 times more likely to have heaves if one parent was affected and 4.6 times as likely if both parents had heaves.14 There is no association between major histocompatibility markers (equine leucocyte antigens) and occurrence of heaves.15 However, genetic and environmental factors are often closely associated, in that horses of similar genetic background are often housed in similar situations, making elucidation of inherited susceptibility to heaves difficult.

Exposure to inciting agents is associated with a variety of environmental factors, including potentially outdoor concentrations of aeroallergens and climatic factors,15 but most importantly housing and feeding practices.

Environmental risk factors
There is a clear association between housing, feeding of hay, and development of the disease.16,17 Typically, susceptible horses are clinically normal when at pasture and develop signs of disease within hours to days of being housed in stables and fed dusty hay. Moving affected horses to pasture, or improving air quality by increasing ventilation and feeding processed feedstuffs, results in resolution of the disease.16

Development of disease is related to inhalation of respirable particles that gain access to the lower respiratory tract. Respirable particles are less than 5 μm diameter, the principal source of these particles in stalls is hay, and the majority of particles are fungal spores.18 The concentration of particles in air of the stable is determined by the rate of release of particles from hay, which is dependent in large part on the quality of the hay, concentration of fungal spores in the hay, and the rate of clearance of dust from the stable, a function of the ventilation rate.19,20 Concentrations of respirable dust particles in the breathing zone of stalled horses can be as high as 20 mg/m3.21 The severity of increases in neutrophil count and proportion and decreases in pulmonary function in experimental models of heaves are related in a dose-dependent fashion to the amount of dust inhaled.4 The presence of dust particles, and not the soluble products in hay dust, is responsible for most of the airway neutrophilia induced by inhalation of hay dust.5

Hay is the usual original source of spores in stable air. However, decomposing wood shavings are also a source of spores of fungi that multiply during degradation of plant-based materials, and housing horses in poorly ventilated stalls deeply bedded with wood shavings may be detrimental to their respiratory health.22 Spores from hay enter the bedding either directly or after dispersal through the air and multiply in the bedding if it is not removed regularly. Diced paper and wood shavings, when fresh, usually contain very few spores. Barley and wheat straw are usually free of any small spores such as A. fumigatus or M. faeni.19 Bedding horses on fresh wood shavings, and feeding a nutritionally complete pelleted ration, results in a respirable dust burden of 3% of that of horses fed hay and bedded with straw.23 Dust burdens measured in the air of the stall underestimate the respirable particle challenge of horses because of the high concentration of particles in hay and bedding, areas from which the horse inhales while eating.23

Respiratory health of horses is related to stable design and ventilation, with horses in poorly ventilated barns having more respiratory disease than horses in well-ventilated barns.22 See 'Control' for recommendations regarding stable design.

PATHOGENESIS
Susceptible horses, when exposed to adequate concentrations of respirable dust in the breathing zone, develop airway inflammation, excess mucus accumulation, and respiratory dysfunction within hours to days of exposure. The putative inciting agents include fungal spores and debris, endotoxin, and particulate matter; however, the exact role for each of these agents is unclear, partly because of the difficulty in obtaining uncontaminated material. For instance, fungal material is commonly contaminated with endotoxin which has a synergistic interaction with hay dust in inducing airway neutrophilia in susceptible horses.3

The mechanisms underlying these responses to inhalation of dust are not well defined but can be considered in the contexts of immune and inflammatory responses, mucus secretion, and pulmonary dysfunction.

Inflammatory and immune responses
Inflammation is associated with excessive mucus production, airway swelling, and abnormal lung function.24,25 The inflammatory response in horses with heaves is neutrophilic, with lesser numbers of mast cells and rarely eosinophils. The mechanisms underlying this inflammatory response have not been fully elucidated, although it involves activation of nuclear factor kappaB and there is support for an acquired immune-mediated process.26,27

The presence of allergen-specific IgE antibodies in bronchoalveolar lavage fluid is supportive of a hypersensitivity reaction, although others have proposed type 3 and type 4 immune reactions as the basis of the disease.28 One proposed explanation is that heaves-susceptible horses exhibit a Th2-like immune response to inhalation of hay or barn dust characterized by increased expression of interleukins 4 and 5 and decreased expression of interferon-γ in cells obtained by bronchoalveolar lavage.29,30 Others have not detected a pure Th2-like cytokine profile finding instead a mixed inflammatory response including increases in expression (mRNA) in cells obtained from bronchoalveolar lavage fluid of affected horses of interferon-γ, tumor necrosis factor-α, interleukins 1β and 4, and interleukins 8 and 17 (potent attractors of neutrophils) but not interleukins 2, 5, and 13.2,10,31–35 However, all the studies cited above were performed on crude preparations of cells obtained by bronchoalveolar lavage and the results could have been influenced by the varying proportions of types of cells in these preparations.36 A study examining just CD4 and CD8 lymphocytes in blood and bronchoalveolar lavage fluid of heaves-affected horses demonstrated a general downregulation in expression of interferon-γ and interleukins 4, 5, and 13 and no evidence of a cytokine profile consistent with either sole or predominate Th1 or Th2-like responses.26 The magnitude of the inflammatory response varies depending on the challenge (i.e. nature of the inhaled material) with responses to endotoxin characteristically being less than that of hay dust.36 Regardless of the underlying mechanism, exposure to inciting agents results in airway inflammation and interference with normal respiratory function.

Following inhalation of inciting agents there is recruitment of neutrophils, but not eosinophils or platelets, into the lungs in most horses that develop changes in lung function.36,37 Histologically there is peribronchioral accumulation of lymphocytes and luminal accumulations of neutrophils in affected horses. The entry of neutrophils into the airways is mediated at least in part by IL-8 and IL-17.31,33 The neutrophils of horses during episodes of heaves, but not when the horses are asymptomatic, have increased adherence in vitro to protein coated plastic suggesting a mechanism for the increased migration of neutrophils into airways of affected horses.38 Inhibition of neutrophil phosphodiesterase-4 activity does not alleviate clinical signs of heaves or decrease neutrophil numbers in bronchoalveolar lavage fluid in affected horses suggesting that neutrophils are not primarily involved in the genesis of airway obstruction.39,40 The extent to which neutrophils in the airways are activated has not been determined and their role in the development of respiratory dysfunction is unclear given that glucocorticoid administration attenuates the
respiratory dysfunction but not airway neutrophilia in horses with heaves (see under ‘Treatment’).41

Airway inflammation is associated with increases in concentration of inflammatory mediators including leukotriene B4, prostanooids including thromboxane, and proteases.42 Activity of matrix metalloproteinase-9 is higher in horses with heaves than in unaffected horses and is induced in a dose-dependent manner by inhalation of inciting substances including hay dust and endotoxin.42-45 MMP-9 is likely important in the inflammatory process associated with heaves through excessive gelatinolytic proteolysis that can contribute to lung injury, and through a role in lung remodelling.43 Inflammation is also associated with increased oxidative stress in lungs of horses with heaves as indicated by elevated concentrations of epi-PGF2α and redox ratio of glutathione in pulmonary lavage fluid.34,46

Mucus
Accumulation of excessive quantities of mucus in the large airways is characteristic of horses affected by heaves and can contribute to nonbronchospastic airway obstruction.46 Accumulation of mucus is attributable to decreased clearance and increased production.48 The mucus in horses with heaves differs in both composition and viscoelasticity from that of clinically normal horses63,65 and this might contribute to its decreased clearance. The viscosity of mucus can increase threefold in horses susceptible to heaves stabled and exposed to hay dust.48 Increased production of mucus is associated with up-regulation of the equine MUC5AC gene, which is responsible for production of mucin, in particular in small airways of horses with heaves.49

Airway function and gas exchange
Inhalation of inciting agents causes changes in lung function characterized by an increase in pulmonary resistance, lower dynamic compliance, altered distribution of ventilation, impaired gas exchange, increased functional residual capacity, and an altered breathing strategy.7 Airway obstruction is a result of bronchospasm, inflammatory thickening of airways, and accumulation of mucus and cells in the airways. Bronchospasm is largely relieved by administration of bronchodilator drugs or removal of the inciting cause, but residual effects on lung function remain and are attributable to inflammation and fibrosis and bronchoconstriction of small airways.7 Bronchoconstriction in both normal and affected horses is caused by parasympathetic activity and release of acetylcholine that reacts with muscarinic receptors on airway smooth muscle. However, the response is exaggerated in horses with heaves. Stimulation of airway sensory receptors results in an exaggerated bronchoconstrictive response, possibly because of the action of inflammatory mediators and/or by-products. The exaggerated bronchoconstrictive response is not specific for allergens, and any substance that activates airway sensory receptors may incite bronchoconstriction once the sensitivity of the receptors is enhanced by inhalation of the inciting allergens. Exaggerated airway responsiveness to inhaled irritants persists for up to 3 days after a single exposure to the inciting agent and is likely important in the development of clinical signs of the disease.50 Bronchoconstriction increases work of breathing but hypoventilation probably contributes little to the hypoxemia of affected horses, given that PaCO2 is rarely increased.39

Hypoxemia, which can be severe (<60 mmHg, 8 kPa), is due to ventilation-perfusion mismatches and increased dead space ventilation.51 The increased minute ventilation of affected horses, a result of maintained tidal volume and increased respiratory rate, mainly supplies dead space and regions with high V/Q ratios.51 Pulmonary hypertension in affected horses is probably due to hypoxia and perhaps inflammatory mediators with vasoconstrictor activity.7,51 The elevated functional residual capacity and characteristic breathing strategy of affected horses is due to airway obstruction. Airway obstruction causes trapping of gas in alveoli and a higher end-inspiratory volume. The high end-inspiratory volume maximizes airway diameter and facilitates the high expiratory and inspiratory flow rates necessary for affected horses to maintain a normal tidal volume while increasing their respiratory rate.

Bronchiectasis (irreversible dilatation and deformation of bronchi or bronchioles) occurs in some horses affected with heaves for a prolonged duration.52 Neutrophilic inflammation is essential for the development of bronchiectasis.

CLINICAL FINDINGS
The degree to which horses are affected varies considerably. Minimally affected horses have airway inflammation evident on endoscopic or cytological examination of the airways, but few other signs on physical examination, whereas severely affected horses have very obvious clinical signs.

The usual history is that of chronic cough in a stabled horse.12 Typically, the disease is precipitated by exposure to hay and stabling, and disease remission occurs in most horses when pastured and removed from hay. There may be a history of reduced exercise tolerance.

Affected horses are usually bright and alert and have a normal appetite and rectal temperature. Severely affected horses appear anxious and have a greatly increased respiratory effort.

Coughing is common in horses with heaves, although it is neither particularly specific nor sensitive as an indicator of the disease. Coughing may consist of a single cough every few seconds to minutes or there may be a paroxysm of coughing. The cough can also be elicited by digital massage of the larynx and proximal part of the trachea because horses with airway inflammation have increased sensitivity of the cough reflex. Stimulation of the larynx or proximal trachea by digital massage does not elicit coughing in normal horses. The cough becomes more pronounced and wheezing with exercise. It also occurs more frequently when the horse is exposed to cold air, physical activity, excitement, and when placed in a dusty environment, or if dusty feed is offered. The amount of coughing, which must be counted over at least 15 minutes and preferably 1 hour for accurate determination of its severity, correlates closely with the amount of mucus in airways, maximal change in pleural pressure (a measure of bronchoconstriction), and neutrophil count in bronchoalveolar lavage fluid.41 Coughing is more frequent in horses with heaves, and affected horses often have paroxysmal coughing especially after barn cleaning and feeding.

An intermittent, bilateral mucopurulent to serous nasal discharge is a common sign in affected horses.

The resting respiratory rate is increased from a normal of 12/min up to 24-36/min. There is a pronounced effort during expiration and markedly affected horses have an obvious abdominal component to respiration. Normal horses have a biphasic pattern of airflow during inspiration and expiration while affected horses lack the second phase of respiration.53 Long-standing cases develop a ‘heave-line’ in the flank due to hypertrophy of the abdominal oblique musculature. It is evident as a trough or furrow along the costal arch. In advanced cases the nostrils may be visibly dilated during inspiration and the force of the expiratory effort causes the anus to protrude.

Heart rate is commonly within the normal range or only slightly increased. In horses with heaves, the heart rate is significantly higher during exercise than in healthy horses.

Abnormal lung sounds are one of the most frequent abnormalities detected on clinical examination and the sensitivity of this finding can be increased from 70%
to almost 90% by auscultating the thorax while the horse breathes for 60 to 120 seconds with an airtight plastic bag over its nostrils. The bag should be large enough to enable the horse to breathe unhindered (10–15 L) and should not leak. Accumulation of carbon dioxide in the bag increases the horse’s respiratory rate and tidal volume and accentuates lung sounds. Auscultation of the lungs in the early stages of the disease may reveal only a slight increase in the amplitude of normal breath sounds. Abnormal lung sounds become audible as the disease progresses.

**Wheezing and crackling sounds** occur at the end of inspiration and the end of expiration. These abnormal sounds are audible over most of the lung but are usually easiest to detect over the upper one-half of both lung fields. **Auscultation of the trachea** usually reveals moist sounds characteristic of fluid in the trachea. Some affected horses have quieter than expected lung sounds.

Percussion of the thorax may reveal an increase in the area of resonance by as much as one to two intercostal spaces caudally. However, the area of resonance delineated by percussion is too labile and ill-defined to be of diagnostic value.

**Endoscopic examination** of the upper airways, trachea, and bronchi reveals an abundance of mucopulent material in the trachea which, in severe cases, is also present in the nasopharynx. The amount of mucus can be graded on a 0–5 scale:

- Grade 0 – no visible mucus
- Grade 1 – small blobs of mucus that are not confluent
- Grade 2 – multiple blobs of mucus some of which are confluent
- Grade 3 – mucus confluent in a stream in the ventral aspect of the trachea or multiple large blobs around the circumference of the lumen
- Grade 4 – large pool of mucus in the ventral aspect of the airway
- Grade 5 – Profuse amounts of mucus occupying more than 25% of the tracheal lumen.

Observation of tracheal mucus of grade 4 or 5 has a high specificity (92%) but low sensitivity (52%) for detection of heaves.

**Radiographic examination** of the thorax usually reveals evidence of bronchial disease with some evidence of interstitial disease. Radiography is more useful in ruling out other diseases, such as granulomatous or interstitial pneumonia, than in confirming heaves.

Sophisticated techniques for measuring pulmonary function, such as determination of tidal flow–volume loops, nitrogen washout or forced expiratory flow–volume loops, may identify mildly or subclinically affected animals but have limited day-to-day clinical utility.

Measurement of pleural pressure changes by insertion of an esophageal balloon is relatively simple and may be useful in monitoring response to treatment. Affected horses have pleural pressure changes during respiration greater than 6 cm H₂O. Administration of atropine (0.02 mg/kg, IM or IV), isoproterenol (isoprenaline), or a β₂-adrenergic agonist such as terbutaline (0.04 mg/kg, PO) reduces the maximal change in pleural pressure of horses with heaves.

The **course of the disease** is dependent on the removal or continual presence of the precipitating cause. If the cause is removed in the early stages, complete recovery can occur. In the continual presence of the precipitating cause relapses occur commonly or the disease becomes progressive and affected horses become severely incapacitated. **Bronchietasis**, evident on radiographic examination of the thorax, develops in horses with heaves of prolonged duration. With conscientious management and adequate housing, breeding animals and hunters or show-jumpers with heaves can remain useful for many years.

**CLINICAL PATHOLOGY AND SPECIAL EXAMINATIONS**

There are no significant changes in the hemogram or serum biochemistry of affected horses. The PaO₂ is below normal in moderately to severely affected horses and the PaCO₂ is usually normal although it may be increased in severely affected horses. Blood oxygen tension measurements should be corrected for the temperature of the animal and the altitude. At approximately sea level, PaO₂ values of normal horses are usually greater than 90 mmHg (12 kPa), whereas affected horses have PaO₂ less than 82 mmHg (10.9 kPa). With increases in altitude the values in both normal and affected horses decrease. The normal hypoxemia that occurs in horses during intense exercise is exacerbated by heaves.

**Bronchoalveolar lavage fluid** from affected horses during symptomatic episodes has a relative neutrophil count greater than 5 to 10%, and usually over 50%, of the absolute nucleated cell count. It is recommended that horses not be considered to have airway inflammation unless >15% of cells in bronchoalveolar lavage fluid are neutrophils. During periods of remission, the bronchoalveolar lavage fluid of previously affected horses is not different from that of normal horses. Absolute nucleated cell counts in bronchoalveolar lavage fluid of affected horses are reported, but the values depend on the collection technique used.

The relative proportions of macrophages and lymphocytes in bronchoalveolar lavage fluid of affected horses are lower than those of normal horses. Eosinophil numbers in bronchoalveolar or tracheal aspirate (fluid of affected horses may be mildly elevated (up to 10%), but are usually low (<5%). Higher values should raise the index of suspicion for *Dictyocaulus arnfieldi* or *Panstrongylus equorum* infestation. Aspirates of tracheal fluid reveal a profound neutrophilia (>90%).

Measurement or identification of **precipitins** in serum of horses is not useful in identifying horses with heaves.

**Intradermal testing** using putative allergens has been investigated as a means of identifying horses with heaves or of identifying antigens with which to hypersensitize affected horses with variable or undetermined efficacy. Retro­sppective examination of records of horses with a history of heaves suggests that they are more likely to react, and react to a larger number, of intra-dermally injected allergens than horses without a history of heaves. However, reactions to individual allergens cannot be used to determine hypersensitivity to particular allergens, although it is suggested that overall patterns of reactivity, with a history of exposure of the horse to these allergens, might be useful in guiding management of affected horses. Contrary to these results, a prospective study demonstrated that horses with heaves did not have a greater rate of reaction to intradermal skin tests than did horses not affected by heaves. Intradermal testing did not distinguish clinically relevant reactions from those that were not clinically relevant. Horses with heaves have greater sensitivity to intradermal injection of histamine, which is commonly used as a positive control, than horses without heaves. Overall, intradermal skin testing is neither useful in detecting horses with heaves nor in determining hypersensitivity to particular allergens in individual horses. Results of such testing might be useful in management of horses, but this has not been demonstrated. The usefulness of intradermal skin testing and subsequent administration of preparations of antigens selected on the basis of intradermal testing, in an effort to hyposensitize horses with heaves, has not been determined. The apparent lack of efficacy of intradermal testing might be because the extent of reactivity to intradermal injection of mold preparations does not correlate with the severity of pulmonary dysfunction after inhalation of the same preparation in horses with heaves.

**Lung biopsy** demonstrates peribronchiolar lymphoplasmacytic inflammation, goblet cell metaplasia, alveolar...
fibrosis, and bronchial lumen exudate and neutrophils. The severity of bronchial neutrophil and mast cell infiltration correlates well with the severity of the clinical signs.12

NECROPSY FINDINGS
The major findings are restricted to the lungs, which are pale, voluminous, and do not collapse when the chest cavity is opened. The tissue damage is primarily centered on airways which are less than 2 mm in diameter. Microscopically, a variable degree of alveolar emphysema is accompanied by a chronic bronchiolitis featuring diffuse epithelial hyperplasia, goblet cell metaplasia, peribronchiolar fibrosis, and cellular infiltration by lymphocytes, plasma cells, mast cells, and sometimes eosinophils. Plugs of mucus with entrapped neutrophils often occlude bronchiolar lumina.

Samples for postmortem confirmation of diagnosis
Formalin-fixed lung for light microscopic examination.

DIAGNOSIS CONFIRMATION
Confirmation of the disease is based on the presence of a history and clinical signs consistent with the disease, in particular the response to stable and pasturing, and demonstration of reversible airway obstruction. Objective confirmation can be achieved by measuring the response of maximal changes in pleural pressure in response to bronchodilator drug (atropine or glycopyrrolate) administration.

DIFFERENTIAL DIAGNOSIS
Horses with respiratory distress may have:
- Interstitial pneumonia
- Heart failure
- Bacterial pneumonia
- Pleuritis
- Pulmonary or mediastinal neoplasia including leiomyosarcoma66
- Parasitic pneumonia (O. annfieldi).

Nasal discharge may be caused by:
- Guttural pouch diseases including empyema
- Dysphagia of any cause
- Esophageal obstruction
- Sinusitis
- Pneumonia.

TREATMENT
The principles of treatment are:
- Removal of the inciting cause
  - Reduction of airway inflammation
  - Bronchodilation
  - Correction of hypoxemia.55

Heaves is an inflammatory disease caused by inhalation exposure to inciting agents. Bronchoconstriction is secondary to inflammation. Control of the disease is based upon preventing inhalation of inciting agents and suppression of inflammation by administration of corticosteroids. Relief of bronchoconstriction should be necessary only during acute exacerbations of the disease, and administration of bronchodilatory drugs for more than several days is not optimal treatment in most horses. Drugs used in the treatment of heaves are summarized in Table 34.2.

It is essential that the horse is not exposed to the inciting agents and irritant substances that could provoke or worsen the disease. Even relatively brief exposure of susceptible horses to the inciting agents, such as can occur if a horse is brought into a poorly ventilated barn to be fed, can result in airway hyper-sensitivity and the development or maintenance of clinical signs. Affected horses should be moved to a clean environment, ideally pasture, in which the concentration of airborne allergens is reduced to an absolute minimum. If the horse cannot be kept at pasture, then it should be housed in a well ventilated barn (see ‘Control’ for details), bedded with clean wood shavings or shredded paper, and fed a complete pelleted ration. If affected horses are fed hay, it should be thoroughly wetted to minimize the release of spores. Remission of clinical signs can be expected in 4–21 days if the environmental changes are adequate.67 This may be all that is necessary to control the disease in many horses.

Antinflammatory drugs
The disease is essentially one of inflammation of the airways and therefore one of the mainstays of treatment is administration of anti-inflammatory drugs. Non-steroidal anti-inflammatory drugs such as phenylbutazone and flunixin meglumine are not effective. Corticosteroids including dexamethasone, prednisolone, triamcinolone, and betamethasone are effective in controlling the disease.

Dexamethasone (0.04–0.1 mg/kg, intravenously, intramuscularly or orally every 24–48 hours) can be given to control the acute signs of the disease, and then the dose reduced and eventually discontinued as environmental alterations have their effect. Similarly, prednisolone (1–2 mg/kg, orally once daily), but not prednisolone,68 can be given initially, then the dose reduced by approximately one half every 5–10 days as the disease is controlled. Often prednisolone or dexamethasone sodium phosphate is effective when administered every second day when the disease has been controlled. Dexamethasone-21-isonicotinate (0.04 mg/kg, intramuscularly) is effective when administered every 3 days, but not when administered only once.69,70 Isoflupredone (0.03 mg/kg, intramuscularly once daily) is as effective as dexamethasone in alcohol control of exacerbations of heaves, although it does cause hypokalemia.71 Triamcinolone (0.09 mg/kg, intramuscularly) administered once provides long-term (weeks) relief of signs in some horses.72

Inhaled corticosteroids, such as beta-methasone, beclomethasone, or fluticasone, are useful in controlling the disease.73,74 Both inhaled and parenterally administered corticosteroids suppress adrenal function of horses75 but 500 μg of beclomethasone propionate inhaled twice daily effectively alleviates signs of heaves and causes less adrenal suppression than doses of 1000 μg or 1500 μg.76 It is important to reiterate that the use of glucocorticoids should only be as an adjunct to control of the horse’s environment and reduction in the inhaled particle burden.

Clebuterol decreases the production of inflammatory cytokines by cells obtained from bronchoalveolar lavage fluid of horses with heaves, suggesting that clenbuterol can have anti-inflammatory effects in such horses.77 The clinical applicability of this finding remains to be determined.

In summary, a number of different corticosteroid preparations are useful in the control of heaves. Drugs administered by inhalation appear to have a reduced potential for adverse effects including adrenal suppression, but are more difficult to administer and require more frequent administration than drugs administered orally, intravenously, or intramuscularly. Improvements in respiratory effort and clinical signs are evident in approximately 3 days and persist for the duration of treatment. Cell counts and the neutrophilia in bronchoalveolar lavage fluid are not reduced by administration of corticosteroids. Affected horses, after institution of appropriate measures to control inhalation of hay and barn dust, should be treated with the lowest dose that controls the disease and only for as long as necessary. The dose of corticosteroid can be reduced gradually and the frequency of administration decreased from once daily to once every second or third day (or greater, depending on the preparation) to achieve this effect. Administration of the lowest effective dose is important because of the effects of corticosteroids in suppressing immune and adrenal function. It is suggested that dexamethasone and triamcinolone increase the likelihood of horses developing laminitis, but this relationship has not been conclusively demonstrated.

**Bronchodilator drugs**

Bronchodilator drugs might be needed to provide acute relief of airway obstruction but should not be used as maintenance therapy. **Atropine** (0.02–0.04 mg/kg, intramuscularly) can be used to provide short-term relief of bronchoconstriction, but its use is associated with gastrointestinal side-effects, including colic, that preclude its long-term use. **Glycopyrrolate** (0.1 mg/kg, intramuscularly every 8–12 hours) is a potent bronchodilator with minimal gastrointestinal effects. **Ipratropium bromide**, a parasympatholytic drug with minimal extrapulmonary effects when given by inhalation, is very effective in relieving airway obstruction in severely affected horses.77
β₂-adrenergic agonists are potent bronchodilators frequently used in the management of horses with heaves. They can be administered orally or by inhalation.73,78 Clenbuterol hydrochloride is used as maintenance therapy at a dose of 0.8–3.2 μg/kg, orally every 12 hours, and is effective in controlling signs in 75% of affected horses.79 The lower dose should be used initially and then increased to 0.8 μg/kg increments until the desired effect is achieved or side-effects of tachycardia, muscle fasciculation, and sweating are apparent. Gradual, incremental increases in dose lessen the frequency and severity of side-effects. Terbutaline is not absorbed after oral administration to horses.80 Terbutaline and clenbuterol can also be given intravenously, at a dose one-tenth of that given orally, to severely affected horses in which the need for bronchodilation is urgent. Side-effects of β₂-agonist administration include tachycardia, sweating, and apprehension.81 Prolonged administration of clenbuterol is associated with potentially adverse effects on cardiac structure, alterations in body composition, and an impaired response to training.82 Delayed parturition may occur in mares treated in late pregnancy. β₂-adrenergic agonists may transiently exacerbate hypoxemia in severely affected horses. Intra-tracheal administration does not produce detectable bronchodilation.84

Bronchodilators administered by inhalation to horses include the β₂-agonists Albuterol, salbutamol, and salmterol, and the parasympatholytic ipratropium. The efficacy and duration of action of each of these drugs varies somewhat, but all are effective in producing bronchodilation in affected horses. Salmeterol produces bronchodilation in horses with heaves that persists for up to 6 hours, although onset of action requires 30–60 minutes.85 Similarly, ipratropium reduces pleural pressure changes and attenuates clinical signs of airway obstruction in horses with heaves.77,86

Theophylline (aminophylline) is a non-adrenergic bronchodilator given at a dose of 10–12 mg/kg, orally every 12 hours. Signs of toxicity include tachycardia, excitement, and convulsions. Theophylline is not a drug of first choice for the treatment of heaves and is now used infrequently because of the availability of efficacious anti-inflammatory drugs and other bronchodilators.

Other drugs Sodium cromoglycate is useful for the prophylaxis of heaves, but has no direct bronchodilatory activity.55 Its mechanism of action is unclear, but it may act to prevent the degranulation of mast cells. It can be given at a dose of 20–30 mg per 425 kg horse by inhalation once daily for 4 days, and then repeated in 1–2 weeks.87

Pentoxifylline at high doses improves respiratory function, but not bronchoalveolar lavage fluid cytology, of horses with heaves.88 However, bioavailability after oral administration is quite variable, contributing to variations in the responses of horses to the drug.

Drugs that reduce leukotriene production or activity do not appear to be useful in the treatment of heaves. An experimental leukotriene D4 receptor antagonist was not effective in relieving signs of heaves.89 Similarly, montelukast did not improve respiratory function in 5 horses with heaves.88

Mucolytics are often used but their efficacy is not established and is doubtful. Cough suppressants should not be used as they may impair clearance of mucopurulent material from the airways.

Antibiotics are often given to affected horses but are probably not necessary in the vast majority of cases. Acupuncture is not effective in the treatment of heaves.90

Administration of large quantities of isotonic electrolyte solution intravenously is associated with a decrement in respiratory function in both normal and heavy horses and is not recommended as a treatment for heaves.91

Integrated therapy

Initial treatment of affected horses usually involves changes to the horse’s environment and feed in combination with administration of corticosteroids. Corticosteroids and β₂-adrenergic agonists can be given as combined therapy to severely affected horses until the disease is controlled, at which time therapy should consist of environmental control and, if needed, administration of the lowest effective dose of corticosteroids. Bronchodilators are sometimes used as sole therapy, but their use without correction of the housing and feeding factors, and attempts to control inflammation, is not rational. Long-term administration of bronchodilators is not optimal therapy and, given the documented adverse effects, is not recommended. Long-term control of heaves is achieved by environmental management and administration of corticosteroids.

CONTROL

Housing horses in stalls with good air quality is essential in reducing the occurrence of the disease. Adequate ventilation is critical in maintaining good air quality in stalls. Few horse housing units have adequate ventilation, although a well-designed individual box stall can meet the needs of the horse both for air hygiene and thermal comfort.19 Many horse barns have inadequate open space for ventilation in still air conditions when the doors are closed at both ends of the building. When the release rate of spores is low, ventilation rates of 4 air changes per hour are satisfactory. However, suggested minima are 8–10 air changes per hour, airspace of 44 m³/head, and floor space of 9.2 m²/head.23 In practical terms, if the upper half of the stable door is open, and faces open air and not into a barn, the natural ventilation should exceed the minimum specifications.23 Hay and dusty feed materials should not be stored above stalls or in the same airspace as horses. Bedding should be changed frequently, preferably daily. Use of cardboard as bedding material is effective as part of an overall regimen to improve air quality.92

A portable slit sampler is an accurate, quick, and simple semiquantitative method of assessing the mold contamination of source materials such as hay, straw, and other feeds and bedding collected from stables.18 The health hazard posed by any moldy source material depends on the types of organisms present and their abundance. The size of the respirable challenge from heated hays and straws arises from the prolificacy of the species involved and their small spore size. The highest respirable challenges are from the presence of thermotolerant and thermophilic mold species. The most critical factors in determining the microbial development in plant-based materials are water content and thermal environment. Hay baled at 15–20% moisture heats little, it is virtually dust-free and contains few spores. Baling hay with 20–30% moisture leads to temperatures of up to 35–45°C. At these temperatures, hazardous contamination may develop with the appearance of thermotolerant fungi and actinomycetes.18 The heaviest contamination of hay and straw occurs with baling at 35–50% moisture when spontaneous heating up to 50–60°C may occur. Microscopically, these hays show large numbers of fungal spores in the 2–5 μm size range.

MILK ALLERGY

Signs of allergy, principally urticaria, are often manifested by cows during periods of milk retention.1,3 Most of these occur as the cow is being dried off. The Channel Island breeds of cattle are most susceptible and the disease is likely to recur in the same cow at subsequent drying off periods; it is almost certainly inherited as a familial trait.

The important clinical signs relate to the skin. There is urticaria which may be visible only on the eyelids or be distributed generally. Local or general erection of the hair may also be seen. A marked muscle tremor, respiratory distress, frequent coughing, restlessness to the point of kicking at the abdomen and violent licking of themselves, and even maniacal charging with bellowing may occur. Other cows may show dullness, recumbency, shuffling gait, ataxia, and later inability to rise. The temperature and pulse rates are usually normal or slightly elevated but the respiratory rate may be as high as 100/min.

Diagnosis of milk allergy can be made by the intradermal injection of an extract of the cow's own milk. A positive reaction occurs with milk diluted as much as 1 in 10,000, and the edematous thickening is present within minutes of the injection. Other clinicopathological observations include the development of eosinopenia, neutrophilia, and hyperphosphatemia during an attack.

Spontaneous recovery is the rule but antihistamines are effective, especially if administered early and repeated at short intervals for 24 hours. Prevention is usually a matter of avoiding milk retention in susceptible cows, but in many cases it is preferable to cull them.

PASTURE-ASSOCIATED HEAVES (PASTURE-ASSOCIATED OBSTRUCTIVE PULMONARY DISEASE OF HORSES)

Summer pasture-associated heaves occurs in horses in the southeastern region of the United States and in Great Britain.1,3 It appears to be a disease of adult horses that are on pasture most of the time in the summer. It occurs most commonly in the warm, humid summer months of June to September. Affected horses gradually recover during the cooler months of winter and early spring, and the disease may recur in the same horse each successive summer. Most severe signs occurred during late spring and early summer during times of high airborne pollen counts. It has been suggested that pulmonary allergy to pollens is a factor but this has not been validated. Affected horses have increased expression of interleukin-4 and interferon-? in cells of bronchoalveolar lavage fluid and peripheral blood mononuclear cells but not increased concentrations of IgE in bronchoalveolar lavage fluid.5 Affected horses have clinical findings typical of heaves including nasal discharge, coughing, tachypnea, labored expiratory effort, and crackles and wheezes on auscultation.6 There is moderate-to-severe accumulation of mucus in the large airways evident on endoscopic examination. Lung function testing is consistent with bronchoconstriction on bronchoalveolar lavage fluid contains large numbers of nondegenerate neutrophils and lesser numbers of lymphocytes and mast cells.6 Necropsy reveals overinflated lungs that do not collapse when the chest is opened and that retain the impressions made by the ribs.6 The predominant histologic finding is accumulation of mucus in small airways. Inflammation is not severe and most inflammatory cells present are neutrophils and lymphocytes in peribronchial tissues.6 Treatment includes staining and administration of corticosteroids and bronchodilators, as discussed for heaves and Table 34.2).
ENZOOTIC NASAL GRANULOMA OF CATTLE (ENG, BOVINE ATOPIC RHINITIS)

Of the three known clinical types of chronic nasal obstruction in cattle, two have been identified etiologically and have clinical or epidemiological features that distinguish them from enzootic nasal granuloma. One is recorded predominantly in beef cattle appears to be caused by a fungus, most commonly *Rhinosporidium* spp., or *Drechslera* spp. Another is caused by the parasite *Schistosoma nasalis*. The third type, enzootic nasal granuloma, occurs commonly in southern Australia, less commonly in New Zealand and is recorded as a sporadic disease in South America and an occasional disease in North America, Britain, and Europe.

Enzootic nasal granuloma occurs sporadically in some herds but may reach an incidence of 30%. In one area, as much as 75% of herds may have the disease. Animals aged between 6 months and 4 years are most commonly affected, and the chronic disease may or may not be preceded by an attack of acute rhinitis. Most cases commence in the summer and autumn months. It is apparent that nasal granuloma develops as a continuous and progressive response to acute episodes of hypersensitivity to an allergen present in the nasal mucosa, of the presence of mast cells in all seasons, but the regression of eosinophils in the winter months.

An extensive survey of Australian dairying areas showed that 22% of cattle had lesions, and that the prevalence was greater in areas where the average annual rainfall was over 70 cm, than where it was less than 70 cm; the prevalence varied between 4% and 48%; Jerseys were more commonly affected than Friesians. In New Zealand, 40% of farms and 36% of culled cattle were affected, whereas only 3.6% of young beef cattle showed lesions.

The disease has been identified as an allergic rhinitis and has been produced experimentally. Specific antigens have not been identified as the cause but cows with nasal granuloma are much more sensitive to a number of common allergens in the environment than are unaffected cows. Bovine herpesvirus 1 is often isolated from lesions of ENG and is thought to be the cause. A loss of condition and marked reduction in milk yield, affected animals do not die. A good proportion of them have to be culled as uneconomic units.

The clinical picture in *mycotic nasal granuloma* is superficially similar with respect to noisy breathing, respiratory distress, and nasal discharge, but there is no seasonal association. The visible and palpable lesions in the anterior part of the nasal cavities are polyphs up to 5 cm in diameter which occur singly or in confluent masses. Their cut surfaces are yellow to green and they are sometimes ulcerated. Histologically the lesions are eosinophilic granulomas containing fungal spores and sometimes hyphae. Fungi (*Drechslera rostrata*) have been isolated from the lesions.

**Equine allergic rhinitis** is a clinically and epidemiologically similar condition, but without mucosal lesions, recorded in horses as a common cause of persistent head shaking.

Introduction

GENERAL
Genetic disorders are a small but important cause of wastage in farmed animals. Most occur in pure-bred animals and are inherited as autosomal recessive traits. Because dominant disorders tend to be self-limiting, or affected animals are excluded from the breeding pool. Incomplete dominants occasionally occur in which there are three potential phenotypes, i.e. normal, affected, and more severely affected. The classic example is in the original Dexter cattle where the slightly dwarfed Dexter phenotype is dominant to the normal and is selected for. Animals homozygous for the gene abort with a non-viable 'bulldog' type fetus.1,2 Sex-linked disorders may occur but are uncommon. Some monogenic disorders may arise de novo due to new mutations of germ plasm. Those with a dominant mode of inheritance are present in offspring of the animal in question, usually affecting genes for structural proteins such as collagen. A new mutation should be considered with disorders such as osteogenesis imperfecta or skin fragility.3

The proportion of offspring with the defect may vary depending on what stage of gametogenesis the mutation occurred.

In-breeding, knowingly or unknowingly practiced, is an important feature in the manifestation of most outbreaks of a recessive disorder. Founder effect is an aspect of this that has been important when new breeds have been introduced to a country by importation of genetic material from a small number of individuals. Artificial breeding on a large and international scale has sometimes exacerbated this, particularly in cattle.

Genetic disorders may be manifested as disease or bodily malformation. When diagnosed, an entity may reflect the tip of an iceberg only and it can be expected that many other cases go undiagnosed. Spread across an industry their economic importance may be limited, but as particular disorders tend to be concentrated in certain herds/flocks they may have considerable importance to an individual breeder, particularly those involved with pedigree breeding. Animal welfare is also a concern to be addressed, being driven by a greater awareness of ethical standards in livestock production and by potential market access requirements.

The two main problems for the clinician investigating a suspected inherited disorder are to confirm a primary genetic cause and then to institute control in a cost-effective manner.

DIAGNOSIS
For a number of inherited diseases or malformations known to occur in a breed, morphology or histopathology may be so characteristic as to be essentially pathognomonic. However, for some disorders environmental agents (teratogens) may cause similar morphological anomalies, e.g. arthrogryposis, so care should be taken. Pedigree analysis may help if there are sufficient animals of known breeding to show that the incidence of the disorder follows a Mendelian pattern. However, in many herds/flocks animals may be closely related and pedigree analysis can sometimes be misleading and produce a fictitious relationship between inheritance and disease. As the biochemical anomaly is now known for many diseases, or perhaps can be deduced from histopathological lesions, laboratory tests may confirm a presumptive diagnosis. Test mating of a sire to daughters, related females, or females that have given birth to an affected animal is the ultimate confirmation of the genetic nature of a disorder, provided the appropriate numbers of progeny are generated. Disproving a genetic cause of a disorder may be as important as proving it. Matings of a sire to produce a minimum of 24 progeny from his daughters or 12 from putative heterozygotes (females that have given birth to affected individuals) are usually considered satisfactory numbers to exclude a likely inherited cause if no affected individuals are born (P<0.5).

The birth of a proportion of affected offspring is strong evidence of inheritance. The use of super-ovulation and embryo transfer techniques may facilitate this, particularly if insufficient daughters or putative heterozygotes are available. The time to accomplish this may be decreased by caesarian section of the surrogate dams if the defect can be detected in the fetuses.

The degree of in-breeding is an important indicator of whether a congenital disorder is inherited or not. Consistency of the defect is a characteristic of inherited disorders but there may be some variation in age of onset or expressivity of lesions. Other epidemiological factors include the occurrence of the defect over more than 1 year and occurrence or repetition of it in the same mating group, but not in others on the property.

CONTROL OF INHERITED DISEASE
Appropriate control measures may vary, depending on the importance of the disorder and may be aimed at the herd/flock level or at the breed as a whole. It may be prospective but, at the farm level, it is mainly reactive with the purpose of preventing further losses by immediate action. This should include not breeding from putative heterozygous sires or females which should preferably be culled. Replacement sires are best acquired from another breeder but, if the defect is common in the breed, then the risk may remain and cross breeding with a sire from another breed may be considered if the type of farm operation permits it. If a test is available for detecting heterozygous animals then this can be used in new sire selection.

Control of genetic disorders in pedigree herds is more complex and to be effective depends on ability to detect heterozygotes or prove animals do not carry the recessive gene in question. Test mating is time consuming, expensive, and of limited application. The explosion of knowledge concerning the biochemical and molecular genetic basis of inherited diseases across species has opened up effective means of diagnosing genotype
for many of them. Control may be at an individual herd/flock level or applied to all at risk. It is best instigated with the help of breed societies who may exert control over the fate of animals diagnosed as heterozygous through control of registrations. Apart from the accuracy of genetic tests in genotype diagnosis, there is the added advantage that particularly valuable animals may be kept within the herd/flock for breeding as their offspring can in turn be tested as normal or heterozygous.

The first generation of tests for heterozygotes was biochemical being based on knowledge of the enzyme deficiency and the gene dosage phenomenon. Heterozygous animals having one normal and one mutant gene have enzyme values midway between normal and diseased values, although there may be some overlap. Supplementary tests or knowledge of the parents' genotype may assist with clarification of equivocal results. Such tests were used to control the economically important lysosomal storage diseases α-mannosidosis in Angus and Murray Grey cattle in New Zealand and Australia and Glycogen storage disease type II in Shorthorn and Brahman cattle in Australia. These have now given way to more accurate second-generation technology based on DNA for these diseases as well as a number of others. Such tests may be performed on blood samples but are increasingly being done on hair roots.

The genome for the major farm species is essentially known and, given the will and enough affected families, the technology exists to develop tests for most disorders. If the disorder in question is poorly defined biochemically, then tests are still possible by finding a closely linked polymorphic gene marker. This is usually the first step in investigating the molecular genetics of an unknown disease but it is expensive. In contrast, if a candidate gene can be deduced from the pathology of the disease, then it is much simpler to define the mutation and through polymerase chain reaction (PCR) technology develop a DNA based test.

Artificial breeding techniques have the capacity to spread undesirable genotypes widely before they are recognized. Many artificial breeding organizations involved in the dairy industry prospectively screen for genetic disorders by mating prospective sires over a proportion of their daughters. This is possible because of the time taken to prove a sire before he enters the industry on a large scale.

Diseases characterized by chromosomal anomalies

The principal advance in cytogentic studies in agricultural animals has been in the field of fertility in cattle but freemartinism and structural translocations are the only groups to have been well documented. Other chromosomal abnormalities in other species are recorded but not in sufficient numbers to make a coherent account possible, details of them should be sought in the theriogenology literature. Besides the many identifications of individual infertile males and females by this means there is the probability that chromosomal aberrations characterized by aneuploidy are the cause of many stillbirths and multisystemic anomalies that make neonates non-viable.1,2 A true hermaphrodite in a horned goat with 60 XX/60 XY chimerism has been described.3

Chromosomal analysis techniques are based on tissue culture using leukocytes collected in a highly aseptic manner. The blood is placed in tissue culture medium containing a stimulant to cell division. After brief incubation, cell division is arrested by the addition of a cytotoxic agent and the cells are then swollen osmotically by treatment with a hypotonic solution, then fixed and dried onto slides and stained. Microscopic examination of dividing cells allows the total number of chromosomes in each cell to be counted, and the sex chromosomes and abnormal chromosomes identified. The individual chromosomes are cut out from photographic prints, paired, and stuck onto cards to create the document used for identification — the karyotype. The number of cells subjected to chromosomal analysis in each case is usually 10–20, but 50 are recommended for satisfactory accuracy.

FREEMARTINISM IN CALVES

A freemartin is defined as a sterile female partner of a pair of heterosexual twins. In cattle, 92% of females born co-twins to males are freemartins.

In normal calves the chromosomal identification of females is 60 XX (60 chromosomes, both X chromosomes) and of males is 60 XY (the Y being smaller and not readily paired with its opposite X chromosome). The freemartin is the classical example of the chimera in cytogenticists. They are the individuals which contain two or more cell types which originated in separate individuals. The only way in which chimeras can develop is via the fusion of circulating or zygotes in utero. Sex chromosome chimerism is also reported in goats, sheep, and pigs, and, although the male partners of female twins are usually anatomically normal, they often have reduced fertility. Bulls born co-twin with freemartin females may also be chimeric and have low reproductive efficiency.

The diagnosis of freemartinism has been based on physical examination, karyotyping, or blood typing and each has its limitations. There is variation in the degree of reproductive tract abnormalities in freemartins. The external genitalia may appear normal, the vulval hair may be coarser than usual or the clitoris may be enlarged. The vagina is generally expected to be shorter than normal. The cervix, uterus, uterine tubes, and ovaries may be absent, present in underdeveloped form, or may appear normal on rectal palpation.

Special cytogenetic techniques are also available which facilitate the diagnosis of freemartinism in a female calf of a male–female twinning. In freemartins (phenotypically female, but carrying also male cells) there is a mixture of mostly 60 XX chromosomes to a cell, and a small proportion of 60 XY cells. A large number of cells need to be analyzed if only the

ONLINE MENDELIAN INHERITANCE IN ANIMALS (OMIA)

Online Mendelian Inheritance in Animals (OMIA) is a database of genes, inherited disorders and traits in animal species (other than human and mouse) authored by Professor Frank Nicholas of the University of Sydney, Australia, with help from many people over the years. The database contains textual information and references, as well as links to relevant records from OMIM, PubMed, Gene, and soon to be NCBI's phenotype database.

The number of cells subjected to chromosomal analysis in each case is usually 10–20, but 50 are recommended for satisfactory accuracy.

FREEMARTINISM IN CALVES

A freemartin is defined as a sterile female partner of a pair of heterosexual twins. In cattle, 92% of females born co-twins to males are freemartins.

In normal calves the chromosomal identification of females is 60 XX (60 chromosomes, both X chromosomes) and of males is 60 XY (the Y being smaller and not readily paired with its opposite X chromosome).

The freemartin is the classical example of the chimera in cytogenticists. They are the individuals which contain two or more cell types which originated in separate individuals. The only way in which chimeras can develop is via the fusion of circulating or zygotes in utero. Sex chromosome chimerism is also reported in goats, sheep, and pigs, and, although the male partners of female twins are usually anatomically normal, they often have reduced fertility. Bulls born co-twin with freemartin females may also be chimeric and have low reproductive efficiency.

The diagnosis of freemartinism has been based on physical examination, karyotyping, or blood typing and each has its limitations. There is variation in the degree of reproductive tract abnormalities in freemartins. The external genitalia may appear normal, the vulval hair may be coarser than usual or the clitoris may be enlarged. The vagina is generally expected to be shorter than normal. The cervix, uterus, uterine tubes, and ovaries may be absent, present in underdeveloped form, or may appear normal on rectal palpation.

Special cytogenetic techniques are also available which facilitate the diagnosis of freemartinism in a female calf of a male–female twinning. In freemartins (phenotypically female, but carrying also male cells) there is a mixture of mostly 60 XX chromosomes to a cell, and a small proportion of 60 XY cells. A large number of cells need to be analyzed if only the
freemartin calf is available because the proportion of abnormal cells present may be as low as 2%. It is, however, possible to make a diagnosis on the examination of 10–20 cells, provided the male twin is also analyzed; the female may have very few chromosomally abnormal cells. The technique is much more accurate than blood group analysis, or clinical observations of a short vagina, enlarged clitoris and the presence of a vulval tuft of hair. Karyotyping is a definitive method of freemartin diagnosis but it is tedious, time consuming, and expensive. Blood typing analysis may be performed on both the male and female co-twins in order to demonstrate two blood group populations, but it is expensive and requires blood samples from both co-twins.

The polymerase chain reaction (PCR) method of freemartin diagnosis using sex-specific DNA sequences is rapid, accurate, relatively simple, and inexpensive to perform and a blood sample is required only from the female co-twin. It allows for the accurate decision of freemartining down to a level of 0.05% of male chimeric cells present.

CHROMOSOMAL TRANSLOCATIONS IN CATTLE

When two chromosomes which have previously been broken have fused to form a morphologically distinct chromosome this is known as a translocation. It is further identified by the chromosomal series involved. Thus a 1/29 translocation represents a fusion between a chromosome of each of the pairs numbered 1 and 29.

Translocation 1/29 has been identified in many breeds of cattle and has been associated with significant reductions in the fertility of cows bred by artificial insemination (AI) services. Early embryonic death occurs in embryos produced by fertilization of affected gametes or fertilization of normal gametes by spermatozoa carrying the 1/29 translocation. There is no abnormality of serving behavior or semen quality. The translocation has been shown to be inherited in most European beef breeds including the Blonde d’Aquitaine, Swedish Red and White, Charolais, Danish Limousin, British Friesian and Red Poll breeds and in the wild British White cattle. In Bolivian Creole cattle breeds, the Creole-like cattle, the average frequency was 10.42%, with a variation from 0 to 28.2%. In contrast, Yacumeno and Creole-type cattle did not show the centric fusion. The highly significant differences between Creole cattle breeds in relation to the 1/29 translocation could be the consequence of factors such as founder group, genetic drift, and selection. The low frequency observed in the Saavendreho Creole dairy cattle might be due to breeding under a more intensive system, and selection according to milk yield and fertility traits. The frequency of affected animals in a breed may vary between 1 and 20%. Karyotyping and culturing of abnormal bulls in most artificial breeding centers has reduced the impact of the defect.

Translocations 1/21, 2/4, 14/20, and 13/2 have also been identified in bulls, the 1/21 in Holstein Friesian cattle, and the latter two seeming to be widespread in Simmental cattle. None of them has been linked with a disease but it is becoming accepted practice not to use such animals for artificial insemination, and in some countries to refuse their importation.

A cytogenetic survey of Holstein bulls at a commercial AI unit to determine the prevalence of bulls with centric fusion and chimeric anomalies found that chimeric fusion is extremely rare in Holstein blood lines available by AI in the United States. However, chimeric bulls are more common and reportedly have decreased reproductive performance. Because of the possibility of de novo onset of chimeric fusion at any time, early cytogenetic screening should be encouraged for prospective bulls intended for AI programs.

Translocation 27/29 is suspected of being associated with reduced fertility in Guernsey cattle. These and other abnormalities of chromosomal structure were detected in an examination of a large number of infertile dairy heifers.

CHROMOSOMAL TRANSLOCATIONS IN SHEEP

The literature on chromosomal aberrations in sheep has been reviewed. Centric-fusion (Robertsonian) translocations have been described in sheep in New Zealand. There is no evidence to suggest that these centric-fusions, in a variety of combinations, affect the overall total reproductive performance of domestic sheep, as unbalanced spermatids failed to mature and take part in fertilization.

Inherited defects of the body as a whole

Many inherited defects, other than those listed in this section, probably have a metabolic defect as their basic cause, for example the abiotrophies, but they are listed elsewhere because of lack of certainty about their exact cause. Three known inherited enzyme deficiencies - bovine citrullinemia, bovine protoporphyria - are described in system groupings where their clinical signs are most prominent. Inherited vitamin C, D, and E deficiencies are dealt with in the chapter on nutritional deficiency diseases. Inherited immune deficiencies are listed in this section.

DEFICIENCY OF UMP SYNTHASE (DUMPS)

This is a partial deficiency of an enzyme which is involved in the conversion of orotate to uridine 5'-monophosphate (UMP) as a step in the synthesis of pyrimidine nucleotides. It is recorded at a high prevalence in Holstein Friesian cattle in the US and is characterized by an autosomal recessive form of inheritance and the secretion of high levels of orotate in the milk. Heterozygous animals have a partial deficiency of UMP synthase; they have no individual or herd clinical abnormalities but can be detected biochemically by their half-normal levels of erythrocyte UMP synthase. Bovine homozygotes die at about the 40th day of pregnancy. Embryonic mortality is the only form of loss.

REFERENCES

INHERITED GOITER

This disease is recorded in Merino sheep, Afrikaner cattle, crossbred Saanen dwarf goats, Boer goats, possibly Poll Dorset sheep, and pigs, and appears to be inherited as a recessive character. The essential defect is in the synthesis of abnormal thyroid hormone leading to increased production of thyrotropic factor in the pituitary gland, causing in turn a hyperplasia of the thyroid gland. In Afrikaner cattle the defect stems from an abnormality of the basic RNA.
heterozygotes can be identified by blot hybridization analysis. Clinically in sheep there is a high level of mortality, enlargement of the thyroid above the normal 2.8 g, but varying greatly up to 222 g, and the appearance of ‘lustrous’ or ‘silky’ wool in the fleeces of some lambs. Other defects which occur concurrently are edema and floppiness of ears, enlargement of, and outward or inward bowing of, the front legs at the knees, and dorsoventral flattening of the nasal area. The thyroglobulin deficiency in the neonatal lamb may result in defective fetal lung development and the appearance of a neonatal respiratory distress syndrome; there is dyspnea at birth. The clinical picture in goats is the same as for lambs. It includes retardation of growth, sluggish behavior, rough, sparse hair coat, which worsens as the goats get older, and a thick scaly skin. In Afrikaner cattle most of the losses are from stillbirths or from early neonatal deaths. Some are caused by tracheal compression from the enlarged gland. It is the calves with the largest glands that have the greatest mortality. In these cattle there may be a concurrent inherited gray coat color, a defect in a red breed. In pigs hairless and swollen piglets with enlarged thyroid glands occur, in the proportions with normal piglets consistent with an autosomal recessive mode of inheritance.

REFERENCES

INHERITED IMMUNODEFICIENCIES

Many of these diseases have been previously characterized as diseases of other body systems but are now correctly classified by the wider acceptance of clinicopathological examinations, especially those involving immunological studies. The group is probably still in a period of transition (see Chapter 9).

REVIEW LITERATURE

BOVINE LEUKOCYTE ADHESION DEFICIENCY (BLAD)

This granulocytopenia is inherited as an autosomal recessive trait in Holstein-Friesian cattle. Homozygotes are not viable because of their low resistance to infection. Heterozygotes are unaffected. Signs are observed first between 2 weeks and 8 months, and are characterized in most cases by bouts of infectious disease, e.g. persistent fever, diarrhea, cough, dyspnea, delayed wound healing, and stunted growth. Some cases exhibit a striking peridontal gingivitis with marked retraction of the gingiva, and severe resorption of mandibular bone causing premature teeth loss. In a small proportion of cases the signs are limited to unthriftiness. Severe ulcers on oral mucosa, severe periodontitis, loss of teeth, chronic pneumonia, and recurrent or chronic diarrhea are common.

The clinical pathology is characterized by a severe and persistent neutrophilia, without a left shift, and a significantly increased cellularity of bone marrow. At necropsy there are very large numbers of intravascular neutrophils in all tissues, especially the spleen, but not in infected tissues, which may include bronchopneumonia, pseudomembranous or necrotizing enteritis, and granulomatous gingivitis. Intestinal ulcers are an essential part of the pathogenesis of the disease in chronically affected animals which receive intensive medical care. Affected animals are stunted and unlikely to live as long as 2 years.

The gene frequency is widespread in the Holstein-Friesian breed. The genetic basis for the disease is a single point mutation in the gene coding for CD18, a subunit of the β3 integrins, surface glycoproteins which are important to cell adhesion processes, causing a deficiency of adhesion on the surface of leukocytes. Neutrophils from BLAD cattle have impaired expression of β2 integrin (CD11a, β2/CD18) of the leukocyte adhesion molecule. The biochemical basis for the disease is a deficiency of interaction between receptors on the leukocytes with adhesion glycoproteins in the mediation of immunological functions. A polymerase chain reaction test is available for the detection of heterozygotes and an eradication program is operating in Japan. Control of BLAD in Holstein cattle requires publishing the genotypes and avoiding the mating between BLAD carriers which is successful. Heterozygote calves are not affected.

REVIEW LITERATURE

INHERITED DEFICIENCY OF LYMPHOCYTE MATURATION (LETHAL TRAIT A46, PARAKERATOSIS, ADEMA DISEASE)

This defect is recorded in Black Pied Danish cattle but probably occurs in a number of European breeds of cattle, including Friesian-type cattle, and in beef Shorthorn calves in the US. It is a defect of lymphocyte maturation and is inherited as an autosomal recessive character. Calves are normal at birth and signs appear at 4–8 weeks of age; untreated animals die at about 4 months of age. There is exantheme and loss of hair, especially on the legs, parakeratosis in the form of scales or thick crusts around the mouth and eyes, under the jaw, and on the neck and legs, and a very poor growth rate. Lymphocyte numbers and function are reduced when the patient is in a zinc-deficient state, and antibody responses are suppressed.

At necropsy the characteristic skin lesion is acanthosis and hyperkeratosis and there is atrophy of the thymus, spleen, lymph nodes, and gut-associated lymphoid tissue. There is a significant response to oral treatment with zinc (0.5 g zinc oxide/day) and an apparently complete recovery can be achieved in a few weeks if treatment is continued. The disease reappears if treatment is stopped. The dose rate needs to be increased as body weight increases. It is thought that the disease is an inherited excessive requirement for zinc and that the thymic hypoplasia is due to the dietary deficiency. Absorption studies with radioactive zinc have shown that there is impaired absorption of the element.

REFERENCES

INHERITED DEFICIENCY OF IMMUNOGLOBULIN SYNTHESIS

An inherited complete deficiency of IgG2 occurs in Red Danish cattle at a low level of incidence. Affected animals are unusually susceptible to severe infections including gangrenous mastitis and pneumonia.
CHEDIAK–HIGASHI SYNDROME

This inherited disease occurs in humans, in mink, and in Hereford, Japanese Black, Brangus cattle, and possibly other breeds of cattle. Clinically affected animals grow poorly; they are incomplete albinos with generalized oculocutaneous hypopigmentation, e.g., pale gray hair, ocular iridal and fundic hypopigmentation, photophobia and lacrimation, and have anemia, enlarged, edematous lymph nodes, and a defect in immune defense mechanisms so that they often die of septicemia. Their average life span is about 1 year. The immunological defect has been identified as one of insufficient bactericidal activity within abnormal leukocytes. The clinical, morphologic, and biochemical characteristics of Chediak–Higashi syndrome in Japanese cattle has been described.

A mutation in the Chediak–Higashi LYST gene is likely responsible for the disease in Japanese Black cattle. The LYST gene responsible for the mutation has been cloned.

The disease is readily diagnosed by the detection of anomalous enlarged cytoplasmic granules in neutrophils, lymphocytes, monocytes, and eosinophils. The granules are swollen lysosomes, and the disease is a lysosomal storage disease. There is also a defect in blood clotting, and this has been identified as a metabolic defect within structurally abnormal platelets. The platelets have a storage pool deficiency of dense granules and produce much less serotonin, ATP, and ADP than normal platelets. The platelets also fail to aggregate normally in response to the presence of collagen. The disease is conditioned by a factor inherited as a single autosomal recessive.

A DNA diagnostic system using allele-specific PCR for detection of the nucleotide substitution has been developed as an effective DNA diagnostic aid.

PSEUDOALBINISM AND LETHAL WHITES

There are a number of forms of pseudoalbinism in domestic animals. There is a non-lethal form in cattle and a lethal dominant in horses in which 25% of conceptions produced by mating dominant white horses die in utero in early gestation. The only pigment in the affected foals is in the eyes.

The disease in cattle occurs in Angus, Brown Swiss, Holstein, and Hereford cattle. The Angus cattle have a brown coat and two-tone irises with an outer pale brown ring and an inner blue one. There appears to be no defect in digestion or metabolism. Hereford incomplete albinos have the Chediak–Higashi syndrome. The other breeds do not appear to have defects other than in pigmentation and the defect in Angus is probably more accurately called 'oculocutaneous hypopigmentation'. They do have one problem; they are photophobic and prefer to be out of the sun.

A complete albinism in Icelandic sheep is manifested by white skin color, pink eyes, and impaired vision in bright light. It is an autosomal recessive. Albinism is also a problem in Karakul sheep.

True albino horses rarely if ever occur in nature, but white horses with pigmented eyes do. They are more accurately called pseudoalbinos. A recessive lethal white can also be produced by mating two Overo paint horses (an Overo is a horse with a coat color pattern where white is continuous over the body, but there is pigmented hair in a patch stretching from the ears to the tail). Affected foals develop colic soon after birth, fail to pass meconium, and die at 2–4 days of age. At necropsy there is an irreparable atresia or contraction of the colon associated with a congenital absence of myenteric ganglia in the terminal portion of the ileum and the cecum and colon. The colon is patent but unable to dilate. Another variety of paint horses, the Tobiano (white markings extend from the dorsal midline ventrally with limbs usually white, and white covering a large part of the horse or very little), are expected to produce lethal whites also but there is no record of it. Both of these varieties of paints have blue or heterochromic irises.

REFERENCE

FELL PONY SYNDROME

This is a familial disease of Fell ponies characterized by immunodeficiency, anemia, opportunistic infection, and death at 2–3 months of age.

ETIOLOGY

The disease is a putative autosomal recessive genetic defect of the immune system, although the exact nature of the defect has yet to be determined.

EPIDEMIOLOGY

The disease is restricted to Fell pony foals less than 3 months of age. The disease is reported in this breed in the United Kingdom, one case is reported in the United States (which has a total population of Fell ponies of <200) and a case is reported in the Czech Republic. The frequency of the disease is not reported. The case fatality rate is 100%.

PATHOGENESIS

There is immunodeficiency associated with low concentrations of immunoglobulins in serum and B lymphocytes in blood. T lymphocytes are present in normal concentration and respond appropriately in vitro proliferation tests. Death is coincident with declines in concentrations of antibodies derived from colostrum. Immunodeficiency results in development of opportunistic infections including glossitis, adenoviral pneumonia, and cryptosporidial diarrhea. Aplastic anemia develops and can contribute to death. Anemia is associated with aplasia of red cell series in bone marrow and is not due to hemolysis or blood loss.

CLINICAL FINDINGS

Affected foals are lethargic at birth, are unable to keep up with the herd, and do not establish a strong bond with the dam. Foals develop ill-thrift, exercise intolerance, and diarrhea beginning at approximately 3 weeks of age. Clinical signs are attributable to anemia and opportunistic infections. At the time that foals develop other clinical abnormalities they are pyrexic and tachyypenic. Most foals have bilateral mucopurulent nasal discharge and abnormal lung sounds consistent with pneumonia. The tongue is covered by a pseudomembranous, hyperkeratotic membrane suggestive of Candida sp. infection. Foals develop diarrhea and progressive illness with death occurring by 3–4 months of age even in cases treated aggressively.

CLINICAL PATHOLOGY

The underlying hematology and serum biochemistry is influenced by the opportunistic infections that develop in all foals affected with Fell pony syndrome. Abnormalities consistently associated with the syndrome and likely as a result of the underlying disease, include anemia, B cell lymphopenia, and variable to low concentrations of immunoglobulins in serum.

Normocytic, normochromic anemia (6–26%, 6–26 LIL/L) is present in almost all affected foals. There is no evidence of regeneration in the blood and examination of bone marrow reveals an elevated myeloid:erythroid ratio (21:1 to 62:1, reference values 0.5:1 to 1.5:1). There is no evidence of hemolysis.

White blood cell concentration in affected foals is usually below or in the...
lower range of the reference range of normal, age-matched foals, and is attributable to a B-cell lymphopenia.\textsuperscript{5,6} Concentrations of CD4\textsuperscript{+} and CD8\textsuperscript{+} cells in blood are normal in affected foals.\textsuperscript{5,6} The concentration of neutrophils is often elevated in affected foals.

Concentrations of immunoglobulins (IgGa, IgGb, IgG(T), and IgM) in serum are variable and depend on the amount of immunoglobulin ingested in colostrum and the age of the foal. Affected foals are unable to produce immunoglobulins and therefore have declining concentrations of immunoglobulins with age. Serum concentrations of IgM and IgA become undetectable before does IgG – a consequence of the shorter half-life of the former immunoglobulins in foals. Measurement of low to undetectable concentrations of IgM at >4 weeks of age provides a reasonable means of diagnosing the disease.\textsuperscript{6}

**NECROPSY FINDINGS**

Gross lesions include pale bone marrow, small thymus and lymph nodes, pneumonia, and pseudomembranous glossitis. The underlying disease is characterized by lesions in bone marrow and lymphoid tissue. Bone marrow has evidence of abnormal hemopoiesis with an elevated myeloid:erythroid ratio. Lymph nodes have sparse to moderate numbers of lymphocytes in cortices and paracortices. The thymus has no clear demarcation of cortex and medulla and the thymic lobules are small.\textsuperscript{1,2} Germinal centers are not present in the spleen and the red pulp is markedly contracted and contains siderophages. Ganglionopathy reported in foals in the original report of the disease has not been found in subsequent cases.

**DIFFERENTIAL DIAGNOSIS**

<tr>
<td>IgM deficiency</td>
<td>Unknown</td>
<td>Epidemiology: Arabian or Quarter horse foals 2–8 months of age. Clinical signs: Pneumonia, septic arthritis, or enteritis.</td>
<td>Low to undetectable serum IgM concentrations with normal to elevated concentrations of other immunoglobulins.</td>
<td>Treatment: None specific. Symptomatic treatment. Rare foal reported to recover. Prevention: None.</td>
</tr>
<tr>
<td>Agamma-globulinemia</td>
<td>Unknown. Suspect sex-linked heritable defect</td>
<td>Epidemiology: Male foals. Sporadic Clinical signs: Chronic infections develop at &gt;2 months of age (corresponds with declining colostral immunity).</td>
<td>Low to absent concentrations of all immunoglobulin classes in serum. No B lymphocytes detectable in blood. Normal concentrations of T lymphocytes.</td>
<td>Treatment: None specific. Supportive and symptomatic but all affected foals die. Prevention: None.</td>
</tr>
<tr>
<td>Common variable immunoodeficiency\textsuperscript{a,b}</td>
<td>Unknown in horses</td>
<td>Epidemiology: Adult horses. Sporadic. Either sex. Clinical signs: Chronic or recurrent infections unresponsive to medical treatment. Meningitis. Liver disease can occur in combination with CVI.</td>
<td>Low to undetectable concentrations of IgG, IgG(T), IgM, and IgA in serum. No or few B lymphocytes in blood or lymph nodes. Elevations in serum markers of liver disease.</td>
<td>Treatment: None specific. AFFECTED animals die because of the opportunistic infections. Prevention: Prolonged antimicrobial administration of affected horses.</td>
</tr>
</tbody>
</table>
CONFIRMATION OF DIAGNOSIS
The disease is confirmed by presence of characteristic lesions at necropsy. Antemortem diagnosis is confounded by the presence of opportunistic infections, but should be suspected in any Fell pony foal with anaemia, illness, and declining serum concentrations of immunoglobulin.

TREATMENT
There is no effective treatment. Supportive treatment of transfusions of blood or plasma, and administration of antibiotics does not affect the eventual outcome of the disease.

CONTROL
There are no control measures for the disease pending determination of the nature of its genetic transmission. Should the presumed autosomal recessive inheritance be demonstrated, then identification of carriers and elimination of these animals from the breeding population will permit control of the disease.

REFERENCES

Inherited defects of the alimentary tract

INHERITED DEFECTS OF THE MOUTH AND JAW
Harelip in cattle often has a distinct familial tendency but little work appears to have been done on the mode of inheritance. An apparently inherited harelip combined with poor growth and accompanying cryptorchidism is recorded in Holstein-Friesian cattle. Bilateral cleavage of the lip which also involves the maxilla is recorded in Texel sheep as being conditioned by a single recessive autosomal gene.

Cleft palate is inherited as a simple recessive character in Hereford and Charolais cattle, concurrent with arthropysis in the latter, and is commonly thought to be inherited in sheep and pigs. The progeny of a commercial swine herd (Landrace × Duroc) and Large White Boar contained a number of piglets with cleft palates. Chromosomal analysis of affected piglets found all had identical unbalanced karyotype with partial monosomy of chromosomes 16 and partial trisomy of chromosome 3, compared to normal piglets in the litters with balanced karyotypes.

Jaw deformity. Shortness of the maxilla is thought to be inherited in Jersey cattle and Large White pigs, sometimes in association with chondrodysplasia. Shortness of the mandible is also inherited in cattle, in Angus in combination with cerebellar hypoplasia and osteopetrosis.

Smooth tongue (epithelogenisis imperfecta lingue bovis). A defect of Holstein-Friesian and Brown Swiss cattle, this condition is inherited as an autosomal recessive factor. The filiform papillae on the tongue are small, there is hypersalivation and poor hair coat, and the calves do not fare well. The heterozygote is normal.

Tongue aplasia. Congenital absence of the median part of the tip of the tongue occurs rarely in piglets, often in association with cleft palate and/or harelip.

Rectal prolapse may be inherited in piglets as a result of agenesis of the anal sphincter (see below).

INHERITED RECTOVAGINAL CONstriction
The defect is inherited in Jersey cattle and is manifested as stenosis of the rectum in either sex and stenosis of the vaginal vestibule in females. The tone of both rectal and vaginal sphincters is increased but attempts to detect heterozygotes by electromyographic measurement of these tones have been unsuccessful. The defect is regulated by an autosomal recessive gene. Affected cows are difficult to inseminate and have difficulty in calving. Their udders are small and hard and productivity is low. The condition is due to the presence of bands of non-elastic fibrous tissue. Edema of the udder is also a common complication. Some assistance in the identification of affected animals is available by the detection of collagen type II in muscle biopsies. 50% of heterozygotes also test positively, and so do a small percentage of normals.2

HEPATIC LIPODYSTROPHY IN GALLOWAY CALVES
Hepatic lipodystrophy has been reported occurring in Galloway calves on 5 farms in the UK over a 10-year period. Calves appear normal after birth but die by 5 months of age. Clinically there is tremor, opisthotonus, and dyspnea before affected calves become recumbent and die. At necropsy the liver is enlarged, pale and mottled. Histologically there is evidence of hepatic encephalopathy. The cause is unknown, but limited evidence suggests a storage disease is possible.

REFERENCES

INHERITED ATRESIA OF ALIMENTARY TRACT SEGMENTS
Anal sphincter atresia occurs rarely in piglets, causing rectal prolapse.

Atresia ani occurs quite commonly in pigs, sheep, and, to a lesser extent, in cattle. Affected animals may survive for up to 10 days and are identified by their depression, anorexia, colic, marked abdominal distension and lack of feces, feces being replaced by thick white mucus. Abdominal distension in utero occasionally causes dystocia. Surgical repair is possible in some cases but in others a large segment of rectum is missing and creation of a colonic fistula in the inguinal region is necessary. The condition is thought to be inherited in pigs and calves but supporting evidence is slim: the evidence is less clear in sheep. A suggestion that the defect may be also associated with the manipulation of the fetus during pregnancy examination has not been supported. A calf with atresia ani and diphallus and separate scrotum has been described.

Inherited atresia coli, with complete closure of the ascending colon at the pelvic flexure, has been recorded in Percheron horses. A clinically similar defect in Overo horses, described in the section on pseudalbuminism, is in fact an aganglionicomia. Death occurs during the first few days of life. The defect appears to be inherited as a simple recessive character.

Inherited atresia ilei has been recorded in Swedish Highland cattle. Affected calves manifest marked abdominal distension causing fetal dystocia. The distension is caused by accumulation of intestinal contents. Inheritance of a single recessive gene conditions the occurrence of the defect in some species and breeds but the prevalence may be higher than would be expected with that form of inheritance, especially in Jersey cattle with atresia coli.

Inherited defects of the circulatory system

BOVINE HEREDITARY DILATED CARDIOMYOPATHY
Bovine hereditary dilated cardiomyopathy is a group of progressive degenerative diseases of the myocardium causing congesti-
tive heart failure. At least three different types have been reported: dilated cardiomyopathy in cattle of Canadian Holstein origin; cardiomyopathy in Japanese Black cattle; and, cardiomyopathy in Hereford cattle.

Pedigree analysis of 75 animals in three age classes and five diagnostic classes based on clinical and pathological findings using the Pedigree Analysis Package provided strong evidence for autosomal recessive inheritance of a single major gene responsible for the disease. Pedigree analyses of affected animals in Canada, Japan, and Switzerland, revealed that the Holstein bull ‘ABC Reflection Sovereign’, the son of Canadian Holstein sire Montwick Red Apple Sovereign, as the common ancestor. The disease in cattle is being used as a research model of human dilated cardiomyopathy. Using proteomic analysis, the examination of tissue from younger that are genetically diseased but have not yet developed clinical disease, a number of proteins have been identified whose abundance is altered significantly to suggest a possible pathogenetic mechanism for the onset of the disease.

The disease has now been reported in Denmark in the Red Danish Dairy breed, Holsteins, and Red Holsteins. Pedigree analysis of 12 cases found both maternal and paternal relationship to the Canadian sire Monwick Red Apple Sovereign, and several sires were identified as carriers of the disease. These sires originated from breeding lines used to upgrade Danish cattle populations and pose a potential animal health problem. The introduction of the defect into the Danish cattle population is an example of how widespread a genetic disease can become in a short period of time. During their active life, two sires used for artificial insemination obtained a total of approximately 62,000 living progeny.

There can be a high incidence in certain herds, possibly associated with some unrecognized environmental precipitating factor but probably caused by autosomal recessive trait concentrated by a high coefficient of inbreeding.

There are three types recorded in cattle:

**Type 1 calf – acute heart failure**

Sudden death of Poll Hereford and homed Hereford calves up to 3 months of age may be due to inherited cardiomyopathy. The calves are often identifiable before death by their very rapid growth rate, short curly coat, and moderate bilateral exophthalmos. Death is usually precipitated by stress or exercise and is characterized by dyspnea, the passage of bloody froth from the nose, and a course of a few minutes to a few hours. Less acute cases have a syndrome of congestive heart failure for several days before death. Life expectancy is less than 6 months. At necropsy there is an obvious patchiness of the myocardium, reminiscent of a bad case of white muscle disease. The disease appears to be conditioned by a single autosomal recessive gene.

**Type 2 calf – pulmonary edema**

A second form of inherited cardiomyopathy is recorded in Japanese Black cattle. Death is preceded by a brief period (a few minutes to a few hours) of agonizing dyspnea in calves aged 30 up to 120 days. At necropsy there is edema, ascites, hydrothorax, and marked dilatation of the left ventricle. This is matched by acute myocardial necrosis. A new autosomal recessive gene is credited with initiating the disease.

**Type 3 – young adult congestive heart failure**

This occurs in young adult cattle and has been reported in Holstein-Friesian cattle in Japan, Canada, the UK, Australia, and in Simmental-Red Holstein crossed cattle and Black Spotted Friesian cattle in Switzerland. Similar family lines in Holstein breed have been identified in affected cattle in all three countries and it has been suggested that there is an inherited predisposition to cardiomyopathy in the Holstein breed. Pedigree analysis of hereditary dilated cardiomyopathy in Holstein-Friesian cattle in Japan suggests an association with hereditary myopathy of the diaphragmatic muscles. The disease is endemic in Switzerland, occurring mainly in the Simmentaler x Red Holstein cross-bred cattle.

The disease occurs in cattle from 1.5 to 6 years of age with the peak prevalence in 3-4-year-old cattle. The stress of pregnancy and lactation may precipitate clinical disease and the majority of cases occur in late pregnancy or early lactation. The onset is sudden and the majority of cases have signs of congestive right heart failure. Edema of the subcutaneous area, brisket, ventral abdomen, and udder is prominent and there is venous engorgement, hepatomegaly, interstitial nephritis, pleural and pericardial effusion, and ascites. Muffling of the heart sounds, tachycardia, and a gallop rhythm are evident on auscultation of the heart. There is no characteristic biochemical or hematological change.

Necropsy findings include congestive heart failure and histological findings compatible with congestive cardiomyopathy. There is dilation of the chambers of the heart, thickening or thinning of the ventricular wall, subcutaneous, mesenteric and pulmonary edema, hydrothorax, hepatomegaly, and ascites. Histologically there is fibrosis, myocardial degeneration, and vacuolation of cardiomyocytes and infiltration of mononuclear cells into the myocardium. In some cases, interstitial non-suppurative nephritis is present. Electron microscopically, the sarcoplasm of the hypertrophic fibers is filled with fine structures of low electron-density, together with thin filamentous material, suggesting myofibrillar lysis.

Following introduction of an eradication program based on culling of carriers in the sire population, the incidence in Switzerland has decreased.

**REFERENCES**

**INHERITED LYMPHATIC OBSTRUCTION**

This defect has been recorded in Ayshire and Hereford calves. Males are more often affected than females; it has been suggested that some affected females may not be detected. The defect is inherited as a single, autosomal recessive character, with variable expressivity and incomplete penetrance.

The outstanding clinical feature is edema, the degree varying from slight to severe; severe cases causing dystocia to the point where embryotomy or cesarean sections is necessary. Some mortality occurs among the dams. Many calves are dead at birth and those born alive may be reared but the edema persists. Before parturition the cow may show evidence of hydrops amnii and have difficulty in rising. In calves the edema may be generalized or, more commonly, be localized to the head, neck, ears, legs, and tail. Drooping of the ears caused by increased weight is characteristic, and accessory lobes are commonly situated behind and at the base of the ears.

The edema is caused by a developmental abnormality of the lymphatic system. The lymph nodes are small and contain cystic dilatations and the lymphatic vessels are enlarged, tortuous, and dilated. Edema of the subcutaneous tissues and body cavities varies in degree; the skin is usually thickened and there is edema of the stomach wall.

**REFERENCE**

INHERITED VENTRICULAR SEPTAL DEFECT

Ventricular septal defects are common in food animals; reports of their occurrence in lambs and Hereford cattle suggest that the condition can be inherited.

INHERITED AORTIC ANEURYSM

An inherited defect of the abdominal aorta, resulting in a high mortality from intraperitoneal hemorrhage, has been observed in an unidentified breed of cattle in Holland, and is an important feature in Marfan syndrome of humans.

BOVINE MARFAN SYNDROME

A model of human Marfan syndrome, this disease of cattle is an autosomal dominant disorder caused by mutations in the fibrillin-1 gene. It is manifested primarily by cardiovascular lesions and signs, but lacks the skeletal abnormalities of the human disease. Necropsy lesions include aortic and pulmonary artery aneurysms, with consequent cardiac tamponade in some cases. Fragmentation of elastic laminae in the vessels is also characteristic.

REFERENCES

INHERITED CONGENITAL PORPHYRIA

Synopsis

A congenital defect of porphyrin metabolism in cattle and swine characterized by excessive excretion of porphyrins in urine and feces and deposition of porphyrins in tissues, especially bones and teeth. Photosensitization occurs in affected cattle.

ETIOLOGY

Congenital porphyria is similar to erythropoietic or Gunther's porphyria of humans. Most cases in cattle are due to the inheritance of a single recessive factor, heterozygotes being clinically normal. A deficiency of uroporphyrinogen III cosynthase results in the accumulation of porphyrin type I isomers. Although there is no strict sex linkage in the mode of inheritance, the incidence is higher in males than in females. In pigs the pattern of inheritance is uncertain but may be due to one or more dominant genes.

EPIDEMIOLOGY

Porphyria is recorded only in cattle and pigs. Shorthorn, Holstein, and White Danish, Jamaica Red and Black cattle, and Ayrshires carry the defect.

PATHOGENESIS

The porphyrins are natural pigments but in these diseases they are present in larger than normal concentrations in the blood, urine, and feces. In porphyria the metabolic defect is one of abnormal synthesis of heme due to an enzymatic insufficiency at the stage of conversion of pyrrolo groups to series 3 porphyrins. Excess series 1 porphyrins, physiologically inactive substances are produced as a result, and there is flooding of the tissues with these coloring and photosensitizing substances. The high tissue levels of porphyrins sensitize the skin to light and photosensitive dermatitis follows.

CLINICAL FINDINGS

In cattle the passage of amber to port wine colored urine, a pink to brown discoloration of the teeth and bones, and severe photosensitization are characteristic. Additional signs include pallor of the mucosae and retardation of growth.

AFFECTED PIGS are usually normal and photosensitivities do not occur, but the disease can be recognized by the red-brown discoloration of the bones and teeth, which is present even in the newborn.

CLINICAL PATHOLOGY

In porphyria the urine is amber to port wine in color when voided, due to the high content of porphyrins. The urine of affected cattle may contain 500–1000 μg/dL of uroporphyrins and 356–1530 μg/dL of coproporphyrins. The urine of normal cattle contains 1.84 μg/dL of coproporphyrins and no significant quantity of uroporphyrins. The color of the urine darkens to brown on exposure to light. Spectroscopic examination is necessary to identify the pigment as porphyrin. Erythrocyte survival time is reduced considerably. A macrocytic, normochromic anemia occurs, and its severity appears to be related to the level of uroporphyrins in the erythrocytes, and there is evidence of a hemolytic anemia. Cattle with the highest erythrocyte uroporphyrin levels are also the most sensitive to sunlight.

NECROPSY FINDINGS

In porphyric animals the teeth and bones are stained brown or reddish purple, the pigment occurring chiefly in the dentine in teeth and often in concentric layers in the bones. Affected bones and teeth show a red fluorescence under illumination with ultraviolet light. The histological findings are unique to this disease.

DIFFERENTIAL DIAGNOSIS

Confirmation of the diagnosis depends on identification of greatly increased levels of porphyrins in the blood and urine. Presumed affected cattle and pigs can be detected at birth by the discoloration of the teeth. Breeding trials are necessary to detect heterozygous, normal carrier animals.

TREATMENT

Non-specific treatment for photosensitization may be necessary. Affected cattle should be reared indoors.

CONTROL

Elimination of affected carrier animals from the breeding program is the only measure available. Periodic examination of the urine and feces for excessive quantities of coproporphyrin is carried out on bulls used for artificial insemination in breeds in which the disease occurs.

REVIEW LITERATURE

INHERITED ERYTHROCYTIC PROTOPORPHYRIA

Inherited erythropoietic protoporphyrria is an autosomal recessive disease which occurs in Limousin and Blonde d'Aquitaine cattle. It is similar to the same disease in humans and to porphyria but is milder. There is deficient activity of the enzyme uroporphyrinogen III cosynthetase, resulting in excessive photosensitizing protoporphyrin accumulation with high levels appearing in the erythrocytes and feces. The total amount of the enzyme is normal but up to 96% of it is non-functional.

Protoporphyrin is clinically differentiated from porphyria by the absence of anemia and discoloration of the teeth and urine. The major clinical abnormality is photosensitive dermatitis affecting particularly the tips of the ears and the edges of the nostrils. There may be intense pruritus and exudative dermatitis involving the head and upper aspect of the thorax. The hemocrit values are within normal ranges, the teeth are normochromic, and there is no fluorescence of urine; however, whole blood fluoresces under ultraviolet light. Protoporphyrin binds to proteins that are not excreted by the kidney and thus protoporphyrin will not be detected in the urine. In a Limousin calf, the disease was characterized by ataxia, and intermittent seizures. At necropsy...
there is hepatic portal fibrosis, bile ductule hyperplasia, and swelling of parenchyma cells. Phagocytic cells in the dermis contain large heterogeneous lysosomes. Histologically, in some cases, the earliest lesions are moderate to severe acanthosis, hyperkeratosis, and para- keratosis with dermal angiofibrosis. There may be intercellular edema, and intraepithelial vesicles and pustules. Elimination of affected carrier animals from the breeding program is the only control measure available.

REFERENCES

HEMOCHROMATOSIS

Hemochromatosis is rare in domestic animals. This inherited defect of iron metabolism in humans has also been observed in yearling Salers cattle in circumstances in which an inherited etiology is suggested. The pattern of inheritance is uncertain because of the small number of pedigrees available from affected cattle. Hemochromatosis occurs when inappropriately large amounts of iron are absorbed from the intestine over an extended period. The excessive accumulation of iron causes iron-induced lysosomal injury and peroxidation by free radicals, which are the two major mechanisms responsible for hepatocellular necrosis and for sequelae such as fibrosis, bile duct hyperplasia, veno-occlusive disease, and hepatic neoplasia. Unlike hemosiderosis, hemochromatosis is associated with high transferrin saturation values in serum (>60%). Clinical disease develops between 9 and 22 months of age. Animals are normal until weaning but then lose weight, develop rough hair coats, and lose incisor teeth. The skeletal changes in hemochromatosis are due to abnormal bone development. Bone analysis reveals iron levels in affected animals may be 30 to 50 times greater than normal and decreased percent ash in the outer cortex. Periosteal dysplasia and osteopenia are responsible for the pathologic fractures and tooth loss.

At necropsy, there is emaciation, firm dark brown livers and lymph nodes, soft bones, and brown-colored small intestine. The major histological changes are hepatocellular siderosis and periportal bridging, and perivenular fibrosis. Heavy deposits of iron in the liver, and deposits of hemosiderin are visible in liver tissue obtained by biopsy. Hepatic iron concentrations in clinically affected cattle range from 1500 to 10 500 wet weight (reference range for cattle = <300 g/g). Ultrastructurally, the heaviest intrahepatic deposition is in the hepatocyte. Iron in bone is associated with osteopenia.

FAMILIAL POLYCYTHEMIA

This inherited defect has been observed only in Jersey cattle. Attention is drawn to the presence of the disease by early calfhood deaths and a clinical syndrome including congestion of mucosae, dyspnea, and poor growth. Hematologically there is marked elevation of erythrocyte count, hemoglobin concentration, and packed cell volume. The disease appears to be a primary polycythemia inherited as a simple autosomal recessive.

INHERITED BLEEDING DISORDERS

Hemophilia

Hemophilia A (deficiency of factor VIII, or classic hemophilia) occurs in Thoroughbred, Standardbred, Arab, and Quarter horses, causing uncontrollable bleeding after injury or surgery, or spontaneously. This may be manifested by the sudden appearance of swellings over joints or the upper cervical region causing dyspnea, or into joints or body cavities causing acute hemorrhagic anemia, and blood can be aspirated from them. The platelet-dependent bleeding time is normal but the fibrin-dependent bleeding time is markedly prolonged. The defect is genetically transmitted as a sex-linked recessive trait, appearing clinically only in males.

von Willebrand's disease has been identified in a Quarter horse which experienced bleeding episodes and a low blood level of vWF, after a normal platelet count and negative coagulation screening tests.

Bovine factor XI deficiency

Factor XI (partial thromboplastin antecedent) is involved in coagulation but animals affected by a deficiency of it may be clinically normal even though their whole blood clotting time is very prolonged. Others may have a severe bleeding tendency but the frequency of hemorrhagic episodes with factor XI deficiency is very low. Heterozygotes experience minor episodes, homozygotes may have serious ones, especially neonates, which may die at birth and be classified as uncomplicated neonatal mortality. Affected cows also experience an increase in repeat breeder problems, apparently associated with a slower luteolysis and the development of small graafian follicles. Both males and females transmit the trait which is inherited as an autosomal recessive.

Prekallikrein deficiency

Prekallikrein is necessary to activate factor XII in the coagulation process. An inherited deficiency of it is recorded in a family of Belgian horses, as a cause of a bleeding tendency in the presence of the conventional coagulation factors. The deficiency is of the order of <1% of normal levels of 63–150%. The activated partial thromboplastin time is markedly prolonged.

Inherited thrombopathia

Thrombopathia causes uncontrolled bleeding in Simmental cattle. Collected blood undergoes good clot retraction but platelet aggregation in response to adenosine diphosphate and collagen in a whole blood aggregation system is badly impaired. Clinical findings include epistaxis, hematuria, the sudden development of subcutaneous swellings, hemorrhagic anemia due to internal bleeding, or bleeding after external lacerations or surgery. Restriction of the problem to the Simmental breed suggests inheritance of a recessive trait. A study of the inheritance of the abnormality using embryo transfer technology and superovulating a donor cow which previously had a calf with platelet aggregation disorder found a very low incidence of the abnormality. This suggests inheritance of the defect is not simple Mendelian recessive.

Afi brinogenemima (related diseases are hypofibrinogenemia, dysfibrinogenemia)

Afi brinogenemima is a rare cause of bleeding diathesis recorded in cattle, sheep, and goats, especially the newborn. Confirmation of the diagnosis and differentiation from the related diseases (above) requires sophisticated laboratory technology.

INHERITED ANEMIAS

Inherited dyserythropoiesis and dyskeratosis (bovine congenital anemia, dyskeratosis, and progressive alopecia)

This disease occurs in 1-16-month-old calves in some Poll Hereford families. It is thought to be inherited as a simple autosomal recessive character. Clinical signs commence at about 2 months of age and include skin lesions which commence on the face and neck, especially around the muzzle and along the edges of the ears, then extend in the midline down the back, then down the sides, and onto the limbs; the long hairs on the tail tip are shed. The hyperkeratotic muzzle accumulates dust. The skin lesions comprise alopecia, with surviving hairs wiry, kinked or tightly curled, accumulations of sebum, and hyperkeratosis and marked wrinkling. The alopecia and hyperkeratotic dermatitis extend and the calves do not thrive, becoming small in stature, intolerant of exercise, susceptible to heat stress, and eventually pining away until they die or are euthanized. Histologically the skin is affected by dyskeratosis, hyperkeratosis, and orthokeratosis, and there are morphological abnormalities of the nucleus in erythroid precursors; anemia results from ineffective erythropoiesis. There is a persistent, non-regenerative anemia due to a failure of maturation of erythrocytes; the blood contains many nucleated erythrocytes, and bone marrow aspirates contain increased numbers of erythroid precursors.

REFERENCES

Inherited glucose-6-phosphate dehydrogenase enzyme deficiency

A single case of this persistent hemolytic disease has been recorded in a yearling American Saddlebred colt. The disease in humans is well recognized as an inherited defect. A similar clinical disease is recorded in Murray Grey calves in Australia. Signs are observed first when affected calves are 3-8 weeks old. Both sexes are affected. Signs include poor growth, exercise intolerance, progressive weakness, severe jaundice, and death. There is a severe regenerative anemia, hemoglobin levels of 25-30 g/L, and an absolute nucleated erythrocyte count of 9-18 x 10^6/L.

Necropsy lesions include jaundice, a grossly enlarged, in some cases miss-hapen, greenish liver, and brown urine. Histological lesions are suggestive of a persistent intravascular hemolysis. A series of cases of hemolytic anemia of undetermined origin, recorded in a familial pattern in horses, was characterized by high blood levels of methemoglobin.

INHERITED BILATERAL RENAL HYPOPLASIA

This usually lethal condition is inherited as an autosomal recessive character in Large White pigs.

INHERITED INTRAVASCULAR HEMOLYSIS

Inherited dyserythropoiesis and dyskeratosis (bovine congenital anemia, dyskeratosis, and progressive alopecia)

In hereditary defects of the urinary tract

INHERITED NEPHROSIS (MESANGIOCAPILLARY GLOMERULONEPHRITIS)

An apparently inherited mesangiocapillary glomerulonephritis occurs in Finnish Landrace lambs less than 4 months old and in newborn Yorkshire pigs. The lambs absorb an agent from the colostrum which causes an immunological response in the lamb and the deposition of immune complexes within the glomerular capillary walls. Many affected lambs are asymptomatic before being found dead. Some have tachycardia, conjunctival edema, nystagmus, walking in circles, and convulsions. Enlarged, tender kidneys are palpable, and there is severe proteinuria, low plasma albumin, hyperphosphatemia, hypocalcemia, and BUN levels greater than 100 mg/100 mL. Necropsy findings include pale swollen kidneys and severe vascular lesions in the choroid plexuses and the lateral ventricles of the brain. Uremia supervenes in 75% of lambs by 27 days of age. Cases also occur in crossbred lambs.

CHRONIC INTERSTITIAL NEPHRITIS

Chronic interstitial nephritis with diffuse zonal fibrosis (CINF) occurs in Japanese Black cattle (Wagyu) as an autosomal recessive disorder leading to death prior to puberty. Clinically there is growth retardation between 3 and 5 months of age. A genome-wide scan using microsatellite markers in a Wagyu pedigree segregated for CINF, mapped the CINF locus to bovine chromosome 1.

INHERITED CYSTIC RENAL DYSPLASIA

Inherited, possibly conditioned by an autosomal dominant gene, this disease occurs in lambs sired by carrier Suffolk rams out of mixed ewes. Signs include recumbency and coma by days 2-3. Abortions and stillbirths occur in the same flocks at the same time. The kidneys are enlarged and cystic.

REFERENCES

INHERITED RENAL LIPOFUSCINOSIS IN DANISH SLAUGHTER Cattle

Dark brown or black discolored kidneys ("black kidneys") have been reported as incidental findings in slaughter cattle for more than 100 years. A pigment with characteristics similar to those of lipofuscin is present in secondary liposomes in epithelial cells of the proximal tubules. Cases occurred only in Holstein cattle or the Red Danish Dairy Breed and mainly in animals aged 3 years or older. The prevalences of the abnormality were 0.44% and 2.51%, respectively. Epidemiological and genealogical analyses strongly indicate an autosomal recessive inheritance.

REFERENCES
Inherited defects of the nervous system

INHERITED LYSOSOMAL STORAGE DISEASES

These are diseases in which there is a genetically determined deficiency of a specific lysosomal hydrolase enzyme causing a defective glycoprotein metabolism. As a result of the deficiency, metabolic substrates accumulate in the lysosomes. The lysosomes themselves are concerned with hydrolyzing polymeric material, which enters the vacuolar system, and converting it to monomeric units, such as amino acids, monosaccharides, and nucleotides, which can be dealt with by the better known metabolic processes.

There are other lysosomal storage diseases caused by poisonings and these are dealt with elsewhere. The best known ones are caused by poisoning with Swainsona, Astragalus, Oxytropis, and Phalaris spp. (the chronic form of that disease).

The diseases included in this section are not strictly diseases of the nervous system because the lysosomes in both neuronal and visceral sites are affected, but the effects of the disease are most obvious in terms of nervous system function.

MANNOSIDOSIS

Mannosidosis is the best known group of the inherited lysosomal storage diseases in agricultural animals.

α-Mannosidosis

This is a lysosomal storage disease in which a deficiency of the enzyme α-mannosidase results in the accumulation of a metabolite rich in mannose and glucosamine in secondary lysosomes in neurons, macrophages, and reticuloendothelial cells of lymph nodes, causing apparent vacuolization in them. Similar vacuoles are found in exocrine cells in pancreas, abomasum, and lacrimal and salivary glands. Storage appears to be cumulative in the fetus, but after birth stored material is lost from the kidney into the urine via desquamated tubular epithelium. On the other hand, postnatal storage continues in the brain, pancreas, and lymph nodes. The disease occurs in Angus, Murray Grey, and Brangus cattle from Australia. The latter mutation was first identified in Galloway cattle and is manifested by stillbirth, moderate hydrocephalus, enlargement of the liver and kidneys, and arthrogryposis.

CLINICAL PATHOLOGY

Normal heterozygotes carrying genes for mannosidosis are identifiable because of their reduced tissue or plasma levels of α-mannosidase. The mannosidase test for α-mannosidosis in goats is specific and does not cross-react with α-mannosidase. One of the mutations is associated with α-mannosidosis in Galloway cattle. The other mutation is uniquely associated with α-mannosidosis in Angus, Murray Grey, and Brangus cattle from Australia. The former mutation was also detected in the ion Red Angus cattle exported from Canada to Australia as embryos. The two breed-specific mutations may have arisen in Scotland and by the export of animals and germplasm disseminated to North America, New Zealand, and Australia.

CONTROL

A control program can be based on the identification of heterozygotes using the PCR based assays for detection of breed-specific mutations. A program of screening cattle in herds which produce bulls for sale to commercial herds should stop the spread of the disease very quickly because the number of heterozygous females in the population will be irrelevant to the continuation of the disease in the absence of affected sires.

The α-mannosidosis gene prevalence is now insignificant and disease incidence has been reduced from an estimated 3000 cases/year to negligible levels.

β-Mannosidosis

β-mannosidosis occurs in Salers cattle and Anglo-Nubian goats and has been recorded in a sheep. In the cattle some affected calves are stillborn. The remainder is euthanized forthwith because of the severity of the congenital defects.

CLINICAL FINDINGS

All cases are affected at birth with craniofacial deformity and inability to stand. The cranium is domed and there is mild proptosis, narrow palpebral fissures, and a tough, hidebound skin. When in sternal recumbency the head is moved in a combined motion of circling and bobbing, eventually converting to an extended position. In lateral recumbency there is opisthotonos and paddling convulsions.

CLINICAL PATHOLOGY

The diagnosis is confirmed by a reduced level of β-mannosidase in the blood.

NECROPSY FINDINGS

Include a deficiency of cerebral cortical and cerebellar substance, distended lateral ventricles, and bilateral meningeal neuritis. The biochemical defect is one of acidic β-mannosidase, and is conditioned by an autosomal recessive character. The carrier rate of the causative gene is very high in the Saler breed.
GM₁ gangliosidoses

GM₁ gangliosidosis

GM₁ gangliosidosis occurs in cattle and sheep. In Friesian cattle it is inherited as a lysosomal storage disease in which the activity of an enzyme, β-galactosidase, in nervous tissue is greatly reduced. As a result there is an accumulation of the ganglioside (GM₁) in the tissue. Clinical signs of progressive neuromotor dysfunction and a reduction in growth rate appear at about 3 months of age. The growth rate is reduced, and the animal is in poor condition, blind, and has a staring coat. The neuromotor signs include lack of response to external stimuli, sluggish mastication and swallowing, hindquarter sway while walking, a wide stance, a tendency to fall, reluctance to move, stiff high-stepping gait, aimless walking, head-pressing, and convulsions. Abnormal ECG tracings are common. The blindness results from lesions in the retina and the optic nerve. Ophthalmoscopic examination of the retina is recommended as an aid to diagnosis. A positive diagnosis is made on the grounds of intraneuronal lipid storage plus reduced β-galactosidase activity plus identification of the stored lipid. The stored ganglioside is visible under the electron microscope as stacks and concentric whorls of lamellae. In the live animal enzyme assays are carried out on leukocytes. The enzymatic defect is also detectable in liver, skin, and leukocytes.

The disease is also present in Suffolk and Suffolk-cross sheep. Visceral and neuronal lysosomal storage are both evident but the neuronal lesion is more severe. Deficiencies of β-galactosidase and α-neuraminidase are evident. Affected sheep become ataxic at 4–6 months old and worsen to recumbency and death in up to 2 months.

GM₂ gangliosidoses

This has been identified in Yorkshire pigs and also causes decreased growth rate, incoordination appearing after 3 months of age, gray-white spots in the retina and dark blue granules in neutrophils, and azurophilic granules in lymphocytes. A serum enzyme assay is a suitable method of detecting ‘carrier’ heterozygous pigs. The test is based on the amount of N-acetyl-β-D-hexosaminidase in tissues.

**CEREBRAL LIPOFUSCINOSIS**

The ceroid-lipofuscinoses are a group of inherited storage diseases, inherited as autosomal recessive traits. They are grouped together because of common clinical and pathological phenomena related to brain and retinal atrophy, premature death, and accumulation of a fluorescent lipopigment in neurons and many other cell types within the body.

The disease is recorded in South Hampshire sheep,1 Rambouillet sheep,2 Borderdale sheep,3 Merino sheep,4 Nubian goats, and Devon cattle.5 It resembles neuronal ceroid lipofuscinosis of humans and is not strictly a primary lysosomal disorder; it is classified as a proteolipid proteinosis, and provides a good animal model for discussing the similar disease (Batten’s disease) of humans. It is inherited as an autosomal recessive trait.7 Secondary lysosomes fill with subunit C of mitochondrial ATP synthase because of excessive peroxidation of polyunsaturated fatty acids.9 The mechanism of the accumulation is that protein is formed which is normal for mitochondria but is misdirected so that it accumulates in the lysosome.10 The brains of affected lambs grow till they are 4 months old, then they commence to atrophy. The disease in Merino sheep is a subunit c-storing abnormality, clinically and pathologically similar to ceroid-lipofuscinosis in South Hampshire sheep.12 The South Hampshire form of the disease maps to chromosome 7q13-15, which is synthetic with human chromosome 15q21-23, the site of human CLN6.1

The occurrence of a neuronal ceroid-lipofuscinosis in Borderdale sheep in New Zealand has been described.13 The severity of neurodegeneration and minor differences in the ultrastructure of storage material suggests this is a different disease from other forms of ovine ceroid-lipofuscinosis which accumulate subunit C of mitochondrial ATP synthase. An autosomal recessive mode of inheritance is considered probable.

Clinical findings include slowly progressive ataxia of the hindlimbs, commencing usually at about 4 months but possibly as late as 18 months of age, and lasting for 6 months leading to euthanasia at up to 4 years. Inability to keep up with the flock is noticed first, followed by a sawhorse stance, obvious ataxia, severe depression, and an increasing failure of the menace and pupillary light reflexes. Terminal blindness is a constant sign. Positional nystagmus, circling, and head pressing occur in some. Eating, drinking, and defecation are normal, but there is slight weight loss.13

The lesion in lambs and calves is atrophy of the cerebrum, especially the optic cortex, with eosinophilic granulation of neurons and macrophages in the central nervous system followed by progressive retinal atrophy. There is a progressive storage of lipopigment in nervous tissue, especially retinal photoreceptors; its presence can be demonstrated by quantitative autofluorescence using a modified slit lamp microscope. Other clinicopathological aids include lysosomal enzyme assay, organ biopsy, and computed tomography, which reveals the enlargement of the lateral ventricles of the brain resulting from cerebral atrophy.

Neuronal ceroid lipofuscinosis has been described in three horses.13 Clinically, there was developmental retardation, slow movements and loss of appetite at 6 months of age. Torticollis, ataxia, head tilt, and loss of eyesight were present at 1 year of age. There were abnormalities in posture and movements, decreased spinal reflexes, and some cranial nerve dysfunction, dorsal strabisms, and absence of the menace reflex. At necropsy, there was flattening of the gyri and discoloration of the brain. Histologically, eosinophilic, autofluorescent material in the perikarya of neurons were present throughout the brain, spinal cord, neurons of the retina, submucosa, and myenteric ganglia and in glial cells.

GLOBOID CELL LEUKODYSTROPHY (GALACTOCEREBROSIDOSIS)

Globoid cell leukodystrophy has been identified in Poll Dorset sheep in Australia. Incoordination in the hindlimbs progresses until the animals are tetraplegic. Only histological changes are evident at necropsy. These include myelin destruction and the accumulation of characteristic globoid cells in nervous tissue. There is greatly decreased galactocerebrosidase activity in affected tissue.

REFERENCES

INHERITED NERVOUS SYSTEM ABORTIVITIES

These diseases are characterized by premature, progressive loss of nervous function due to spontaneous, late degeneration of nervous tissue. As a result, most affected animals are born normal but develop signs of a progressive neurological disease that is either fatal or leads to such a serious neurological deficit that euthanasia is the only reasonable solution. In a few rare diseases the patient is abnormal at birth but worsens, and usually dies, during the neonatal period. Again there are exceptions and rare cases in calves recover completely. The genetic nature of some of the cases included may not be certain; they are included here if the evidence that they are inherited can be reasonably presumed. The lysosomal storage diseases, listed in the preceding section, are a specific group of abortivistic diseases.

REFERENCE

CEREBELLAR ABOTROPHY

This disease occurs in Holstein and Poll Hereford cross calves, pigs, and Merino sheep.

Cattle
In the calves ataxia appears for the first time when they are 3–8 months old. The calves are not blind but they often fail to exhibit a menace reflex. The onset of clinical signs is sudden but progression is slow or inapparent. Some become recumbent. Those that remain standing have a spastic, asymmetric ataxia, and a broad-based stance; they fall easily and have a fine head tremor. All are strong and have good appetites. Abiotrophy, or premature aging, is evident only microscopically and consists of axonal swellings and segmental degeneration and loss of cerebellar Purkinje cells. The disease appears to be inherited, but recovery of some late cases is recorded.

Sheep
The disease in sheep does not appear until about 3 years of age. There is incoordination and dysmetria so that the gait is awkward and disorganized and there is frequent falling. There are also a reduced menace response, an apprehensive manner, and a wide-based stance in the hindlimbs. At necropsy there is diffuse cerebellar degeneration and severe loss of Purkinje cells.

Pigs
A congenital progressive cerebellar abiotrophy is also reported in piglets of the offspring of Saddleback sows and an unrelated Large White boar. The disorder behaves epidemiologically like an inherited disease conditioned by a simple autosomal recessive trait. Clinical signs include dysmetria, ataxia, and tremor at standing but not at rest. There is gradual adjustment so that the piglets can walk and stand at 5 weeks of age but by 15 weeks they are no longer able to do so. Affected pigs also have a coarse matted hair coat caused by a disproportionate number of coarse hairs to fine hairs. Histopathological lesions are confined to the cerebellum where there is a significant loss of Purkinje cells.

Horses
The disease is recorded principally in Arabs but occurs also in the Australian pony, which was developed from the Arab, and in the Gotland breed from Sweden. A similar clinical syndrome occurs in the Oldenberg breed but the pathological picture is quite different. The disease may be present at birth but is often not observed until the foal is 6–9 months old. The characteristic signs are vertical head-nodding (some cases show horizontal head tremors), especially when excited, and ataxia which is most noticeable at a fast gait. It may not be evident while the foal is walking. Very badly affected foals are unable to stand or suckle at birth, less severe ones are normal until about 4 months of age when head-nodding becomes obvious. The degree of ataxia varies from slight incoordination to inability to stand. A ‘goose-stepping’ gait which slams the front feet into the ground occurs in some. All foals can see but there is an absence of the menace reflex in many. Nystagmus is not recorded as occurring in this disease.

Necropsy findings are limited to histopathological lesions in the cerebellum. These include widespread loss of Purkinje cells and the presence of a gliosis. There are no degenerative lesions in the spinal cord. In the similar disease in Oldenberg horses the cerebellum is often reduced in size. The disease is an abiotrophy, a premature aging of tissues.

There have been doubts about the heritability of the disease but analysis of European data confirms that it can be inherited as an autosomal recessive.

Familial convulsions and ataxia, especially of Angus cattle, is an abiotrophy and on histopathological criteria belongs in this group, but because it is usually present at birth it is included, for ease of diagnosis, in the section on congenital cerebellar defects.

REFERENCES

CAPRINE PROGRESSIVE SPASTICITY

A possibly inherited progressive paresis of Angora goats is recorded in Australia. Signs first appear at about 2 months of age, commencing with lethargy, followed by ataxia, then paresis progressing to sternal recumbency and eventual euthanasia. Tendon reflexes are normal but the kids have difficulty getting to their feet, especially in the hindlimbs. The gait is ataxic with frequent stumbles, and the kids are unwilling to run. At necropsy there are many large, clear vacuoles in many neurons of the spinal cord, posterior brainstem and midbrain, and degeneration of nerve fibers in the same areas and peripheral nerves.

REFERENCE

INHERITED NEURODEGENERATION (SHAKER CALF SYNDROME)

This is an inherited, degenerative disorder of horned Hereford calves. Newborn calves show severe tremor, difficulty in rising, spastic gait, and aphonia. Terminally there is spastic paraplegia. Histologically there are accumulations of neurofilaments within neurons. A similar disease in Holstein-Friesians occurs only in males. There are severe degenerative changes in the spinal cord with spongiiform lesions and some cavitation. It has the epidemiological distribution of a sex-linked recessive mutation.

REFERENCE
INHERITED PROGRESSIVE DEGENERATIVE MYELOENCEPHALOPATHY (WEAVER SYNDROME)

The defect is inherited in Brown Swiss cattle. It appears first in calves when they are 6 months to 2 years old with a small number more than 2 years, and is manifested by progressive bilateral hindlimb weakness and proprioceptive deficits causing difficulty in rising and a weaving, hypermetric gait, goose stepping with the forelimbs, and dragging the hindlimbs. The limb reflexes are normal. The calves are bright and alert throughout. There is a broad-based stance and finally recumbency and, after a course of 12–18 months, inevitable euthanasia. Necropsy lesions include axonal degeneration, including spheroid formation, and vacuolation of white matter in the cerebellum and at all levels of the spinal cord and especially in the thoracic segment. There is some neurogenic atrophy of muscles but there is no muscular dystrophy. The defect can be identified by examination of chromosomes. The defect appears to be linked chromosomally with high milk yield traits.

REFERENCES

INHERITED SPINAL DYSMELINATION

Bovine spinal dysmelination is a congenital neurological disease occurring in several national cattle breeds upgraded with American Brown Swiss cattle. The disease was first described in Red Danish Dairy breed. In Denmark, all cases are genetically related to the ABS bull White Cloud Jason’s Elegant. It is inherited as an autosomal recessive trait. Genetic mapping of the gene in cross-bred American Brown Swiss cattle to the bovine Chromosome II has been done.

Clinically, in calves there is lateral recumbency, opisthotonos, limb extension, normal to increased reflexes and mental alertness and by dysmelination, including axonal degeneration and astroglisis, in spinal tracts, especially the ascending gracile funiculus and dorso-lateral spinocerebellar tracts and the descending sulcomarginal tract. This is probably the same defect as muscular atrophy.

REFERENCES

INHERITED PROGRESSIVE ATAXIA

This well-recognized disease occurs in Charolais cattle. The first onset of signs is at about 12 months of age when the gait is seen to be stiff and stumbling, especially in the hindlimbs, and the hind toes are dragged. The ataxia may be asymmetric, and the animal cannot back up. The ataxia progresses over a period of 1–2 years. Affected animals tend to be down a lot and have difficulty in rising and posturing for urination. Urination is abnormal, being a squirting but continuous flow which soils the tail. Some affected animals nod their heads from side to side when excited. Both males and females are affected. It has been described occurring in 2-year-old Charolais steers in New Zealand. Characteristic necropsy lesions are confined to the central nervous system and are histopathological. The white matter of the cerebellum and internal capsule contains multiple foci of oligodendroglial dysplasia. The somatic lymph nodes contain nodules of hyperplastic lymphoid follicles, some catarrh of the medullae of the nodes, and an accumulation of eosinophils.

REFERENCES

INHERITED MULTIFOCAL SYMMETRICAL ENCEPHALOPATHY

Two forms of the disease are recorded, in Simmentals and in Limousin and Limousin-cross cattle. The Limousin calves are normal at birth but from about 1 month of age develop a progressive forelimb hypermetria, hyperesthesia, blindness, nystagmus, weight loss, and behavioral abnormalities, especially aggression. The signs gradually worsen for up to 4 months when euthanasia is necessary. Necropsy lesions include brain swelling, optic chiasma necrosis, and multifocal, symmetrical areas of pallor, up to 0.5 cm diameter in the brain. These lesions show partial cavitation and multiple, pathological abnormalities especially myelin lysis and vacuolation and demyelination. The distribution of cases suggests an inherited defect.

The disease in Simmental and Simmental-cross cattle recorded in Australia and New Zealand also has a distribution suggesting an inherited defect. The disease is clinically similar to that in Limousin cattle except that affected animals are not blind and it develops later, 5–8 months; calves may survive longer, up to 12 months and, although the characteristic abnormality of gait is hypermetria, the hindlimbs are affected, not the forelimbs. Other signs observed are dullness, a swaying gait and, terminally, gradually developing opisthotonos and forelimb hypertonia in extension. Necropsy lesions are also similar to those in the Limousins but the distribution is in the midbrain and the entire brainstem.

A multifocal symmetrical necrotizing encephalomyelopathy in Angus calves has been described. Clinically calves exhibited ataxia, nystagmus, strabismus, muscular tremors, opisthotonos, bruxism, hyperaesthesia, tetanic spasms, and episodic convulsions at 2–6 weeks of age. Death occurred 4–7 days after the onset of clinical signs. Lesions consisted of symmetrical degenerative foci affecting the dorsal vagal motor, lateral cuneate and olivary nuclei in the medulla oblongata and occasionally in the spinal cord, substantia nigra and cerebellar peduncles. While an inherited basis for the disease is suspected, the etiology is unknown.

REFERENCES
of opisthotonos and tetanic spasms when stimulated. At necropsy the consistent lesion is a severe, diffuse, axonal swelling and loss in the spinal cord and brainstem. The cause is unknown but the indicators point to heredity.

REFERENCE

INHERITED OVINE DEGENERATIVE AXONOPATHY (NEURAXONAL DISTROPHY)

A heterogeneous group of diseases of genetic or acquired etiology is characterized by spheroidal swellings of axons, the result of accumulation of axoplasmic organelles including neurofilaments.

This is reported in Suffolk, Merino, and Coopworth sheep. An inherited defect is suspected in all three diseases.

In Coopworths the lambs are affected at birth but have a progressive syndrome in which cerebellar and proprioceptive signs predominate. Most die by 6 weeks of age. Large axonal spheroids are present in the spinal cord and midbrain, and there is a severe depletion of Purkinje cells in the cerebellum.

In Suffolks the disease does not appear until 1–6 months; signs are a gradual onset of ataxia, followed by recumbency, leading to death or euthanasia. Spheroids in central nervous system axons are characteristic, mostly in the spinal cord and cerebellum.

The disease in Merinos is in fine-wool sheep, is probably the same disease as that previously called Murrurundi disease, and does not appear until 4–6 years of age. Most cases require to be euthanized after about 2 months but some mild cases survive for up to 3 years. The clinical signs include a wide-based stance, dysmetria of all limb movements with a pronounced hypermetria of the forelimbs resulting in frequent falling, a fine intention tremor of the head, and a diminished menace reflex. A similar disease of medium-wool Merinos, characterized by progressive posterior ataxia and degeneration of sensory tracts in thoracic segments of spinal cord, commencing after 5 months of age and terminating fatally before 2 years of age, is also recorded in Australia. The probability is that it is also an inherited defect.

 REVIEW LITERATURE

INHERITED SPONTANEOUS LOWER MOTOR NEURON DISEASE

This progressive disease of Yorkshire piglets 5–10 weeks of age is presumed to be inherited. Clinical signs include hindlimb tremor, weakness, and ataxia appearing at 2–5 weeks of age. The gait includes fetlock knuckling, short choppy steps, and a tendency to collapse after a few steps. Segmental and postural reflexes are normal. By 10 weeks there is complete hindlimb paralysis, the pig is in sternal recumbency and front limb paralysis has begun. The appetite is good and the pig is bright and alert. On necropsy there is symmetrical degeneration and loss of motor neurons in the spinal cord, in some ventral spinal nerve roots.

A lower motor neuron disease in newborn Romney lambs has been described. Lambs are normal at birth but within 1 week they developed weakness and ataxia, which progressed until they were unable to stand. The principal histological lesions were degeneration and loss of neurons in the ventral horns of the spinal cord and brain stem, Wallerian degeneration of ventral rootlets and motor nerves, and associated denervation atrophy of skeletal muscle fibers. Large fibrillar spheroids were found in white and gray matter including nuclei in the brain stem. A similar, though not identical, disease of newborn lambs has been recorded in a Dorset Down flock affecting about 20% of lambs. They lay with hindlimbs tucked under the body and forelimbs splayed sideways.

REVIEWS LITERATURE

REFERENCES

INHERITED CITRULLINEMIA

This autosomal recessive disease is inherited in Australian Holstein-Friesians, USA Holsteins, and Red Holsteins in Europe. A previous report of a high incidence of the disease in a German Holstein herd has been refuted by a negative result in the breed in a wide-ranging survey.

Affected calves are normal at birth but develop signs in the first week of life and die 6–12 hours after the onset of illness. The signs are depression, compulsive walking, blindness, head-pressing, tremor, hyperthermia, recumbency, opisthotons, and convulsions. Arginosuccinate synthetase deficiency is the likely cause. Blood citrulline levels are of the order of 40–1200 times normal and the assay can be used to detect heterozygotes. The alternative method of detecting heterozygotes is to use a polymerase chain reaction, a restriction endonuclease test designed to identify the mutation that causes the disease. Prenatal diagnosis has been achieved by examination of cell cultures derived from amniotic fluid.
EQUINE DEGENERATIVE MYELOENCEPHALOPATHY

Equine degenerative myeloencephalopathy is characterized by symmetrical, slowly progressive spasticity and ataxia in foals and horses less than 2 years of age. The disease occurs in most breeds in North America and Europe and is reported in captive zebra and Mongolian Wild Horses in North America. Neuronal dystrophy of the cuneate and gracilis nuclei is considered a form of equine degenerative myeloencephalopathy.

The prevalence of the disease varies widely, with up to 40% of susceptible animals on a farm being affected, although the disease is usually sporadic. There is a familial predisposition to the disease apparently involving an increased requirement for vitamin E, although other factors, including housing, are contributory.

The pathogenesis of the disease is unknown. Abnormal expression of integral synaptic vesicle, synaptic vesicle-associated presynaptic plasma membrane and cytosolic proteins was observed in two Arabian horses with equine degenerative myeloencephalopathy. These proteins have a role in trafficking, docking, and fusion of neuronal synaptic vesicles, and this finding suggests that there is disruption of axonal transport in equine degenerative myeloencephalopathy.

Loss of axons leads to defects in neurological function and consequent gait abnormalities.

The clinical signs are those of a slowing progressive spinal ataxia that stabilizes when the animal is 2–3 years of age. Affected foals and yearlings have symmetrical signs that are most severe in the hind limbs, of ataxia characterized by pivoting, circumsduction, truncal sway, and difficulty performing complex movements such as backing or walking with the head elevated. At rest, severely affected horses may have an abnormal posture. The cutaneous trunci reflex may be absent. Spontaneous recovery does not occur, but progression to death is unusual. Radiography and myelography of the cervical spine does not reveal evidence of compression of the spinal cord.

Serum vitamin E concentrations may be normal or low. The hemogram, serum biochemical profile, and cerebrospinal fluid analysis are normal. There are no gross lesions on necropsy. Histological lesions include neuronal atrophy, accumulation of lipofuscin-like pigment, and glial cell proliferation.

Differential diagnoses are listed in Table 36.1. Diagnosis is achieved by exclusion of other causes, of abnormal gait without fever or disease in other body systems in horses, such as compressive myelopathy and equine protozoal myeloencephalopathy.

No treatment is curative, but vitamin E (6000 IU orally once daily) may prevent progression of signs. Supplementation of at-risk foals and yearlings with vitamin E can prevent the disease.

INHERITED CONGENITAL HYDROCEPHALUS

Cattle

Congenital hydrocephalus without abnormality of the frontal bones occurs sporadically but is also known to be an inherited defect in Holstein and Hereford and possibly in Ayrshire and Charolais cattle. Two specific inherited entities have been described. In one there is obstruction to drainage of the cerebrospinal fluid from the lateral ventricles which become distended with fluid and may cause bulging of the forehead, often sufficient to cause fetal dystocia. Hereford calves with this defect have partial occlusion of the supraorbital foramen, a domed skull, and poorly developed teeth; at necropsy the cerebellum is found to be small and there may be microphthalmia and skeletal muscle myopathy. They are usually born a few days prematurely, are small in size and unable to stand or suck. In some cows the amniotic fluid is increased in volume.

Another form of inherited hydrocephalus due to malformation of the cranium and with no enlargement of the cranium has also been observed in Hereford cattle. The ventricular dilatation is not marked, and microphthalmia and cerebellar hypoplasia are not features. Affected calves may be alive at birth but are blind and unable to stand. Some bawl continuously and some are dumb. They do not usually survive for more than a few days. At necropsy there is internal hydrocephalus of the lateral ventricles with marked thinning of the overlying cerebrum. Other lesions include constriction of the optic nerve, detachment of the retina, cataract, coagulation of the vitreous humor, and a progressive muscular dystrophy. The condition is inherited as a recessive character.

Internal hydrocephalus inherited in combination with multiple eye defects in White Shorthorns is dealt with elsewhere, as are non-inherited forms of the disease.

Sheep

A defect comparable to the Dandy–Walker syndrome in humans and characterized by internal hydrocephalus caused by obstruction of the foramina of Magendie and Lushka occurs in several breeds of sheep, especially Suffolk, and in cattle. Affected lambs are stillborn or die within a few hours of birth; because of the grossly enlarged cranium many cause dystocia which can only be relieved by a fetotomy.

Pigs

Congenital hydrocephalus in Yorkshire and European pigs has been recorded. The abnormality varies from a small protrusion of dura (meningocele) to an extensive brain hernia in which the cerebral hemispheres protrude through the frontal suture, apparently forced there by increased fluid pressure in the lateral and third ventricles. The condition is thought to be inherited in a recessive manner, but exacerbated in its manifestation by a coexisting hypovitaminosis-A. An outbreak of congenital meningoencephalocele in Landrace pigs is recorded in circumstances suggesting that it was inherited.

Horses

A Standardbred stallion sired a number of hydrocephalic foals in a pattern that suggested the inheritance of a dominant mutation in the germ line and in the form of a single locus defect. Affected foals caused dystocia and were all stillborn.

REFERENCES

INHERITED PROSENCEPHALY

Recorded in Border Leicester sheep, this defect takes the form of fusion of the cerebral hemispheres and a single lateral ventricle. It is widespread in the breed in Australia and is inherited as an autosomal recessive character. Most affected lambs are stillborn. Live ones have dyspnea due to gross shortening of the naso-maxillary region creating a severely overshot mandible and interference with sucking. Blindness, nystagmus, and recumbency are constant signs. The cerebrum and the cranial cavity are much smaller than normal.

REFERENCES
INHERITED HYDRANENCEPHALY AND ARTHROGRYPOSIS

The defect is recorded in Corriedale sheep, and breeding trials indicate that it is inherited as an autosomal recessive character. Most affected lambs are found dead but facial deformity, including shortening of the mandible and distortion of the facial bones will be evident. At necropsy the predominant finding is the fixation and deformity of the joints of the limbs and vertebral column, and the almost complete absence of a cerebral cortex.

REFERENCE

INHERITED CONGENITAL CEREBELLAR DEFECTS

Several inherited cerebellar defects occur congenitally in calves, lambs, and foals. Lesions of the cerebellum may or may not be obvious. They all need to be differentiated from similar defects known to be caused by intraterrine viral infections such as swine fever, bovine mucosal disease, and bluetongue.

Cerebellar hypoplasia

This occurs in Herefords, Guernseys, Holsteins, Shorthorns, and Ayrshires and appears to be conditioned by a factor inherited in a recessive manner. Most calves are obviously affected at birth. While lying down there is no marked abnormality, although a moderate lateral tremor of the neck occurs, causing a gentle side-to-side swaying of the head. Severely affected calves are blind; they have widely dilated pupils and their pupils do not react to light. Such calves are unable to stand, even when assisted, because of flaccidity of limb muscles. When less severely affected animals attempt to rise the head is thrown back excessively, the limb movements are exaggerated in force and range, and are grossly incoordinated, and many calves are unable to rise without assistance. If they are placed on their feet the calves adopt a straddle-legged stance with the feet wide apart and the legs and neck extended excessively. On attempting to move, limb movements are incoordinated and the calf falls, sometimes backwards because of overextension of the forelimbs. Affected animals drink well but have great difficulty in getting to the teat or pail, attempts usually being wide of the mark. There are no defects of consciousness and no convulsions. Tremor may be evident while standing and there may be postrotational nystagmus after rapid lateral head movements. Sight and hearing are unimpaired and, although complete recovery does not occur, the calf may be able to compensate sufficiently to enable it to be reared to a vealing weight. Diagnosis can be confirmed by magnetic resonance imaging.1

At necropsy the most severe defect comprises complete absence of the cerebellum, hypoplasia of the olivary nuclei, the pons and optic nerves and partial or complete absence of the occipital cortex. Less severe defects include a reduction in size of the cerebellum and absence of some neuronal elements in a cerebellum of normal size.

Although the disease is dealt with generally as an inherited one there is no firm evidence to substantiate this view, and there are sporadic, non-inherited cases in other breeds.

Cerebellar atrophy of lambs (daft lamb disease 1)

This has been recorded in many sheep breeds in Britain, Corriedales in Canada and New Zealand, and in Driesdales.2 Affected lambs are normal at birth but are weak and unable to rise without assistance. At 3 days of age it is obvious that there is severe incoordination of limb movement, opisthotonus, tremor, and a straddle-legged stance. At necropsy the cerebellum may be of normal size but on histological examination there is gross atrophy of cerebellar neurons. The disease appears to be conditioned by a recessive gene but not as a simple homozygous recessive. A clinically similar disease has been observed in Border Leicester lambs. There is no histopathological lesion in the cerebellum, but there are significant lesions in the cervical muscles and the nerve supply to them. The disease is inherited, most likely as an autosomal recessive trait.

Star-gazing lambs (daft lamb disease 2)

An hereditary disease clinically similar to cerebral cortical atrophy has been described in newborn Leicester lambs in the UK but without histological evidence of Purkinje cell loss or reactive changes, considered the hallmark of 'cerebellar cortical atrophy'. Affected lambs exhibit 'dorsal arching of the neck with the head being pressed backwards', which has is also described as 'star-gazing'. Histological lesions are present in neck muscles and nerves but it is uncertain if these are primary or secondary.

Inherited ataxia of calves

This is a true cerebellar ataxia inherited as a recessive character in Jerseys, Shorthorns, and Holsteins. Clinically the condition resembles cerebellar hypoplasia except that signs may not occur until the calves are a few days to several weeks old. At necropsy the cerebellum is normal in size but histologically aplasia of neurons is evident in the cerebellum and also in the thalamus and cerebral cortex. An inherited condition, manifested by cerebellar ataxia which does not develop until calves are 6 weeks to 5 months old, has also been recorded but the cerebellum is small and macroscopically abnormal. Conspicuous degeneration of cerebellar Purkinje cells is evident on histological examination.

Cerebellar abiotrophy

This fourth disease in this group is described under the heading of abiotrophies. Familial convulsions and ataxia in cattle

A neurological disease is recorded as being inherited in Aberdeen Angus cattle and their crossbreds and Charolais. In young calves there are intermittent attacks of convulsions, and in older animals these are replaced by a residual ataxia. The first signs appear within a few hours of birth; up to several months later there are single or multiple tetanic convulsions lasting for 3–12 hours. As these episodes disappear a spastic goose-stepping gait becomes apparent in the forelimbs and there is difficulty placing the hindlimbs. The characteristic necropsy lesion is a very selective cerebellar cortical degeneration. A proportion of cases make a complete recovery. The epidemiology of the disease is consistent with the operation of an autosomal dominant gene with incomplete penetrance.

Inherited congenital spasms of cattle

This condition has been recorded only in Jersey cattle and appears to be conditioned by a factor inherited in a recessive manner. Affected calves show intermittent, vertical tremor of the head and neck, and there is a similar tremor of all four limbs which prevents walking and interferes with standing. Although the calves are normal in all other respects, they usually die within the first few weeks of life. No histological examinations have been reported but a cerebellar lesion seems probable.

INHERITED SPASTIC PARESIS (ELSO HEEL)

This disease occurs in the Holstein, Aberdeen Angus, Red Danish, Ayrshire, Beef Shorthorn, Pbl Hereford, Murray Grey, and many other breeds of cattle. It has been observed in crossbred Brahman
cattle and in an Ayrshire x Beef Shorthorn crossbred steer. The disease occurs principally in calves, with signs appearing from several weeks to 6 months or more after birth. Occasional cases are reported as developing in adult European cattle and there is one report of the occurrence of the disease in adult Indian cattle.

It has been held for a long time that the disease is inherited, and the principal argument has centered on the mode of inheritance. Attempts to determine this have shown that the rate of occurrence in planned test matings is so low that, if inheritance is involved, it can only be the inheritance of a susceptibility to the disease. It is suggested that different time appearances represent a single disease entity with varying expressivity, the late appearances representing a single disease form being affected by cumulative environmental factors. A hypothesis proposed is of a gene with increased penetrance in the homozygote, with weak penetrance in the heterozygote, acting on a polygenic basis dependent on external factors. Infectious agents causing transmissible sub-a cute spongiform encephalopathies interacting with trace elements such as lithium have been suggested as etiological agents but there is no evidence to support the hypothesis.

In all forms of the disease there is excessive tone of the gastrocnemius muscle and stiffness of the hock, usually more marked in one hindleg. If only one leg is affected it may be thrust out behind while the calf is walking and advanced with a restricted, swinging motion often without touching the ground. There is no resistance to passive flexion of the limb. The gastrocnemius and perforator muscles are rigid and in a state of spastic contraction. There is a characteristic elevation of the tail. The lameness becomes progressively worse and affected animals spend much time lying down. Much body weight is lost and the animal is usually destroyed between 1 and 2 years of age.

Minor lesions described as regressive changes in the neurons of the red nucleus, in the reticular substance and the lateral vestibular nucleus are of doubtful significance, as are the observed reduction in inorganic phosphate and ascorbic acid levels in the blood and cerebrospinal fluid of affected calves. A lower CSF concentration than normal of a central neurotransmitter, dopamine, could also be an effect rather than a cause.

There are demonstrable lesions on radiologic examination of the tarsus but exhaustive examinations of muscles and tendons fail to reveal histological abnormalities. The absence of any structural lesion and the variation in intensity of the abnormality suggests that it is a functional one. The hypersensitivity of the myotic reflex which has been observed could be such a defect.

In Europe affected animals are kept for breeding purposes, especially if they are double-muscled. They are kept for this reason because of the efficacy of the curative surgical operation of partial tibial neurectomy and in view of the high incidence of double muscling in such calves. In the Holstein breed, and several German breeds, bulls which are affected calves have been observed to have very straight hocks and to suffer from various forms of stiff and hock lameness early in life.

Several surgical techniques including tenectomy, partial tibial neurectomy, and triple tenectomy have been described. Partial tibial neurectomy under caudal epidural anaesthesia was done on 113 Belgian blue calves with spastic paresis. A telephone follow-up of the owners 3 months later revealed good results in 83%; a considerable improvement in 4.4%; and severe hyperflexion of the hock necessitated early culling for slaughter; and in 8% there was little or no improvement.

**REVIEW LITERATURE**

**INHERITED PERIODIC SPASTICITY OF CATTLE**

This disease has been observed in Holstein and Guernsey cattle and usually does not appear until the animals are adults. A recent report described it in a Canadian Hereford bull with an early onset between 1 and 2 years of age. It is a particular problem in mature bulls maintained in artificial insemination centers. In the early stages the signs are apparent only on rising, the hindlimbs being stretched out behind and the back depressed. Marked tremor of the hindquarters may be noted. Initially the attacks persist only for a few seconds but are of longer duration as the disease progresses and may eventually last for up to 30 minutes. Movement is usually impossible during the attacks. The tetanic episodes fluctuate in their severity from time to time but there is never any abnormality of consciousness. Lesions of the vertebrae have been recorded but no lesions have been found in the nervous system. Idiopathic muscle cramps have been suggested as a cause. The disease is familial and the mode of inheritance appears to be by inheritance of a single recessive factor with incomplete penetrance.

Administration of the spinal cord depressant, mephenesin (3–4 g/100 kg body weight given orally in 3 divided doses and repeated for 2–3 days) controls the more severe signs. A single course of treatment may be effective for some weeks.

**INHERITED NEONATAL MYOCLONUS (HEREDITARY NEURAXIAL EDEMA)**

This congenital defect of the nervous system has been reported only in Pol Hereford cattle or their crossbreds and appears to be transmitted by inheritance in an autosomal recessive pattern. A similar disease has been tentatively recorded in Peruvian Paso horses. At birth affected calves are unable to sit up or rise and are very sensitive to external stimuli, manifested by extreme extensor spasm, including fixation of thoracic muscles and apnea, especially if lifted and held upright. The response is one of hyperesthesia with myoclonic jerks of skeletal muscles in response to external stimuli or spontaneously. The intellect of the calves seems unaffected. Vision is normal, they drink well, and can be reared but at a great cost in time. Intercurrent disease is common and calves usually die of pneumonia or enteritis before they are 1 month old.

All affected calves have subluxations of the hip joints or epiphyseal fractures of the femoral head caused by muscle spasms in the fetus. Their gestation length is shorter than that of normal calves by 9 days.

There are no microscopic lesions in the central nervous system, but there is a biochemical defect, severe alterations in spinal cord glycine-mediated neurotransmission. The specific and marked defect in glycine receptors and the increase in neuronal...
uptake of glycine are accompanied by a change in the major inhibitory system in the cerebral cortex. It has also been shown that there is a specific and marked deficit of [3H] strychnine-binding sites in the spinal cord. The disease needs to be differentiated from two other congenital, presumed hereditary, diseases of newborn Herefords — maple syrup urine disease and ‘congenital brain edema’ — in which spongy degeneration of the CNS is accompanied by severe edema of the gray and white matter. These two diseases are assumed to represent those cases of congenital disease, originally bracketed with inherited congenital myoclonus, in which there was vacuolation of nervous tissue in the central nervous system.

REFERENCES

INHERITED CONGENITAL POSTERIOR PARALYSIS

Two inherited forms of congenital posterior paralysis are recorded in cattle. In Norwegian Red Poll cattle posterior paralysis is apparent in affected calves at birth. Opisthotonos and muscle tremor are also present. No histological lesions have been found. The disease is conditioned by an inherited recessive factor. In Red Danish and Bulgarian Red cattle a similar condition occurs but there is spastic extension of the limbs, particularly the hindlimbs, and tendon reflexes are exaggerated. Histological examination has revealed degenerative changes in midbrain motor nuclei. Both defects are lethal because of prolonged recumbency. An inherited posterior paralysis has been recorded in several breeds of swine in Europe. Affected pigs are able to move their hindlimbs but are unable to stand on them. They are normal in other respects. Degeneration of neurons is evident in cerebral cortex, midbrain, cerebellum, medulla, and spinal cord. The disease is conditioned by the inheritance of a recessive character. An inherited progressive ataxia is also recorded in Yorkshire pigs.

INHERITED CONGENITAL MYOTONIA

This disease has been observed in goats and possibly in a horse. Because of its great similarity to Thomsen’s disease (myotonia congenital) of humans, affected goats have been used in experimental studies to determine the nature of the disease. There is no apparent defect of the nervous system and the condition is thought to be due to abnormality of the muscle fibers. The specific defect is thought to be one of generalized cell membrane abnormality including muscle fibers. Affected animals run when startled but quickly develop extreme rigidity of all four limbs and are unable to move. Relaxation occurs in a few seconds and the animal can then move again. Signs are not usually present until sometime after birth and may vary from day to day for no apparent reason. They tend to diminish immediately before and after parturition. Clinical signs disappear when water is withheld from affected goats for 2–3 days but reappear when drinking is permitted. The disease is inherited but the mode of inheritance is unknown.

INHERITED HYPOMELINOGENESIS

CONGENITAL TREMOR OF PIGS

Congenital tremor of pigs has a multiple etiology and some of the causes are not yet identified. For this reason the disease as a whole is dealt with in Chapter 36. The inherited diseases are noted here. There are two of them, congenital tremor type A-IV of British Saddleback pigs, and congenital tremor type A-III, a sex-linked inherited form of cerebrospinal hypomelino genesis of Landrace pigs. The A-IV disease is characterized by the presence of poorly myelinated axons in all parts of the central nervous system. The specific defect in A-IV is one of fatty acid metabolism. The structural abnormalities in the A-III disease have been identified; splayleg is a common accompaniment.

Both diseases are characterized by muscle tremor, incoordination, difficulty in standing, and some squealing. The A-III disease occurs only in males. Both are inherited as recessive characters.

EXOPHTHALMOS WITH STRABISMUS

This disease has been recorded in Shorthorn, in which it is not manifested until the first pregnancy or lactation, in Jerseys, in which it may appear at 6–12 months of age, and in German Brown Swiss. Defective vision is the first sign and is followed by severe protrusion and anteromedial deviation of both eyelids. The defects may get worse over a long period and appear to be inherited in a recessive manner, with relative absence of neurons in the abducens nerve.

REFERENCE

FAMILIAL UNDULATORY NYSTAGMUS

This is an inherited defect of Finnish Ayrshire cattle characterized by a tremor-like, synchronous movement of the eye-balls. The tremor has small amplitude (1–2 mm) and fast (200/min) rate and is usually vertical. It is present at all times, there is no sign of impaired vision, and the eye reflexes are normal. The condition is a blemish rather than a disease because there is no functional deficiency.

INHERITED IDIOPATHIC EPILEPSY OF CATTLE

Idiopathic epilepsy has been reported as an inherited condition in Brown Swiss cattle and appears to be inherited as a dominant character. Typical epileptiform convulsions occur, especially when the animals become excited or are exercised. Attacks do not usually commence until the calves are several months old and disappear entirely between the ages of 1 and 2 years.

FAMILIAL NARCOLEPSY

Affected horses, including Shetlands, Miniature Horses, and Suffolks, suffer recurrent episodes of several minutes duration during which they fall and lie motionless, without voluntary or involuntary movements except respiratory and eye movements. Between episodes there is no clinical abnormality. Handling or the excitement of feeding may precipitate an attack, and a sharp blow may terminate one.

REFERENCES

DODDLE CALVES

This is an inherited congenital defect in Hereford cattle produced by intensive breeding of half-siblings. It is no longer recorded. It was characterized by continuous clonic convulsions, nystagmus, and pupillary dilatation. Stimulation by touch or sound exacerbated the convulsions.

INHERITED DEFECTS OF THE MUSCULOSKELETAL SYSTEM

INHERITED DISASES OF BONES

INHERITED OSTEOARTHRITIS

There are strong indications from field evidence that both degenerative arthropathy, in which the hip joint is principally involved, and degenerative osteoarthritis, affecting particularly the stifle joint, are inherited in cattle. In both diseases other factors, particularly nutritional deficiency and the stress of lactation, exert an
important influence on the appearance of the clinical disease, and in degenerative arthropathy, described in the chapter on nutritional deficiency diseases, there is no clear evidence that it is in fact inherited. On the other hand there is good evidence that osteoarthrosis can be inherited, at least in Holstein-Friesian and in Jersey cattle.

In inherited degenerative osteoarthitis, in which the stifle joints are most severely affected, there is usually a gradual onset of lameness in both hindlimbs in aged animals of both sexes. Occasionally only one limb appears to be involved. Progression of the disease takes place over a period of 1–2 years and is evidenced by failure to flex the limb, resulting in the foot not being lifted high from the ground. Crepitation in the stifle joint can be heard and felt, the muscles of the limb atrophy, and the joints are enlarged. Movement is slow, the hindlimbs at rest are placed further forward than normal, the stifles are abducted and the feet held together. Joint fluid can be aspirated and is clear and straw-colored. Appetite and milk yield remain normal until the late stages, except in cattle running at pasture.

At necropsy there is severe osteoarthitis involving particularly the stifle, with extensive erosion of the articular cartilages, great increase in synovial fluid, and the development of many osteophytes around the edges of the articular surfaces. Less severe changes are evident in other joints. It is suggested that the disease is conditioned by the inheritance of a single autosomal recessive character.

**INHERITED OSTEOMYELIOGENESIS IMPERFECTA**

The term osteogenesis imperfecta covers a heterogeneous group of connective tissue diseases caused by quantitative or qualitative defects in Type 1 collagen. The disease is recorded as being inherited in Holstein-Friesian cattle and New Zealand Romney sheep.

**Cattle**

It is transmitted as an autosomal dominant trait. Calves are clinically abnormal at birth with the main presenting signs being bright pink teeth and slackness of the flexor tendons on all four feet so that they are unable to stand. The calves become progressively worse to the point where they cannot walk. The full list of abnormalities in this syndrome includes smaller than normal body size at birth, a dome-shaped cranial vault, and fragility of bones, manifested by multiple fractures occurring during birth. The defect is one of connective tissue cells so that there is a faulty production of collagen and intercellular cement. Radiological examination demonstrates growth-arrest lines and multiple fractures in the long bones, and thin dentine and enamel layers on the teeth which are pink because of the exposed condition of the enlarged pulp. The excessive mobility of the joints results from the small bulk of the ligaments and tendons.

A syndrome of simple bone fragility occurs in Charolais cattle and is called osteogenesis imperfecta.

**Sheep**

The disease in New Zealand Romney sheep is similar to that in Holstein-Friesian cattle with additional lesions of thickness of the diaphyses and reduction in size of the medullary cavity, moderate brachynathia inferior, subcutaneous edema, skin fragility, and a dark blue color of the sclera. It is inherited as an autosomal dominant trait, and was thought to have developed as a new mutation in the testicular cell line of the parent ram.3

**REVIEW LITERATURE**

**INHERITED DWARFISM**

Most inherited food animal dwarfs are chondrodysplastic; they occur commonly in cattle and are of two kinds, snorter dwarfs and Dexter bulldog calves.

**Snorter dwarves**

Snorter dwarves are no longer important because of successful efforts in eliminating carriers of the gene. These calves are short-legged with short, wide heads and protruding lower jaws. The mandibular teeth may protrude 2–4 cm beyond the dental pad, preventing effective grazing and necessitating hand-feeding if the animal is to survive. There is protrusion of the forehead and distortion of the maxilla, and obstruction of the respiratory passages results in stertorous respiration and dyspnea. The tip of the tongue usually protrudes from the mouth and the eyes bulge. There is some variation between affected animals in their appearance at birth. In most cases the defects are as described above but they become more exaggerated as the calf grows. In addition abdominal enlargement and persistent bloat develop. The head is disproportionately large. The calves fail to grow normally and are about half the weight of normal calves of the same age.

The predominant form of the condition appears to be inherited as a simple recessive character, although the relationship of the 'comprest' types to the total syndrome is more complex. Heterozygotes vary widely in conformation but some of them show minor defects which may be attractive to cattle breeders who were seeking a chunkier, short-legged type of animal. For this reason, indiscriminate selection towards the heterozygote undoubtedly occurred, resulting in widespread dissemination of the character. Herefords and Aberdeen Angus are the breeds most commonly affected but similar dwarves occur also in Holstein and Shorthorn cattle, and typical dwarf animals have been produced by mating heterozygous Aberdeen Angus and Herefords. Besides the shortness of limbs there is also a looseness of attachment of limbs and abnormal mobility of joints.

Bovine chondrodysplastic dwarfism in Japanese brown cattle is an autosomal recessive defect with the phenotype of short limbs, joint abnormality, and ateliosis.1 Long bones of affected animals have insufficient endochondrial ossification with irregularly arranged chondrocyte, abnormal formation of cartilaginous matrix, and partial disappearance of the epiphyseal growth plates. The gene LBN is the causative gene for bovine chondrodysplastic dwarfism. The bovine fibroblast growth factor receptor 3 (FGFR3) gene is not the locus responsible for the defect.2

Inherited congenital achondroplasia with hydrocephalus

First recorded as bulldog calves in Dexter cattle, this inherited defect has since been observed in a variety of forms in other breeds, including Jerseys, Guernseys, Holsteins, and Japanese Brown cattle.3 Chondrodysplasia in the Holstein-Friesian breed sharing morphological features with the Dexter bulldog calves have been reported from the United States, the Netherlands, Great Britain, and recently in Denmark.4 Dexter bulldog type calves have occurred in French and Danish Holstein calves in a familial pattern related to the sire Igale Masc, and it is likely that the genetic disorder is present in the Holstein breed worldwide.4

Characteristic features of lethal chondrodysplasia (Dexter bulldog) calves in Australian Dexter cattle include abortion, disproportionate dwarfism, a short vertebral column, marked micromelia, a relatively large head with retracted muzzle, cleft palate and protruding tongue and a large abdominal hernia.5 Histological changes in limb bones are consistent with failure of endochondral ossification. Dexter chondrodysplasia is considered to be inherited in an incompletely dominant manner with the homozygous form producing the congenital lethal condition. Based on analysis of the contribution of
three obligate heterozygotes whose semen has been widely used in artificial insemination in Australia, it is estimated that the heterozygote frequency is 19% within the registered Australian Dexter herd.3

Affected calves are often aborted but some reach full term and cause fetal dystocia because of the extreme hydrocephalus. The forehead bulges over a foreshortened face with a depressed, short nose. The tongue protrudes, the palate is cleft or absent, the neck is short and thick, and the limbs are shortened. Accompanying defects are fetal anasarca and hydrops amnii in the dam.

The defect is primarily chondrodystrophy rather than achondroplasia; the nasal bones and maxillae do not grow. Hydrocephalus develops because of the deformed cranium. In most breeds the condition is inherited as a simple recessive character but a dominant form has occurred in Jerseys. The heterozygous form in Dexters is easily recognized by the shortness of the limbs. The heterozygote in other breeds is normal in appearance.

Miscellaneous dwarfs

Other types of dwarfs have been described and include 'comprest' and 'compact' cattle in Herefords and Shorthorns and various other forms of proportional dwarfs. For example, in Charolais, miniature calves that are exact replicas of normal calves but weigh only 5–16 kg at birth and are born 2 or more weeks prematurely, have been recorded. Most are dead at birth or die soon after so that the condition is effectively lethal. Proportional dwarfs occur also in Simmentals.

Other forms of chondrodystrophy, including 'bulldog calves' and one which causes fatal nasal obstruction in the German Black Spotted breed of cattle, have also been recorded. In the latter there are multiple deformities of limb bones and the condition appears to be inherited due to the influence of a single recessive gene.

Dwarf lambs occur sporadically. The best known is the mutant Ancon which has appeared and disappeared three times, with one incidence in New Zealand and one in the United Kingdom. The defect is chondrodysplasia and the lambs are not viable.

REFERENCES

CONGENITAL OSTEOPTEROSIS

This inherited defect is recorded in Aberdeen Angus calves which are stillborn and undersized. The major manifestations are shortening of the mandible with protrusion of the tongue, impaction of the lower molars, a patent fontanelle, and the characteristic lesion of shortness of the long bones and absence of a narrow cavity in them. The absence of the narrow cavity, caused by defective remodeling of the bone, gives it a homogeneous shaft leading to the colloquial name of 'marble bone'. Radiographic examination makes antemortem diagnosis simple. It is considered to be an autosomal recessive trait. It is reported also in foals but there is doubt about its genetic origin in that species.

INHERITED PROBATOCEPHALY (SHEEPHEAD)

This defect is inherited in Limousin cattle. The cranial bones are deformed so that the head resembles that of a sheep. The accompanying defects in heart, buccal cavity, tongue, and abomasum increase the chances of an early death.

INHERITED ATLANTO-OCCIPITAL DEFORMITY

(See Congenital defects of the nervous system).

INHERITED AGNATHIA

Partial or complete absence of the mandibles with ventral displacement of the ears is common in sheep and is categorized as a lethal recession because the sheep are unable to graze properly.

INHERITED DISPLACED MOLAR TEETH

Inherited as a simple recessive character this defect usually results in the death of affected calves within the first week of life. The six premolars of the lower jaw are impacted or erupted in abnormal positions, often at grotesque angles. The mandible is shorter and narrower than normal. There is no abnormality of the incisors or upper jaw.

INHERITED JAW MALAPPOSITION

Defective apposition of upper and lower incisors, or lower incisors and dental pad in ruminants may result in inefficient grazing and malnutrition. Abnormal protrusion of the mandible (mandibular prognathism) is of most importance in ruminants and there is good evidence that abnormal length of the mandible is inherited. Amongst British breeds of cattle the defect is more common in beef than in dairy breeds. In Herefords and Angus the inheritance is thought to be conditioned by a single recessive gene.

Brachygnathia, underdevelopment of the mandible, has also been recorded in Dairy Shorthorn, Jersey, Holstein, Ayrshire, and Simmental cattle, with the defect so severe in some cases that the animals are unable to suck. In Angus brachygnathia can occur linked to a generalized degenerative joint disease, in which all joint surfaces are involved. Affected animals, detected at a few days to 4 months of age, are not viable.1 Inheritance of the defect is probably conditioned by a recessive gene.

A less severe degree of brachygnathia has been recorded in Merino and Rambouillet sheep. The mode of inheritance is suggested to be by the interaction of several pairs of genes.

Mandibular prognathism occurs as a part of other more general defects including achondroplastic dwarfism and inherited displaced molar teeth.

Brachygnathia is also seen in horses.2

The defect is present at birth but is often not apparent until much later.

REFERENCES

INHERITED CRANIOSCHISIS (CRANIUM BIFIDUM)

The disease occurs in a number of pig breeds, but has been shown to be inherited only in Poland China pigs and their crosses. There is a deficit in the cranial bones and meningoceles or encephaloceles may result. The pigs are not viable. Genetic experiments have shown the inheritance to be of a recessive character with varying penetrance.

Many single cases of cranial and spinal deformity in farm animals have been likened to the human Arnold–Chiari malformation but a specific syndrome of protrusion of the medulla oblongata and the cerebellum through the foramen magnum into the spinal canal has not been identified in a hereditary context in these species.

INHERITED CRANIOFACIAL DEFORMITY

The defect is incompatible with life. One form in Border Leicester lambs is characterized by a variable degree of nasomaxillary hypoplasia, often associated with incomplete cerebral development with less pronounced sulci and gyri than normal. It appears to be inherited in a simple autosomal recessive mode. A similar lethal defect is recorded in Angus cattle (as brachygnathia superior) in association with generalized degenerative joint disease.1
Cyclops anomaly occurs sporadically without known cause, but attracts attention when it is part of an inherited, prolonged gestation syndrome when it is often the cause of the investigation being mounted.

REFERENCE

INHERITED ARACHNOMELIA (INHERITED CHONDRODYSPLASIA)

Cattle
This suspected inherited disease of Simmental, Brown Swiss, Italian Brown calves, and other European breeds of cattle is manifested by excessively long, thin, distal extremities which give the calves a spidery look, hence arachnomelia. The bones are very fragile, there is curvature of the spine, foreshortening of the mandible, and associated cardiac and vascular defects. In Swiss Braunvieh cattle it is combined with arthrogryposis.2 It is thought to be inherited as a simple recessive.

Sheep
Spider lamb syndrome
A hereditary chondrodysplasia is recorded in Suffolk and Hampshire lambs in which the limbs are thin, disproportionately long, and have abnormal positions of the joints. About 10% of the newborn lambs die with respiratory distress, and about 25% of affected lambs develop severe degenerative joint disease. Histologically, the osteochondrocytes were disorganized, surrounded by concentric rings of abnormal fibrocartilage. There is less muscle than normal. In severe cases the deformities are obvious at birth and may be lethal. In less severe cases the deformities do not become apparent until the lambs are several weeks old. The defects are readily visible in X-rays before clinical signs develop, and affected lambs can be detected in this way. The diagnostic lesion is multiple irregular islands of ossification in the upper limb joints. Spinal deformities, especially kyphoscoliosis, and cranial deformities including a roman nose, deviation of the nose poll axis, and shortening of the mandible are observed in some lambs. Inheritance by an autosomal recessive gene with complete penetrance and variable expressivity has been demonstrated in the SLC35A3 gene.1

COMPLEX VERTEBRAL MALFORMATION IN HOLSTEIN CALVES

A lethal congenital defect of the axial skeleton of purebred Holstein calves has been reported in Denmark,1 the United States,2 and in the UK which are not carriers of the CVM gene.34 It is caused by a mutation in the gene SLC35A3 coding for an uridine-diphosphate-N-acetylglucosamine transporter. A single-base transversion of guanine to thymine has been located in the abnormal allele at position 559.1 It is present in both copies of the allele and the mutation is lethal. It is a simple recessive genetic defect which requires that both the sire and the dam of an affected calf are carriers.

Most affected calves are born between day 250 and 285 of gestation. Approximately 80% of homozygous affected fetuses are aborted before gestation day 260.2 Birth weights are reduced. Most affected calves are stillborn, but affected calves occasionally are born alive. Euthanasia must be performed for humanitarian reasons.

In premature, stillborn, and neonatal affected calves, the defect is characterized by congenital growth retardation, malformed vertebrae, and tetrameric arthrogryposis.345 There is shortening of the cervical and thoracic parts of the vertebral column due to multiple hemivertebrae, fused and misshaped vertebrae, and scoliosis. Growth retardation and vertebral malformation are typical lesions. Malformation of the head, primarily in the form of dysplasia or palatoschisis, also occurs.

Symmetrical flexures of the carpal and joints and the metacarpophalangeal joint in combination with a slight lateral rotation of the phalanges are also present. Similar low-grade arthrogryposis are present in the pelvic limbs. Heart defects were present in 50% of affected calves (intraventricular septal defects, dextro-position of the aorta, and eccentric hypertrophy of the right ventricle).1

Retrospective genotyping of affected calves according to the mutation in the SLC35A3 gene, and there were homozygous affected, heterozygotes, and homozygous normal.1 The morphological expression of the malformation is wide but certain aspects such as growth retardation, vertebral malformation, and symmetrical arthrogryposis are almost constant findings. A presumptive diagnosis of the malformation can be made in most cases based on necropsy findings combined with pedigree analysis and genotyping.3

Breeding studies were carried out in Denmark using selected cows that were progeny of sires with a heterozygous genotype for the malformation, and were pregnant after insemination with semen from another sire with heterozygous malformation genotype. The number of calves born with the malformation was less than expected suggesting increased intrauterine mortality.7 Fertility traits in Holsteins are severely affected by the malformation phenotype of the fetus.5 If the fetus is homozygous for the malformation, 29% of the cows will abort before gestation day 100 increasing to 45% at day 150, and 77% at day 260. Non-return to service rates, frequency of calvings after the first insemination, and interval from insemination to next calving were significantly reduced by a fetal malformation phenotype.

Pedigree analysis and DNA analyses of semen from sires used for insemination have found a widely branched familial occurrence of the malformation in the Holstein breed.5 The mutation in the SLC35A3 gene has been traced to the US sire Penstate Ivanhoe Star born in 1963 and his widely used son Carlin-M. Ivanhoe Bell born in 1974. The malformation mutation is not restricted to
INHERITED ACROTERIASIS (AMPUTATES)

Patients affected by this deformity, e.g. 'mole' calves of the Danish Black and White breed, are characterized by shortened and malformed limbs, especially the extremities which are sometimes missing altogether. In male calves there is also hydrocephalus, hypoplasia of the mandible, and absence of part of the face. The body is emaciated. Many are aborted during the latter part of pregnancy. The deformity is conditioned by a single recessive gene.

INHERITED PHALANGES (AMPUTATES, ACROTERIASIS, ECTROMELIA)

This defect has been recorded in cattle and appears to be inherited as a single recessive character. The limbs are normal down to the metacarpal and metatarsal bones, which are shorter than usual, but the first two phalanges are missing and the normal hooves and third phalanges are connected to the rest of the limb by soft tissues only. The calves are unable to stand but can crawl about on their knees and hocks.

Hereditary hemimelia. Bilateral absence of the distal half of the limb, e.g. the patella, and shortening or absence of the tibia, often accompanied by hydrocephalus, meningoceles, ventral abdominal hernia, and cryptorchidism, comprise the syndrome known as tibial hemimelia. It is inherited in the Galloway breed of cattle. An autosomal recessive mode of inheritance is assumed. A concerted program of eradicating the defect has been undertaken, based on test matings and examination for defects of 90-days fetuses obtained by terminating pregnancy with prostaglandin.

Hereditary peromelia of mohair goats. This syndrome includes agenesis of the phalanges and parts of the metacarpus and metatarsus affecting one or more limbs, and an autosomal recessive mode of inheritance.2

Amputates. An even more serious defect, in which the mandible and all the bones below the humerus and stifle are vestigial or absent, has been reported in British, French, and German Friesians. It appears to be conditioned by the inheritance of a single recessive gene. Similar 'amputates' have been shown not to be inherited.

REFERENCES

INHERITED MULTIPLE EXOSTOSIS

Multiple exostosis affecting both cortical and medullary bone of the limbs and ribs has been described in Quarter horses and Thoroughbreds in the UK. The lesions are visible externally but cause little apparent inconvenience. It is inherited as a simple dominant autosomal gene. Restriction nuclease analysis is used to diagnose the disease.1

REFERENCE

INHERITED CONGENITAL HYPEROSTOSIS (THICK FORELIMBS OF PIGS)

This defect is thought to be caused by the inheritance of a simple recessive character. Affected piglets show obvious lesions at birth and, although many of them die or are destroyed immediately, a proportion of them may survive. The forelimbs are markedly enlarged below the elbows and the skin is tense and may be discolored. There is difficulty in standing and moving about, and starvation and crushing contribute to the mortality rate. There is extensive edema of the subcutaneous tissues, thickening of the bones, and roughness of the periosteum. It is thought that the primary lesion is a separation of the periosteum from the bone.

INHERITED TAILLESSNESS AND TAIL DEFORMITY

Complete absence of the tail or deformity of the appendage occur relatively commonly as a congenital defect. The condition is thought to be inherited in Holstein cattle and in Landrace and Large White pigs. It is often seen in combination with other deformities of the hindquarters such as atresia ani and urogenital tract abnormalities.
INHERITED DISEASES OF JOINTS

INHERITED ARTHROGRYPOSIS (INHERITED MULTIPLE TENDON CONTRACTURE)

Inherited fixation of limb joints present at birth is recorded in many breeds of cattle especially in the Shorthorn, Charolais, Piedmont, and Swedish Dole. It is thought to be inherited as a single recessive character. There are many environmental causes of the disease, the most common of which is Akabane virus infection of early pregnancy and discussed under that heading.

Simple arthrogryposis

The limbs of affected calves are fixed in flexion or extension and cause dystocia due to abnormal positioning and lack of flexibility. There is no involvement of joint surfaces and the joints can be freed by cutting the surrounding tendons or muscles. There is atrophy of limb muscles and those calves which are born alive are unable to stand and usually die or are destroyed within a few days.

Arthrogryposis with dental dysplasia

This defect in cattle appears to be inherited in a dominant manner. The teeth are soft, fleasy, and easy to bend. There is no defect of bones or joints other than marked softness and the presence of excess cartilage at the epiphyses. There is abnormal ossification of the cartilage. The calves are of normal size, do not cause dystocia, and, although they are unable to stand because of the excessive flexibility of the limbs, they can suck. Hypostatic pneumonia usually develops and causes death of the calf.

Arthrogryposis with palatoschisis (SAP)

This is inherited as a simple recessive with low penetrance in pure French Charolais in France and high penetrance in 7/8 Charolais cattle in Canada, where the gene frequency is high in purebred and crossbred Charolais. Among crossbred Charolais cattle the homozygous condition is almost always markedly expressed and lethal, but a high percentage of purebred homozygous cattle show slight to no visible effect of the gene and survive. Because of the low rate of prevalence in France, attempted eradication does not appear to be economical.

In this syndrome all limbs are usually affected but the front limbs more than the hindlimbs, and the more distal joints are more rigidly fixed than proximal ones. The muscles of affected limbs are atrophic and pale in color. Histological changes in the spinal cord suggest that the muscle atrophy is neurogenic. In affected calves the gestation period may be longer than normal by an average of 2 weeks.

Arthrogryposis with multiple effects

In Simmentals a combined set of defects includes arthrogryposis, often with the limbs in a wrapped-around position around the body, underdevelopment of the mandible, curvature of the spine, and defects of the heart and main vessels.

Arthrogryposis in other species than cattle

Inherited arthrogryposis has also been recorded in Merino and Corriedale sheep, and in Norwegian Landrace pigs in which it is thought to be inherited as a simple recessive. The Corriedale defect is associated with other lesions including brachynathia inferior, hydranencephaly, and thoracic scoliosis. Inherited arthrogryposis in pedigree Suffolk lambs has been described.1 Breeding studies using superovulation and embryo transfer were used to increase the numbers of offspring from females which were carrying the gene or genes responsible for the defect which was inherited as an autosomal recessive trait.

An inherited arthrogryposis also occurs in Norwegian Fjord horses. The arthrogryposis affects the hindlimbs and there are accompanying defects of polydactyly, palatoschisis, and brachynathia in some. Most foals are unable to stand and the defect must be considered to be a lethal one.

INHERITED MULTIPLE ANKYLOSIS

Multiple ankylosis affecting all limb joints has been recorded as an inherited congenital defect of Holstein calves. The abdomen of the dam shows marked enlargement at the 6th to 7th month of pregnancy and this may occasion some respiratory distress. Excessive fetal fluids are present and insertion of the hand per rectum is impeded by the distended uterus. Abortion during the last month of pregnancy is a common occurrence. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion and there is some curvature of the spine. Fetal dystocia always occurs and embryotomy or cesarean section is necessary to deliver the calf.

Ankylosis of limb joints combined with cleft palate occurs occasionally in Charolais cattle and is suspected of being inherited. Ankylosis of the coffin joint, developing at several weeks of age, has been reported in Simmental calves. The etiology of the condition is not clear.

INHERITED PATELLAR SUBLUXATION

Unilateral or bilateral subluxation occurs as an inherited defect in Bos indicus cattle and in water buffalo (Bubalus bubalis). Shetland ponies also have a predisposition and a monogenic autosomal recessive transmission is suspected.2 There is periodic lameness with the affected limb held in rigid extension; the patella is displaced medially. If the animal shakes the limb the patella may go back into its normal position and the problem is relieved.

REFERENCES

INHERITED HYPERMOBILITY (LAXITY) OF JOINTS

This inherited disease is recorded only in Jersey cattle. It has assumed great importance because of the great popularity of a sire which carried the gene. There is abnormal flexure and extension of all joints but especially the hock, stifte, hip, knee, elbow, and shoulder joints. The muscles are much atrophied and the joints look very enlarged as a result. It is impossible for the calves to stand but they are bright, alert, and eat well. The limbs are so flexible that they can be bent into extraordinary positions, and almost tied in knots. A drawer sign, a displacement of the articular surfaces laterally, and produced by manual pressure, can be elicited easily and with a displacement of up to 2 cm. There are no detectable lesions in the nervous or musculoskeletal systems. Although the disease is known to be inherited as a simple autosomal recessive, it has also been seen in circumstances which preclude inheritance being the cause.

INHERITED HIP DYSPLASIA

An inherited defective development of the acetabulum occurs in Dole horses. There is no clinical evidence of the disease at birth but osteoarthritis of the joint and disruption of the round ligament develop subsequently. For this disease in cattle see ‘Degenerative joint disease’.

INHERITED DISEASES OF MUSCLES

GENERALIZED GLYCOGENOSIS (GLYCOGEN STORAGE DISEASE TYPE II)

Generalized glycosogenosis is a glycogen storage disease of Corriedale sheep, Shorthorn, and Brahman beef cattle which resembles Pompe's disease in humans.3 Glycogenosis type II in Shorthorn and Brahman cattle is a lysosomal storage disease in which acidic
α-glucosidase is the defective enzyme. In Shorthorn cattle, glycogenosis type II is caused by a single mutation, but the initial DNA/PCR restriction enzyme test of ampiclons, was occasionally compromised by inhibition of the restriction enzyme by undefined factors. This was overcome by introduction of wild and mutant allele-specific amplifications and the use of two restriction enzymes, which clarified the anomalies and provided a more accurate testing system.2

In Brahman cattle, glycogenosis type II is associated with loss-of-function alleles affecting the α-glucosidase gene that differ from that in Shorthorns. There is a common mutation affecting many Australian Brahman and a less common one affecting descendants of one imported bull. In addition, a third mutation was associated with significantly reduced α-glucosidase activity, but not sufficient to cause clinical disease in the homozygous state.2

Clinical signs include poor growth, muscle weakness, incoordination of gait, and difficulty in rising. The animals become permanently recumbent. The disease is identified as a lysosomal storage disease material in affected tissues. Amongst the lesions are evident and include extensive muscle. This myopathy is associated with exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continuous exercise there are further periods of collapse and recumbency which may become prolonged. Not all homozygous animals are clinically affected if they are allowed to ′pace their exercise′ and some animals have been known to breed despite muscle weakness. A polymerase chain reaction-restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand.3

Genotyping methods using hair root and blood samples to test Shorthorn cattle for generalized glycogenosis are available, and PCR assays have been developed to genotype Brahman cattle for loss-of-function alleles within the acidic α-glucosidase gene.3

GLYCOGEN STORAGE DISEASE TYPE V (MUSCLE GLYCOGEN PHOSPHORYLASE DEFICIENCY)

Glycogen storage disease Type V is one of a number of inherited diseases affecting glycogen metabolism and resulting in abnormal accumulation of glycogen in cells. Glycogen storage disease Type V has been recorded in Charolais cattle in North America.1 As in Type II glycogenosis, Type V is inherited as an autosomal recessive trait α-glucosidase. There is a deficiency of myophosphorylase, mildly elevated muscle glycogen and elevated serum creatine and aspartate aminotransferase. Severely affected animals may develop rhabdomyolysis which may be accompanied by myoglobinuria.2

In Charolais cattle, glycogen storage disease Type V is usually seen in calves at several weeks or months of age and is associated with exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continuous exercise there are further periods of collapse and recumbency which may become prolonged. Not all homozygous animals are clinically affected if they are allowed to ′pace their exercise′ and some animals have been known to breed despite muscle weakness.

A polymerase chain reaction-restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand that were otherwise normal.3 Using a similar test, a Blonde d’Aquitaine cross-bred calf with a double-muscled phenotype and suspected of having myophosphorylase deficiency based on clinical findings of brown-colored transparent urine after exercise, pain, and an elevated creatine kinase was considered negative.3

FAMILIAL POLYSACCHARIDE STORAGE MYOPATHY (EQUINE RHABDOMYOLYSIS SYNDROME)

This myopathy is associated with exertional rhabdomyolysis and occurs with a high incidence in some Quarter Horse, American Paint, Appaloosa, and Quarter Horse cross-bred families. An autosomal recessive pattern of inheritance is proposed.4 Recurrent episodes occur at intervals of about 2 weeks. Clinical signs include exercise intolerance with prolonged recumbency in some. Discomfort varies between stiffness and pain suggestive of colic. Myoglobinuria is common during episodes of clinical illness. Serum activity of creatine kinase are elevated. Biopsy of gluteal or semitendinosus muscles reveals polysaccharide inclusion bodies in some muscle fibers and widespread sarcolemmal vacuoles. The defect is basically an error of glycolysis.

REFERENCES

CONGENITAL MYASTHENIA GRAVIS

Congenital myasthenic syndrome has been reported in Brahman cattle in South America.1 Affected calves develop progressive muscular weakness, beginning at birth and up to 3-4 weeks of age. Within 1 week they are unable to stand without assistance. Some calves are able to stand and walk for 30 to 45 minutes before collapsing, but are still able to suck their dams. The calves remain alert and continue sucking but may collapse after 20 to 60 seconds. The weakness becomes progressively worse and affected calves are usually euthanized. Hematology and serum biochemistry are normal, and muscle biopsies do not reveal any abnormalities.

The underlying defect is a homozygous 20-base pair (bp) deletion in the gene, muscular acetylcholine receptor (bovCHRNE), coding for the β-subunit of the nAChR at the neuromuscular junction.2 A PCR-based DNA test, using blood or semen has been developed and validated.3 The test makes it possible to differentiate rapidly and accurately between homozygous wild-type, heterozygous and homozygous affected animals. Preliminary testing of Brahman cattle in South Africa revealed several carrier animals, some of them influential in the breeding population.

INHERITED DIAPHRAGMATIC MUSCLE DYSTROPHY

This is an inherited defect in diaphragmatic muscle of Meuse-Rhine-Yssel and Holstein-Friesian cattle1 appearing in adults and characterized by anorexia, decreased rumination, and eructation. The disease is basically an error of glycolysis. In Charolais cattle, glycogen storage disease Type V has been recorded in North America.1 As in Type II glycogenosis, Type V is inherited as an autosomal recessive trait α-glucosidase. There is a deficiency of myophosphorylase, mildly elevated muscle glycogen and elevated serum creatine and aspartate aminotransferase. Severely affected animals may develop rhabdomyolysis which may be accompanied by myoglobinuria.2

BOVINE FAMILIAL DEGENERATIVE NEUROMUSCULAR DISEASE

This disease has been reported occurring in Gelbvieh cattle in several separate beef herds in the United States. Affected animals are 4 to 20 months of age, and the mortality rate is 100%. Clinical findings include ataxia, weakness, and terminal recumbency. Gross and histological muscle lesions were indicative of nutritional muscular dystrophy with no myocardial lesions. Acute to chronic lesions in most large skeletal muscle groups consist of degeneration, necrosis, regeneration, fibrosis, and atrophy. Fibrinoid necrosis of arterioles is a common feature in multiple tissues. Lesions in the spinal cord white matter and peripheral nerves consisted of degeneration of the dorsal columns and axons, respectively. Chronic interstitial nephritis with fibrosis, hyaline droplet change, and tubular epithelial vacuolar change were most severe in older calves. Vitamin E levels were deficient in most affected calves. Pedigree analysis found a common ancestry for all but one of the affected calves. It is hypothesized that a hereditary metabolic defect, possibly involving anti-oxidant metabolism may be the causative factor.

REFERENCE

INHERITED UMBILICAL AND SCROTAL HERNIAS, CRYPTORCHIDISM, AND HERMAPHRODITISM

Umbilical hernias in cattle and scrotal hernias and cryptorchidism in pigs have also been considered to be inherited defects for many years but the evidence is uncertain.

Umbilical hernias

Umbilical hernias are commonly identified in dairy heifers. In 18 commercial dairy herds in New York, 15% of heifer calves had umbilical hernias during the first 3 months of age.1 The economic costs of umbilical hernias include the cost of medical and surgical treatment and the loss in value for breeding animals.

It has been generally accepted that umbilical hernias may be inherited in a dominant or recessive mode. Some studies have found the risk of hernias was higher in some breeds: the incidence being much higher in Holstein cattle than other breeds such as Angus, Ayrshire, Brown Swiss, Charolais, Guernsey, Hereford, Jersey, and Shorthorn. However, factors other than genetic may be important. For example, many veterinarians have observed that umbilical infections commonly lead to umbilical hernia by slowing closure of the umbilicus. It is unlikely that the responsible genes are sex-linked, in spite of the apparent greater incidence in females. Umbilical hernias in Holstein-Friesian cattle can also be conditioned by a dominant character with incomplete penetrance, or be due to environmental factors. In a case control study to determine risk factors associated with identification of an umbilical hernia during the first 2 months after birth in Holstein heifers, the sire and umbilical infection were associated with risk of a hernia.2 Heifers born to sires with = 3 progeny with an umbilical hernia were 2.31 times as likely to develop a hernia as were heifers born to sires with = 2 progeny with an umbilical hernia. Heifers with umbilical infection were 5.65 times as likely to develop a hernia as were heifers without umbilical infection. Attributable proportion analysis found that the frequency of umbilical hernias in Holstein heifers with umbilical infection would have been reduced by 82% if umbilical infection had been prevented.3

The risk factors for congenital umbilical hernias in German Fleckvieh calves offered for sale at livestock markets were examined.4,5 An umbilical hernia was defined as a palpable opening in the abdominal wall of the umbilical region >1.5 cm, even if no hernia had developed. Inflammation, abscesses or fistulae were excluded. Data from 53,105 calves were collected from 77 livestock markets over a 2-year period. The overall incidence of congenital hernia was 1.8%. The analyses found significant effects for sex of calf, birth type, age of calf at examination, market place and date, sire line, sire, and frequency of affected herdmate calves in male calves, the incidence was 2.2%, in females 1.5%. The calves varied from 3 to 8 weeks of age. The diameter of hernial openings was between 1.5 and 9 cm with 47% of affected calves with a hernia measuring greater than 3 cm. A significantly higher incidence occurred in twin or triplet calves. Shorter gestation periods increased the risk of hernias linearly by a factor of 1.3% for 10 days. There were differences in the incidence of hernias according to sire lines but the heritability estimates were low varying from h² = 0.04 (>100 progeny) or h² = 0.05 (>25 or 50 progeny). However, analysis of the data found no evidence for an autosomal monogenic recessive inheritance. The analyses indicated that the incidence of congenital umbilical hernia observed could not be explained by one autosomal recessive gene locus, but it seemed much more likely that more than one gene locus is involved or a mixed multifactorial monogenic mode of inheritance may be the underlying genetic mechanism. It is suggested that the incidence of congenital umbilical hernias could be reduced if all breeding bulls are examined as calves and a veterinary certificate confirms a closed umbilical ring.

Breeders should be aware of the implications of congenital hernias and thus, congenital hernia should get more attention in the selection process of young sires.

Breeding studies and genotyping using the Canadian Holstein bull ‘Glenhapton Enhancer’, have provided evidence that Enhancer is the carrier of major dominant or codominant gene with partial penetrance for umbilical hernia.6 Five sons of Enhancer produced progeny with >10% frequency of umbilical hernia, whereas the progeny of 3 sons had <3% umbilical hernia. Genotyping of grand-progeny found significant differences in paternal allele frequencies between the affected and unaffected progeny groups for a marker BMS1591 on bovine chromosome BTA8. The umbilical hernia-associated paternal allele originated from Enhancer.

Scrotal hernias

Scrotal hernias of pigs have also been shown to be inherited in some breeds, e.g. Duroc and Landrace, but not in others, e.g. Yorkshires.6

Cryptorchidism

Evidence suggesting the inheritance of cryptorchidism in swine, sheep, horses, and Hereford cattle and hermaphroditism in swine is also available. Cryptorchidism in horses appears to be inherited with a polygenic pattern of transmission.

REFERENCES

MYOFIBER HYPERPLASIA (DOUBLE MUSCLING, DOPPELENDER, CULARD)

EPIDEMIOLOGY

This is an inherited condition, characterized by an increased bulk of skeletal muscles due to the presence of a greater than normal number of muscle fibers; it is well known in many breeds of cattle but appears to be most common in the Charolais, Belgian Blue, Piedmont, and South Devon breeds. The condition is recorded only rarely in sheep. The mode of inheritance has not been established but heterozygotes usually show some degree of muscle hypertrophy. Many of
the muscle changes are in the direction of the current demand for lean, meaty carcases, and there is interest, especially in Europe, in the exploitation of this anomaly for meat production. Pietrain pigs (see below) exhibit many of the characteristics of double-muscled cattle, including large muscle mass and susceptibility to stress.

**CLINICAL FINDINGS**

Severely affected cattle show a marked increase in muscle mass most readily observed in the hindquarters, loin, and shoulder, an increase in the muscle:bone ratio and a decrease in body fat. Affected calves demonstrate above-average weight gains during the first year of life if well fed and managed, although mature size is somewhat reduced. Well-marked grooves along the intramuscular septa in the hindquarters are a distinguishing feature as is an apparent forward positioning of the tail head. Macroglossia, proptosis, and a tendency toward muscular dystrophy and rickets have been observed in affected calves. Electrocardiographic abnormalities have been reported. The condition often interferes greatly with their economic value.

**NECROPSY FINDINGS**

The skin is thinner than normal, and the muscle mass is characterized by a disproportionate number of glycolytic, anaerobic fibers.

**REFERENCES**

**PIETRAIN CREEPER PIGS**

A progressive muscular weakness is found in stress-susceptible Pietrain pigs. The syndrome commences with muscle tremor at 2–4 weeks of age, leading to complete recumbency by 12 weeks of age. At this stage the pigs move with a creeping gait with the limbs flexed. There are no neuropathological lesions but there are myopathic changes, especially in the forelimbs.

**INHERITED PROGRESSIVE MUSCULAR DYSTROPHY**

This is a primary skeletal muscle disease of sheep with a strong probability of having a genetic mode of transmission. It is recorded in Merino flocks in Australia and is characterized by a gradually progressive failure to flex the joints of the hindlimbs commencing at 3–4 weeks of age. Eventually the limbs are rigid at all times, and running becomes impossible. The forelimbs and the head and neck are normal. Affected sheep are easily detected when they are 1 year old and will have mobility problems by the time they are 2–3 years old. At necropsy there are pale areas in skeletal muscle and sometimes the muscles of the diaphragm in those sheep which have a tendency to float. The histopathology and histochemistry of the muscle lesions is comparable with that of inherited muscle atrophies in humans.1,2

**REFERENCES**

**INHERITED SPINAL MUSCULAR ATROPHY**

A progressive ataxia, weakness, muscle atrophy, and recumbency develops in young calves, mostly during the first 2 weeks of life. Sensory functions are unimpaired. Some are already affected at birth and some may be stillborn.3 No new cases occur after 3 months of age. Conditioned by an autosomal recessive gene the defect occurs in Red Danish cattle which originated from Brown Swiss, and from German Braunvieh and American Brown Swiss. The primary lesion is degeneration of ventral horn cells of the spinal cord, without involvement of the brainstem or cerebellum. The visible lesion is the secondary atrophy of the denervated muscles.1,2

**REFERENCES**

**INHERITED SPLAYED DIGITS**

Recorded only in Jersey cattle, this defect appears to be conditioned by an inherited gene; probably a monogenic autosomal recessive. Lameness becomes apparent at 2–4 months of age, the toes becoming increasingly widely spread and the toes themselves misshapen. Walking and standing are painful, especially on the front feet so that some animals graze and walk on their knees. Affected animals either lie down increasingly or stay standing for very long periods. The apparent abnormality is a defect of the muscles and ligaments holding the phalanges together.

**EQUINE HYPERKALEMIC PERIODIC PARALYSIS**

**Synopsis**

**Etiology** Defect in sodium channel of skeletal muscle.

**Epidemiology** Disease of Quarter Horses and crossbreds. Inherited as an autosomal dominant trait with variable penetrance.

**Clinical signs** Episodes of muscle fasciculation, stridor, muscle weakness, and flaccid paralysis.

**Clinical pathology** Hyperkalemia during episodes. Gene probe to detect mutated gene.

**Lesions** None.

**Treatment** Paliative. Potassium-free intravenous fluids. Acetazolamide.

**Control** Selective breeding. Low potassium diet.

**ETIOLOGY**

The disease is caused by a heritable defect in the sodium channel of skeletal muscle.1 The mutation, of which only one form has been identified, results in substitution of a cytosine for guanine, with consequent replacement of phenylalanine by leucine in a transmembrane protein regulating sodium flux across the cell membrane and T-tubule. The disease is transmitted as an autosomal codominant with the result that homozygotes are more severely affected than heterozygotes, and phenotypic expression (disease severity) differs among heterozygotes.

**EPIDEMIOLOGY**

The disease is familial and affects Quarter Horse and crossbred descendants of a single Quarter Horse sire, Impressive.2 More than 50 000 registered Quarter Horses are related to known carriers of the disease.3 Quarter Horses with the disease are presumably selected because they outperform unaffected animals in the halter classes in which they compete at horse shows,5 although recent rule changes have changed this practice. The disease is occurs in breeds derived from or crossed with Quarter horses including Appaloosas, American Paint horses, and crossbreds.

The disease is inherited in an autosomal codominant manner.1 Therefore, 50% of the offspring of the breeding of a heterozygote and a normal animal will carry the trait, as will 75% of the offspring of the breeding of two heterozygotes. Of the breeding of 2 heterozygotes, 50% of progeny will be heterozygotes, 25% homozygotes for the mutated gene, and 25% homozygotes for the normal gene.
Animals homozygous for the abnormal gene are uncommon, representing only 0.9% of animals tested for the disease. The low prevalence of the homozygote genotype is likely a reflection of severity of disease and the reduced likelihood that homozygotic animals will reach sexual maturity. The risk of a heterozygous animal being affected with periodic paralysis is variable. Most heterozygous horses appear normal and never experience an attack, while others have severe episodes starting at a young age. Homozygous horses are much more likely to have severe manifestations of the disease at a young age.

PATHOGENESIS
The abnormality in the sodium channel coded for by the mutated gene predisposes the horse to episodes of complete depolarization of the muscle membrane and flaccid paralysis. The mutation in the sodium channel increases the probability that any one channel is open, with the result that the resting membrane potential in affected horses is higher (less negative and closer to the depolarization threshold) than that of normal horses. This results in frequent depolarizations of individual muscle fibers causing muscle fasciculations. The weakness associated with severe episodes of the disease results from failure of sodium channels to close after depolarization. Opening of potassium channels when the muscle is depolarized results in movement of potassium out of the muscle cell, and the development of hyperkalemia.

CLINICAL SIGNS
The disease in heterozygous animals is characterized by periods of muscle fasciculation and tremor that progress to weakness, paralysis, and recumbency. Such episodes may last minutes to hours, and most resolve spontaneously. Horses often sweat, have prolapase of the third eyelid, and contraction of facial and locomotor muscles during episodes. Episodes may be mistaken for colic. Inspiratory stertor commonly noted during episodes is probably due to laryngeal and pharyngeal dysfunction.

Episodes are more frequent and severe in homozygous animals and signs of laryngeal and pharyngeal dysfunction, such as stridor and dysphagia, occur in almost all of these animals. Endoscopic examination of homoygotes reveals pharyngeal collapse, laryngopalatal dislocation, and laryngeal paralysis. The disease can manifest in foals as young as 7 days of age. The severity of signs in some homozygotes diminishes with age.

Electromyographic demonstration of myotonic discharges, prolonged insertion activity, and doublets and triplets is a sensitive and specific indicator of the disease.

Horses with HYPP have reduced exercise tolerance compared to normal horses. Homozygotic horses have laryngospasm, airway obstruction, hypoxia, hypercapnia, and ventricular depolarizations during intense exercise, which is not recommended for these horses.

CLINICAL PATHOLOGY
Hyperkalemia (>5.5 mEq/L, 5.5 mmol/L) during or immediately after episodes is characteristic of the disease, although the existence of a normokalemic variant has been suggested.

Diagnostic confirmation has in the past been achieved by provocative testing by administering potassium chloride (88-166 mg/kg, orally) to suspect horses. However, the development of genotyping has rendered provocative testing obsolete and, for humane reasons and because of the risk of death, its use is not recommended. The test of choice for demonstrating the presence of the mutated gene is a specific gene probe.

The probe can be applied to various tissues, but blood or hair, with attached root (a plucked hair), are preferred for diagnostic testing of live animals. This test classifies horses as normal, heterozygous, or homozygous but does not indicate the propensity of heterozygotes to exhibit the disease. Samples can be analyzed in the United States at the Veterinary Genetics Laboratory, University of California (www.vgl.ucdavis.edu).

DIFFERENTIAL DIAGNOSIS
- Colic
- Laminitis
- Hypokalemia
- Botulism
- Exertional rhabdomyolysis
- Upper airway obstruction

NECROPSY FINDINGS
There are no characteristic findings on necropsy examination.

TREATMENT
Acute episodes
Most acute episodes resolve spontaneously or with only minor treatment. The aim in treating more severe or prolonged episodes is to reduce the plasma potassium concentration by intravenous infusion of isotonic, potassium free fluids such as sodium chloride, sodium bicarbonate, or dextrose. Some authors recommend infusion of calcium gluconate but others caution against its use. A practical approach is the slow intravenous administration of 0.25 to 0.5 mL of 23% calcium gluconate per kg of body weight (125-250 mL for a 500 kg horse) diluted in isotonic sodium chloride or, preferably, 5% dextrose.

Administration of NaHCO₃ at 1 mL/kg intravenously has been suggested.

Prevention of episodes
Maintaining affected horses on a low potassium diet reduces the frequency with which episodes occur. Alfalfa (lucerne), some oils including soyabean, molasses, lite salt (a mixture of KCl and NaCl), and many sweet feeds are potassium rich and should be avoided. Grass hay (timothy) and straw and oats, corn, and barley are low in potassium. There are commercial feeds that have a guaranteed low concentration of potassium. Alternatively, diets can be formulated using feed of known potassium concentration, as determined by feed analysis. Care should be taken that diets are nutritious and contain appropriate concentrations and ratios of calcium and phosphorus.

Acetazolamide (2-4 g/kg, every 12 hours) reduces the severity and frequency of episodes and is widely used to control the disease. The drug is poorly absorbed in horses but the concentration required in plasma of horses to achieve a pharmacodynamic effect is lower than that of humans.

CONTROL
The disease is heritable and carriers are readily identified so a breeding program to eliminate the disease is feasible.

RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHBRED HORSES (AZOTURIA, TYING UP, CHRONIC INTERMITTENT RHABDOMYOLYSIS)

Recurrent exertional rhabdomyolysis of Thoroughbred horses is a common dis-
ease characterized by repeated episodes of muscle disease. A similar disease occurs in Standardbred horses but its etiology and epidemiology are not well documented.

**ETIOLOGY**

Recurrent exertional rhabdomyolysis in Thoroughbred race horses is inherited as an autosomal dominant trait with variable expression influenced by temperament, diet, and sex. Horses with recurrent exertional rhabdomyolysis have abnormal muscle contraction and a defect in myoplasmic calcium regulation. These abnormalities are evident after caffeine or halothane challenge of muscle fibers from affected horses examined in vitro. Myotubules from affected horses have higher concentrations of calcium after caffeine stimulation and muscle fibers from affected horses are more likely to contract when exposed to low concentrations of caffeine. The defect does not resemble that found in the ryanodine receptor in animals with malignant hyperthermia, and there is no defect in calcium-ATPase activity or its affinity for calcium in the sarcoplasmic reticulum of Thoroughbred horses with recurrent exertional rhabdomyolysis.

A genetic basis to a similar disease in Standardbreds is suspected, based on analysis of pedigree information of trotters in Sweden.

**EPIDEMIOLOGY**

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis is difficult because studies to date have mostly not differentiated between the recurrent exertional rhabdomyolysis of Thoroughbreds, polysaccharide storage myopathy of Quarterhorses and related breeds, and the sporadic disease in other breeds.

The incidence of 1-year-period prevalence of exertional rhabdomyolysis in Thoroughbreds is 4.9–6.7% in Thoroughbred racehorses in the United States, Australia, and Great Britain, and 6.1% in National Hunt Thoroughbreds in Great Britain. The disease occurs repeatedly in 74% of affected Thoroughbred racehorses in Great Britain.

**Risk factors** for exertional rhabdomyolysis in Thoroughbred horses, not all of which have the familial disease, include exercise, diet, use, and sex. Horses used for racing are more likely to have episodes of the disease than are horses used for pleasure riding or 'other' uses, although racing and breed (Thoroughbred or Standardbred) are confounding factors. Female race horses are three times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) race horses, and young, female Thoroughbreds are at greatest risk. Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males. Female polo ponies are not more likely to develop the disease. Thoroughbred racehorses and polo ponies, but not National Hunt horses, with a nervous or 'flighty' temperament are more likely to experience episodes of the disease. Other apparent risk factors include a rest day before hard exercise, feeding >4.5 kg of grain per day, lameness, and training gallops of shorter distance. Susceptible horses consuming a high calorie diet (>30 kcal/day) with a large proportion of the calories provided by readily digestible carbohydrate, such as starch, are at increased risk of the disease.

The disease is of considerable economic impact because of its frequent occurrence in athletic horses, recurrent nature, and need to rest affected horses. On average, affected Thoroughbred race horses cannot train for 6 days after an episode, and approximately two-thirds of affected horses are unable to race because of the disease. The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wasatch of Thoroughbred race horses in Australia is attributable to exertional rhabdomyolysis, though it is not known if all of these horses are affected by recurrent exertional rhabdomyolysis.

**PATHOGENESIS**

The underlying cause is described above under ‘Etiology’. The disease is due to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase and carbonic anhydrase, and myoglobin. Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function. Necrosis of myocytes caused pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis. The release of cellular constituents results in electrolyte abnormalities, primarily hyperchloremic metabolic alkalosis, systemic inflammatory response, and pigmenturia. Severely affected horses can have a metabolic acidosis. Myoglobin and, possibly, other cell constituents are nephrotoxic and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function are associated with stilted, short stepping gait.

**CLINICAL FINDINGS**

The cardinal feature of the disease is the occurrence of multiple episodes of rhabdomyolysis following exercise of Thoroughbred horses. Clinical findings are variable and range from poor performance to recumbency and death. Signs are usually mild and resolve spontaneously within 1–6 days.

The usual presentation is a young (2–5-year-old) female racehorse with recurrent episodes of stiff gait after exercise. The horse does not perform to expectation and displays a short stepping gait that may be mistaken for lower leg lameness. The horse may be reluctant to move when placed in its stall, be apprehensive and anorexic, and frequently shift their weight. More severely affected horses may be unable to continue to exercise, have hard and painful muscles (usually gluteal muscles), sweat excessively, be apprehensive, refuse to walk, and be tachycardic and tachypneic. Affected horses may be hyperthermic. Signs consistent with abdominal pain are present in many severely affected horses. Deep red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses may be recumbent.

**CLINICAL PATHOLOGY**

Mildly or apparently affected horses have moderate increases in serum creatine kinase (CK) (20 000–50 000 iu/L), aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) activity. Severely affected horses have large increases in CK (>100 000 iu/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5–6 and 24 hours after exercise, respectively, and in the absence of further muscle damage serum AST might not return to normal levels for 7–10 days. The half-life of CK activity in serum is approximately 12 hours and in the absence of continuing muscle damage serum CK declines rapidly. The persistence of increased AST activity, compared to CK, is useful in identifying affected horses days or weeks after the episode.

Serum myoglobin concentrations increase markedly during exercise in affected horses, and decline within 24–48 hours. Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis. Severely affected horses are often hypertonic (<130 mEq/L), hyperkalemic (>5.5 mEq/L), hyperchloremic (>90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations) and acidotic or alkalotic. Hemoconcentration (hematocrit >50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration.
are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used. Measurement of urinary excretion or fractional excretion of electrolytes is not useful in detecting horses susceptible to recurrent exertional rhabdomyolysis.

Myoglobinuria is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria. Measurement of urinary excretion or fractional excretion of electrolytes is not useful in detecting horses susceptible to recurrent exertional rhabdomyolysis.

Muscle biopsy during the acute or convalescent stages reveals myonecrosis of Type II (fast twitch, oxidative) fibers, mild myositis, and fibrosis.

NECROPSY FINDINGS
Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle; principally, the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen, but may have a pale, streaked appearance. The kidneys are swollen and have dark brown medullary streaks. Dark brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly Type II (fast twitch, oxidative) fibers. In horses with recurrent disease there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for postmortem diagnostic confirmation
Formalin-fixed kidney and affected muscle for light microscopic examination.

DIAGNOSTIC CONFIRMATION
Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

TREATMENT
The treatment chosen depends on the severity of the disease. The general principles are rest, correction of dehydration and electrolyte abnormalities, prevention of complications including nephrosis and laminitis, and provision of analgesia.

Mildly affected horses (heart rate <60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (22 mg/kg, orally or IV every 12 hours for 2-4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate >60 bpm, rectal temperature >39°C (102°F), 8-10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to their stable, unless it is unavoidable. Isotonic, polyionic fluids, such as lactated Ringer’s solution, should be administered IV to severely affected horses to correct any dehydration and to insure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4-6 L every 2-3 hours). Affected horses should not be given diuretics.

Analgesia can be achieved by administration of phenylbutazone (22.4-44 mg/kg, IV or orally, every 12-24 hours), flunixin meglumine (1 mg/kg IV every 8 hours) or ketoprofen (2.2 mg/kg IV every 12 hours).

Mild sedation (acepromazine or acetylpromazine 0.02-0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01-0.02 mg/kg) may decrease muscle pain and anxiety. Tranquilizers with vaso­dilatory activity, such as acetylpromazine, should only be given to horses that are well hydrated. Muscle relaxants, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2-4 hours. Severely affected horses should not be forced to stand.

CONTROL
Prevention centers on insuring that horses are fed a balanced ration with adequate levels of vitamin E, selenium and electrolytes, and have a regular and consistent program of exercise.

Thoroughbred race horses in training consume diets providing over 30 Mcal/day. The high energy intake is associated with increased risk of exertional rhabdomyolysis, especially if the diet provides a large (40%) of calories as readily digested carbohydrate (starch). Diets in which fat provides 20% of digestible energy calories and 7% as starch are associated with lower serum creatine kinase activities after exercise on a treadmill. These findings have been extrapolated to provide the recommendation that race horses in training receive no more than 20% of daily digestible energy from hydrolysable carbohydrate (starch) and at least 20% of DE from fat.

Sodium bicarbonate and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented and is suspect.

Phenytoin has proven useful in the treatment of recurrent rhabdomyolysis. It is administered at a dose rate of 6-8 mg/kg, orally, every 12 hours, and the dose adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months.

Dantrolene (800 mg, approximately 2 mg/kg, orally 60 minutes before exercise) was demonstrated in a controlled, cross-over field trial of 77 horses, to be effective in reducing exercise-induced increases in CK and incidence of episodes of recurrent exertional rhabdomyolysis in Thoroughbred race horses. Similar results were obtained in 4 horses with recurrent exertional rhabdomyolysis administered 4 mg/kg orally 90 minutes before exercise on a treadmill.

Dimethylglycine, dantrolene, altenogest and progesterone are all used on occasion in horses with recurrent rhabdomyolysis, but again without documented efficacy.

**PORCINE STRESS SYNDROME (PSS; MALIGNANT HYPERTHERMIA)**

**Synopsis**

**Etiology** Inherited defect caused by an autosomal recessive gene at a single locus with incomplete penetrance. Also known as the halothane sensitivity gene, or PSS mutation, which is a single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.

**Signs**
- Porcine stress syndrome: death during transportation
- Malignant hyperthermia: induced by halothane anesthesia resulting in muscular rigidity and death
- Pale, soft, exudative pork: rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale watery pork. Dark, firm, and dry pork is variation
- Back muscle necrosis: reluctance to move, acute swelling and pain over back and some may die; subacute form too.

**Lesions** Pale skeletal muscles in PSS deaths. Pale muscles in back muscle necrosis.

**Diagnostic confirmation** Necropsy findings. Identification of homozygous animals with tests.

**Etiology**

Three closely related stress syndromes occur in pigs. The **porcine stress syndrome (PSS)** is characterized by acute death induced by stressors such as transport, high ambient temperature, exercise and fighting, which results in progressive dyspnea, hyperthermia, disseminated vasoconstriction and the rapid onset of rigor mortis. **Pale, soft and exudative pork (PSE)** occurs post mortem in some pigs slaughtered by conventional methods. **Malignant hyperthermia (MH)** is a drug-induced stress syndrome characterized by muscle rigidity and hyperthermia occurring in susceptible pigs following the use of halothane or the muscle-relaxant suxamethonium. **Back muscle necrosis** of pigs is a special manifestation of the PSS.

Malignant hyperthermia also occurs in humans. PSS is caused by an inherited defect due to an autosomal recessive gene at a single locus with incomplete penetrance. It is also known as the halothane sensitivity gene, or PSS mutation, which is a single point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.

**Epidemiology**

**Signs**

- Porcine stress syndrome: death during transportation
- Malignant hyperthermia: induced by halothane anesthesia resulting in muscular rigidity and death
- Pale, soft, exudative pork: rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale watery pork. Dark, firm, and dry pork is variation
- Back muscle necrosis: reluctance to move, acute swelling and pain over back and some may die; subacute form too.

**Lesions** Pale skeletal muscles in PSS deaths. Pale muscles in back muscle necrosis.

**Diagnostic confirmation** Necropsy findings. Identification of homozygous animals with tests.

**Differential diagnosis list**

- Mulberry heart disease
- Acute septicemias due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Intestinal volvulus
- Heat exhaustion
- Suffocation during transportation.

**Treatment** None. **Control** Genetic selection. Reduction of environmental and management stressors.

**EPIDEMIOLOGY**

**Prevalence and occurrence**

This subject needs to be kept in perspective. It has recently been suggested that only 4% of inferior quality meat is due to genetics (halothane positive) with the remainder being due to pre-slaughter and post-slaughter treatment.

PSS occurs worldwide, but there is considerable breed and area variation in its prevalence. In some European countries the prevalence is a major problem in pig production because of the inadvertent selection for this trait in genetic improvement programs. This underlies the problems of selection based purely on performance and production characteristics.

The prevalence of PSS in the swine population can be determined by the use of screening tests applied on the farm or when pigs enter swine performance test stations. The halothane test and the creatine kinase (CK) test are useful for this purpose. A DNA-based test with 99% accuracy is also available. Surveys in the UK found that the prevalence in the British Landrace varies from 0 to 23% of herds with an average of 11%. In European breeds, the prevalence varies from 0 to 88% with up to 100% in the Pietrain breed. None is present in the Large White breed although one isolated report describes malignant hyperthermia in a single Large White pig. The prevalence of halothane susceptibility is low in the Danish Landrace breed in Denmark. Based on the halothane test, 1.5% of young boars entering a Record of Performance Test Station in Canada were positive reactors. The reactors originated from 7.5% of 107 herds. The halothane succinylcholine test was a more sensitive test because 18% of the same pigs were identified as reactors.

Using a DNA-based test, in a survey of 10,245 breeding swine of various breeds from 129 farms in the US, Canada, and England, approximately 1 of 5 pigs was a heterozygous carrier of the PSS mutation, and 1% were homozygous. The prevalence of the PSS mutation was 97% for 58 Pietrain, 35% for 1962 Landrace, 15% for 718 Duroc, 19% for 720 Large White, 14% for 496 Hampshire, 19% for 1727 Yorkshire, and 16% for 3446 crossbred swine. The PSS gene frequencies for these breeds were 0.72, 0.19, 0.08, 0.10, 0.07, 0.10, and 0.09, respectively. The PSS mutation has also been identified in Poland China and Berkshire breeds. These gene frequencies were 30–75% lower in Canadian swine than in US swine, with the exception of Yorkshire, for which the literature on the causative mutation for the porcine stress syndrome has been reviewed.
gene frequency is threefold in Canadian swine.6

Risk factors
Animal risk factors
Susceptibility to the PSS is inherited and the biochemical events leading to PSE, transport death, or malignant hyperthermia are triggered by several external influences or stressors in the living animal. PSS probably occurs in all breeds of pigs, but the incidence is highest in pigs selected for heavy muscling, and stress-susceptible pigs are leaner and more meaty. These include the Pietrain and Poland China breeds and also some European strains of Landrace where a score for muscling as well as growth rate, feed conversion, and back fat has been included in the selection index. A recent study has shown that there are considerable breed differences in that halothane stress susceptible pigs and Hampshires suffer more severely from heat stress than Yorkshire, Duroc, and Landrace, and Duroc boars.8

There is a correlation between halothane susceptibility and carcass traits. Halothane status is the most important factor influencing pork quality, although pre-slaughter handling and stunning method also influence the carcass quality.9,10 Halothane-positive animals usually score higher for visual conformation of the loin and ham than pigs which are halothane-negative. The progeny of reactor boars are also more susceptible than the progeny of non-reactors. Until recently it was thought that the major limitation of the halothane test was that it identified only those pigs which are stress-susceptible to the syndrome. It is now known that the halothane-sensitivity gene is expressed in heterozygous pigs where it is likely to cause poor carcass quality.

The gene for the porcine calcium channel has been sequenced and the site of the causative mutation located.2 The mutation was found in 5 major breeds of swine: Landrace, Yorkshire, Duroc, Pietrain, and Poland China. The prevalence of the gene in certain breeds in North America and England is given above.

Landrace pigs can be divided into those which are sensitive to halothane and develop pale, soft, exudative pork post mortem, those which are resistant to halothane but develop pale, soft, exudative pork, and those resistant to halothane and pale, soft, exudative pork (the normal pig). Muscle from pigs susceptible to malignant hyperthermia and pale, soft, exudative pork (the normal pig) develops in a muscle, pH drops to values lower than 5.8 at 45 minutes after death. In normal muscles, the pH decreases from approximately 7 in living muscles to pH 5.3 to 5.8 at 24 hours after death. The lower pH in PSE muscles, combined with a high carcass temperature within the first hour after death, causes the proteins in the muscles to denature. This contributes to the pale color of PSE meat and to its reduced water-holding capacity. Development of muscles with PSE characteristics seems to be initiated by a combination of lower muscle pH already at exsanguination and a faster pH decrease.13

Malignant hyperthermia is the drug-induced, often fatal, stress syndrome occurring in susceptible pigs within 3 minutes following the inhalation of a
mixture of halothane and oxygen.\textsuperscript{14} Susceptible pigs develop limb rigidity and a hyperthermia which are not easily reversed and may result in death. There is an increased rate of intracellular ATP hydrolysis leading to a progressive failure of ATP-dependent Ca\textsuperscript{2+} accumulation by sarcoplasmic reticulum and/or the mitochondria with a rise in myoplasmic concentration of Ca\textsuperscript{2+} and consequent contraction of muscle. The same molecular defect occurs in lymphocytes from affected susceptible pigs. There is no histomorphometric evidence of cardiac abnormalities in malignant hyperthermia susceptible pigs.\textsuperscript{15} The mitochondria from predominantly red muscle fibers have a greater calcium binding capacity than those from predominantly white muscle fiber areas. There is extreme rigidity of skeletal muscles, hyperthermia, tachycardia, cardiac arrhythmia, an increase in oxygen consumption, lactate formation and high-energy phosphate hydrolysis in muscle, respiratory and metabolic acidosis and a rise in the creatine kinase activity and concentration of potassium, lactate, glucose, free fatty acids and catecholamines in blood. There is a large release of glucose and potassium from the liver which contributes to the hyperglycemia and hyperkalemia. There is a marked \(\alpha\)-adrenergic stimulation which is responsible for the heat production in malignant hyperthermia susceptible pigs. However, the \(\beta\)-adrenergic response in stress-sensitive and stress-resistant pigs is inconsistent.\textsuperscript{16} The lactic acidemia is severe due to the overproduction of lactate peripherally and failure of normal lactate uptake.

Malignant hyperthermia can also be induced using methoxyflurane, isoflurane and enfurane, and succinylcholine.

Exposing stress-susceptible pigs to halothane or exercise induces glycolysis but the mechanisms are different. There are no histochemical differences between muscles of susceptible and normal swine. There is some indication that halothane causes a transient but significant vasoconstrictive action which could be a contributing factor in initiating the severe reactions in malignant hyperthermia. Electron microscopy of platelets from stress-susceptible pigs reveals a defect characterized by dilatation of the open canalicular system.

**CLINICAL FINDINGS**

**Porcine stress syndrome (transport death)**

Death during or following transport to market may be significant and is more prevalent when overcrowding occurs and during the hot summer period.\textsuperscript{17} If seen alive, affected pigs initially show a rapid tremor of the tail, general stiffness associated with increased muscular rigidity, and dyspnea to the extent of mouth-breathing. The body temperature is elevated, often beyond the limits of the clinical thermometer, and there are irregularly shaped areas of skin blanching and erythema. At this stage the affected pig is frequently attacked by other pigs within the group. The pig collapses and dies shortly afterwards and the total time course of the syndrome is generally of the order of 4–6 minutes.

**Malignant hyperthermia**

Malignant hyperthermia is also a manifestation of the PSS. It may be induced in stress-susceptible pigs by anesthesia with potent volatile anesthetics such as halothane or by the administration of succinylcholine. It is characterized by the development during anesthesia of increased muscle metabolism with muscular rigidity, lactic acidosis, and a marked increase in basal metabolic rate, increased oxygen consumption, carbon dioxide production and severe hyperthermia and tachycardia, tachyarrhythmia and death. Once fully developed the syndrome is irreversible. The syndrome poses a hazard in swine anesthesia which can be averted by prior medication with dantrolene and has received considerable study as a model for an analogous syndrome in man. It has also been used as a method for determining stress susceptibility for genetic selection programs.

**Pale, soft, and exudative pork (PSE)**

In stress-susceptible pigs, after slaughter, the inferior quality of the meat with its pale, soft, exudative characteristics is obvious. This is due to excessive postmortem glycolysis with lactic acid production and a rapid fall in muscle pH with dehydration and reduced water binding as a consequence. In affected muscle, rigor mortis occurs rapidly after slaughter, but then decreases so that affected carcasses have been ‘set’ and postmortem drip is excessive. Affected pork has a pH of less than 6 and generally a temperature of 41°C (106°F) or greater 45 minutes after slaughter, compared to the normal pork with a pH above 6 and a temperature less than 40°C (104°F). This causes denaturation of muscle proteins leading to affected meat which has inferior taste, cooking and processing qualities, and does not accept curing as readily. The occurrence of this syndrome is considerably influenced by the stress of transport and handling prior to and during slaughter, and this aspect of the syndrome is of major economic importance.\textsuperscript{5,8,19} Rapid chilling helps prevent PSE but chill type has no effect.\textsuperscript{20}

**Dark, firm, and dry pork (DFD)**

Dark, firm, dry pork has darker color and higher ultimate pH than normal meat. In muscles which develop DFD the muscle glycogen is already depleted before slaughter, which may be related to prolonged transport with fasting.

**Back muscle necrosis**

Acute necrosis of the longissimus dorsi occurs in German Landrace pigs and other breeds. The acute syndrome lasts approximately 2 weeks and is characterized by swelling and pain over the back muscles with arching or lateral flexion of the spine and reluctance to move. The swelling and pain then subside, but there is atrophy of the affected muscle and development of a prominent spinal ridge. Some regeneration may occur after several months. Acute cases may die. The syndrome occurs in young adults weighing from 75 to 100 kg. The mild form may be undetectable except for pigs lying down near the feed trough. In the severe form, affected pigs may assume the dog-sitting position with a hunched-up back.

**CLINICAL PATHOLOGY**

Several testing methods are available for predicting susceptibility.

**Halothane test**

The halothane test is highly reliable for the identification of pigs which are homozygous for the single recessive gene responsible for susceptibility to the PSS. However, the test is not 100% accurate because of the incomplete penetrance of the halothane sensitivity trait (not all homozygous malignant hyperthermic susceptible pigs react by developing limb rigidity). Penetration of the halothane sensitivity trait is estimated to vary from 50 to 100% depending on the breed, herd, and investigators. The test detects the worst clinical outcomes, and will not identify all the pigs which will develop PSE. There is now evidence that it will detect the heterozygote.\textsuperscript{21} Stress-susceptible pigs are sensitive to halothane at 8 weeks of age and if the anesthetic challenge is removed immediately after obvious signs of limb rigidity develop and before the development of fulminant hyperthermia, the mortality from the procedure is negligible. Pigs that remain unreactive for a challenge period of 5 minutes are considered normal.

A halothane-sensitive muscle defect can be present in certain individuals which do not develop rigid malignant hyperthermic episodes on brief exposure to halothane. A longer halothane exposure combined with succinylcholine is required if these false negatives are to be identified. The halothane test has good predictive value for the occurrence of PSE.
However, there may be breed variations as mentioned above.

A decrease in the amplitude of the phosphocreatine (PCr) signal in the in vivo $^{31}$P nuclear magnetic resonance spectrum of skeletal pigs is an early and 100% predictive measurement for the detection of malignant hyperthermia in anesthetized piglets. Nuclear magnetic resonance techniques such as magnetic resonance imaging and magnetic resonance spectroscopy are sensitive diagnostic aids for detecting the onset of PSS in young animals and for following the metabolic changes in muscle tissue during the syndrome.

Halothane concentration markedly affects the outcome of halothane testing, and either higher halothane concentrations or longer exposure might be required to identify positive reactors in a heterogeneous population. The ionophore A23187, a lipophilic carboxylic antibiotic which binds and transports divalent cations across both natural and artificial membrane bilayers, allows clear differentiation between the muscles of normal and pathological animals and may be a useful adjunct to the halothane test.

**Blood creatine kinase levels**

The blood creatine kinase (CK) levels are higher in stress-susceptible pigs. Pigs are subjected to a standard exertion test and blood samples taken 8–24 hours later and analyzed for CK. The original work indicated a good correlation between the CK levels and the halothane test. There is also an increase in CK levels in pigs as they are transported from the farm to the abattoir. However, not all pigs which develop PSE have increased serum levels of CK.

Increased CK activity is highest in stress syndrome with an accuracy of 87–91%. A recent study showed that 23% of pigs classified as Hal-1843 free based on a DNA test responded abnormally to halothane anesthesia.

**Pale, soft, and exudative pork**

This is evaluated by a meat quality index which combines meat color, pH at 24 hours postmortem, and water-binding capacity. Susceptible lines can be identified by carcass inspection and the results applied to sibling or progeny selection. A recent approach is the measurement of mitochondrial calcium efflux. Mitochondria isolated from Mm longissimus dorsi muscle exhibit a rate of Ca$^{2+}$ efflux twice that of normal pigs. Most of the tests readily predict the worst examples of the syndrome but are not sufficiently precise to be able to identify tendencies towards it, which restricts their value in breeding programs.

**Erythrocyte osmotic fragility**

Erythrocyte osmotic fragility may be correlated with malignant hyperthermia and is being examined as a possible aid in the determination of susceptibility.

**Other tests**

Any reliable test which can identify stress-susceptible pigs without using halothane testing is attractive. Increased peroxidation of the erythrocytes may be an improved diagnostic test for PSS. Differences in the levels of cortisol, creatinine, aspartate aminotransferase, and lactate dehydrogenase are highly significant between halothane-sensitive and halothane-negative lines of pigs.

**Necropsy findings**

In the PSS, rigor mortis is present immediately following death, and carcass putrefaction occurs more rapidly than normal. The viscera are congested and there is usually an increased quantity of pericardial fluid as well as pulmonary congestion and edema. The muscles—especially the gluteus medius, biceps femoris, and longissimus dorsi—are pale, wet, and soft. In back muscle necrosis, these changes appear grossly to be confined to the epaxial musculature. Histologically, the lesions in skeletal muscle may be minimal, and are easily obscured by autolysis. In some instances only interstitial edema is visible while in animals which have survived repeated episodes there is obvious phagocytosis of degenerate myofibers, with ongoing regeneration and fibrosis. The most typical microscopic finding is hypercontraction of myofibers, characterized by division of the cell into irregularly-sized segments by transverse and sometimes branching bands. Degenerate sarcoplasm of a floccular or sometimes hyaline character may be present. Degenerative changes may also be detected in myocardial cells.

**Samples for confirmation of diagnosis**

- **Genetic analysis** – 50 g frozen muscle (DNA ANALYSIS) and hair for PCR tests.
- **Histology** – formalin-fixed skeletal muscle (several sections, including longissimus dorsi), heart (LM).
- **Biochemistry** – it has been reported that pigs with PSS develop metabolic acidosis in association with respiratory acidosis which is manifested as lower values of acid-base excess and HCO$_3$ – with higher H$^+$ concentrations and pCO$_2$ than resistant pigs.

**Non-reacting pigs**

Pyruvate kinase activity was less variable within groups than CK activity which may allow more effective discrimination between the two different genotypes. However, age-related effects and the failure to identify heterozygotes may restrict the use of plasma pyruvate activity as a diagnostic test.

**Blood typing**

Blood typing is also used as a method for the identification of susceptible pigs. One of the chromosomes of the pig, a region with four known loci has been identified. These loci contain the genes responsible for variants of the enzymes 6-phosphogluconate dehydrogenase and phosphofructokinase isomerase (PHI). The H-blood group system is determined by one of the loci, and halothane sensitivity is also determined by genes at a locus in this region. This region is of special interest because a close connection has been found between this and important carcass traits such as the PSE condition. Thus, blood grouping may be used to detect halothane-sensitive pigs as well as heterozygote carriers.

**A DNA-based blood test**

This can now be used to detect the HAL gene status. It can be adapted for rapid batch analysis of many samples simultaneously, is less invasive, and can be applied to as little as 50 μL of blood. The test is more than 99% accurate, is cost-effective, and can be used to determine the prevalence of the PSS mutation in various breeds of swine in various countries. A recent study showed that 23% of pigs classified as Hal-1843 free based on a DNA test responded abnormally to halothane anesthesia.

**Histology**

- formalin-fixed skeletal muscle (several sections, including longissimus dorsi), heart (LM).
- DNA ANALYSIS and hair for PCR tests.
- Biochemistry – it has been reported that pigs with PSS develop metabolic acidosis in association with respiratory acidosis which is manifested as lower values of acid-base excess and HCO$_3$ – with higher H$^+$ concentrations and pCO$_2$ than resistant pigs.
Differential diagnosis

The acute nature of the PSS and its relation to stress serve to differentiate it from other syndromes causing sudden death in market and adult sized pigs. The sudden death syndrome must be differentiated from:

- Mulberry heart disease
- Acute septicaemia due to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Other causes of sudden death including intestinal volvulus, heat exhaustion, suffocation during transportation
- Hypocalcemic tetany resulting from severe vitamin D deficiency can produce a similar clinical syndrome
- Porcine viral encephalomyelitis may also result in a similar clinical syndrome in postweaned pigs. Pathological and biochemical examinations differentiate these from the PSS.

Treatment

The acute syndromes are usually not treated. Several drugs are available for the protection of pigs against drug-induced malignant hyperthermia. A combination of acepromazine and droperidol will delay the onset or prevent the occurrence of halothane-induced malignant hyperthermia. Dantrolene is also effective for treatment and prevention. The therapeutic dose is 7.5 mg/kg BW. Carazolol is effective for the prevention of transport death when given 3–8 hours before transportation and improves meat quality compared to untreated susceptible animals. Acute back necrosis has been treated successfully with isopyrin and phenylbutazone. Experimentally, the supplementation of the diets of stress-susceptible pigs with vitamin E and C will provide some protective effect on cell membrane integrity.

Control

The control of this syndrome depends on genetic selection and possible eradication of the PSS mutation and reduction of the severity of stress imposed on pigs.

Genetic selection

The best strategy for control of this complex is not clear. Several factors must be considered. Swine homozygous for the PSS mutation are at high risk for developing PSS and severe PSE to make them useful for market pigs. They are used primarily as a source of the PSS mutation for breeding programs and research purposes. Using swine which are heterozygous for the PSS mutation as market pigs may be advantageous. They benefit from the positive effects of the mutation, have minimal risk of developing PSS, and may have acceptable prevalence and severity of PSE, if during marketing and slaughter the environmental and management risk factors which precipitate PSE are minimized. The mutation is not a prerequisite for leanness and muscularity and it is possible for breeders to eradicate the gene from their breeding stock. The negative effects of the halothane gene on fresh pork quality are well known. However, such a policy may result in the loss of an easily accessible and cost-effective selection criterion for favorable carcass characteristics. The PSS mutation has been used successfully in most swine breeds for increasing leanness and muscling. With the development of the DNA-based test for the PSS mutation, the mutation can be selected for with high precision and accuracy, and its expression finely controlled in a breeding program.

The various testing methods described under clinical pathology are used to identify pigs with the halothane gene. The tests can be applied to breeding stock entering swine performance test stations or on a herd basis. A reliable diagnostic test such as a DNA-based blood test to identify it will provide the basis for elimination of the gene or its controlled inclusion in swine breeding programs.

Management of stressors

Control through reduction of stress is not easily applied because frequently the syndrome is induced by routine minor procedures within the piggery. The incidence of transport deaths or the necessity for immediate slaughter salvage of severely stressed pigs on arrival at the abattoir and the occurrence of pale, soft, exudative meat characteristics are a significant economic problem in some countries.

The necessity to climb an upper deck in the transport poses a significant stress, and the use of single-deck transports or mechanical lifts for multiple-deck transports, and the shipment of pigs in containers has resulted in a decreased incidence. The provision of spacious, well-ventilated transport vehicles and spraying of pigs on arrival at the holding pens is also beneficial. Pigs should not be slaughtered directly after arrival at the abattoir but should be rested for at least 1–2 hours if they have been stressed only by transportation. In cases of severe physical exertion even more time should be allowed for recovery. Where possible transport distance should be kept to a minimum and transport should be avoided on excessively hot days.

Inherited defects of the skin

Inherited symmetrical alopecia

This is an inherited skin defect of cattle in which animals born with a normal hair coat lose hair from areas distributed symmetrically over the body. It has been observed in Holstein cattle as a rare disease but its appearance among valuable purebred cattle has economic importance. It appears to be inherited as a single autosomal recessive character. Loss of hair commences at 6 weeks to 6 months of age. The alopecia is symmetrical and commences on the head, neck, back, and hind-quarters, and progresses to the root of the tail, down the legs, and over the forelimbs. Affected skin areas become completely bald. Pigmented and unpigmented skin is equally affected; there is no irritation and the animals are normal in other respects. Failure of hair fibers to develop in apparently normal follicles can be detected by skin biopsy.
INHERITED CONGENITAL HYPOTRICHOSIS

In this congenital disease there is partial or complete absence of the hair coat with or without other defects of development. The main importance of the disease is in cattle, in which there are six syndromes, but it is also inherited in pigs, in which it is associated with low birth weights, weakness, and high mortality, and in Poll Dorset sheep, in which the face, ears, and lower legs are bald, there are no eyelashes, and the patient lacrimates excessively. The skin is thick, wrinkled, greasy, scaly, and erythematous. Hair fibers are completely absent from the follicles, but wool fibers and follicles are normal.1

Viable hypotrichosis

The condition is recorded in North America in Guernsey and Jersey cattle. Calves are viable provided they are sheltered. They grow normally but are unable to withstand exposure to cold weather or hot sun. In most instances hair is completely absent from most of the body at birth but eyelashes and tactile hair are present about the feet and head. Occasionally hair may be present in varying amounts at birth but is lost soon afterwards. There is no defect of horn or hoof growth. The skin is normal but has a shiny, tanned appearance and on section no hair follicles are present in the skin. The condition is inherited as a single, recessive character.

Congenital hypotrichosis has been reported in a Percheron draught horse. At birth there were circumscribed patchy areas alopecia which was progressive becoming almost complete by 1 year of age. Skin biopsy at 7 months of age revealed severe follicular hypoplasia and the animal was still alive at 6 years of age.

Non-viable hypotrichosis

This is a complete hypotrichosis in which the thyroid is abnormally small and hypofunctional and the calves die shortly after birth.

Hypotrichosis with anodontia

Congenital X-linked hypotrichosis with missing teeth in cattle is characterized by abnormal morphogenesis to teeth, hair follicles, and eccrine sweat glands. Two different forms can be distinguished according to the severity of the tooth defects: (1) congenital hypotrichosis with complete or almost complete anodontia; (2) congenital hypotrichosis with completely missing incisors or defective incisors. Impaired body condition and growth of the affected animals result from missing teeth. In addition, animals with sparse hair are more susceptible to cold and more prone to skin lesions. The phenotype and inheritance of hypotrichosis with nearly complete anodontia has been recorded in pedigree German Holstein calves. The phenotype is inherited as a monogenic X-linked recessive trait. A reverse transcription-PCR assay was used to identify the causative large genomic deletion in the bovine EDI gene. The EDI gene for the hypotrichosis and anodontia phenotype appears to have pleotropic effects on hair follicles, eccrine nasolabial glands, apocrine sweat glands, individually expressed contours of the muzzle, and on development of incisor and premolar/molar teeth. A molecular genetic test for the pathological mutation allows the unequivocal classification of animals with congenital hypotrichosis and anodontia and identification of heterozygous carriers and their exclusion from further breeding.

Streaked hairlessness

A sex-linked semidominant gene causes development of a streaked hairlessness in which irregular narrow streaks of hypotrichosis occur in female Holsteins.

Partial hypotrichosis

Recorded in polled and horned Hereford cattle. At birth there is a fine coat of short, curly hair which later is added to by the appearance of some very coarse, wiry hair. The calves survive but do not grow well. The character is inherited as a simple recessive. The disease in Poll Herefords has the same short curly coat but there is also a deficiency of hair in the switch, and over the poll, brisket, neck, and legs in some cattle. Some have a much lighter hair coat color. Histologically there is a characteristic accumulation of large trichohyaline granules in the hair follicles.

Rat tail syndrome in calves

The ‘rat tail’ occurred following the importation of continental European breeds of cattle into the United States when those breeds were crossed with Angus or Holsteins. The abnormality is characterized by short, curly, malformed, sometimes sparse hair and lack of normal tail switch development. Histologically, there are enlarged, irregularly distributed, and clumped melanin granules in the hair shafts, which are asymmetrical, short, curled, and small. The scale surface is rough and pitted, and scale fails to form in some areas. A study of the inheritance of the abnormality found that all rat-tail calves were sired by Simmental bulls and were from cows with various percentages of Angus breeding. The abnormality had no effect on birth weight, weaning weight, or gain from birth to weaning. However, rat-tail calves had significantly lower rates of gain during the winter months from weaning to yearling than non-rat-tail calves. The syndrome is controlled by interacting genes at 2 loci. Cattle which express the syndrome must have at least one dominant gene for black color and be heterozygous at the other locus.

INHERITED HAIR COAT-COLOR-LINKED FOLLICLE DYSPLASIA

Some ‘buckskin’-colored follicular dysplasia occurs in so-called ‘Portuguese’ Holstein cattle, a grade variant of Red Holsteins with a tan color instead of the red. This defect consists of a coat-color-linked hair follicle dysplasia, in which the colored hairs are shorter and less lustrous than the white hair, making the coat much finer and smoother. Test matings seem to confirm an autosomal dominant inheritance.

A black hair colored follicular dysplasia is also recorded in Holstein cattle. Patches of hair loss varying from hypotrichosis to complete alopecia occur in a random fashion but only on black areas. Follicular dysplasia is evident in biopsy samples. The abnormality persists for the life of the animal and is of cosmetic importance only. An inherited etiology is assumed.

A follicular dysplasia in a mature Brangus-cross cow and a mature Angus cow has been described. Adult onset alopecia occurred and skin biopsy revealed follicular distortion and atrophy, with melanin clumping in follicular epithelium, hair bulb matrix cells, hair shafts, and infundibular keratin.

REFERENCES

INHERITED BIRTHCOAT RETENTION

This is recorded in Merino and Welsh mountain sheep and characterized by a coat of hairy medullated fibers in contrast with the non-medullated wool fibers of the normal sheep fleece.

INHERITED LEUKODERMA

The Arab fading syndrome commences in young horses in particular families of Arab horses as round, unpigmented patches of skin around the lips, eyes, peri­neum, preputial orifice. Some cases recover spontaneously but the blemish is usually permanent.
INHERITED ALBINISM AND LETHAL WHITE FOAL SYNDROMES

Albinism is a congenital lack of melanin pigment in the skin, hair, and other normally pigmented structures such as the uveal tract. Albinism is classified as generalized or localized and as complete or partial incomplete. The affected skin in albinism is characterized microscopically as melanopenic rather than melanocytic, which distinguishes partial albinism from piebaldism. Most of the normal, inherited white markings which occur on horses are localized forms of piebaldism. Generalized and complete albinos (oculocutaneous albinism) have white hair, white skin, pink irides and usually exhibit photophobia. Generalized albinism in the horse is inherited as autosomal dominant trait which is only viable in the heterozygous states. These horses have incomplete albinism as there is some coloration to the iris. Matings of heterozygous albino horses produce a nonviable embryo 25% of the time which is resorbed in gestation. This is one form of lethal white foal syndrome. A second form of lethal white foal syndrome is an autosomal recessive defect which occurs by mating of overo paint horses. Lethal white foals from such breedings are characterized by albinism and congenital defects of the intestinal tract.

INHERITED EPIDERMAL DYSPLASIA (BALDY CALVES)

This is a lethal defect of Holstein-Friesian calves inherited as an autosomal recessive character. The calves, most commonly heifers, are normal at birth but at 1–2 months of age begin to lose condition in spite of good appetites. The skin over most of the body is slightly thickened, scaly, and relatively hairless. There are also patches of scaly, thickened, and folded skin especially over the neck and shoulders, and hairless, scaly, and often raw areas in the axillae and flanks and over the knees, hocks, and elbow joints. The skin over the joints is immovable. There is usually alopecia about the base of the ears and eyes. The tips of the ears are curled backwards. The hooves fail to develop and there is persistent slobbering, although there are no mouth lesions. The hooves are long, narrow, and pointed because of gross overgrowth of the walls; these and stiffness of joints cause a shuffling, restricted gait. Calves assume a recumbent posture for most of the time. Severe emaciation leads to death at about 6 months of age.

Histological changes in the skin include acanthosis, hyperkeratosis, and patchy neutrophil invasion. The similarity of this condition to inherited parakeratosis and to experimental zinc deficiency suggests an error in zinc metabolism, but treatment with zinc had no effect on the course of the disease.1

INHERITED CONGENITAL ABSENCE OF THE SKIN

Classical epiderigenesis imperfecta Absence of mucous membrane, or more commonly, absence of skin over an area of the body surface has been recorded at birth in pigs, calves, lambs, and foals. There is complete absence of all layers of the skin in patches of varying size and distribution. In cattle the defect is usually on the lower parts of the limbs and sometimes on the muzzle and extending onto the buccal mucosa. The disease is best known in Holstein-Friesians, but is also recorded in Japanese Black, Shorthorn, Sahiwal, and Angus cattle. In pigs the skinline areas are seen on the flanks, sides, back, and other parts of the body. The defect is usually incompatible with life and most affected animals die within a few days. Inheritance of the defect in cattle is conditioned by a single recessive gene. Tissue-cultured fibroblasts from affected animals produce subnormal amounts of collagen and lipids.3

Familial acantholysis Suspected of being inherited, this defect in Angus calves is characterized by defective collagen bridges in the basal and prickle layers of the epidermis so that skin, normal at birth, is subsequently shed at carpal and metacarpophalangeal joints and coronet, and there is separation of horn at the coronet.

Epidermolysis bullosa This congenital disease of Suffolk and South Dorset Down sheep is autosomal recessive in Simmental and Brangus calves is very similar to epidermolysis bullosa, which occurs in humans has been recorded in foals of the French draft horse breeds.4,5 A mutation in the LAMC2 gene is responsible for the defect. Affected foals were born with skin blistering, skin and buccal ulceration followed by loss of hooves. In the affected skin there was disjunction of the epidermis from the underlying dermis at the dermal-epidermal junction. Genomic DNA testing is used to determine the presence of the mutation in carrier animals.

Hereditary junctional mechanobullous disease This defect is inherited in Belgian foals, Angus and Simmental calves, and Suffolk and South Dorset Down lambs.6,7 It is usually recorded under the heading of epidermolysis bullosa. There may be no shedding of skin but the initial bullous lesions at the coronet, considered to be initiated by abrasions, lead to sloughing of the hooves.

Red foot disease of sheep This is similar to both of the above diseases. It is recorded in Scottish Blackface and Welsh mountain sheep. The lesions are not present at birth but become apparent at 2–4 days of age when there is sloughing of skin of the limbs, the accessory digits, the ear pinna, and of the epidermal layers of the cornea and buccal mucosa, especially the dorsum of the tongue. There is also an absence of head horn and a separation of hoof horn from the coronet. Pieces of horn become completely detached exposing the red corium below, hence 'red foot'. The cutaneous and mucosal lesions often commence as blood-filled or fluid-filled blisters. The corneal lesions are similarly the result of sloughing of epidermal layers. Although the cause is unknown there are indications that it is inherited.

INHERITED CROP EARS

Inherited as a single autosomal, incomplete dominant character in Bavarian Highland cattle, this anomaly affects both ears, appears at birth, and varies from a minor trimming up to a complete deformity and reduction in size.1

REFERENCE

INHERITED HYPERBILIRUBINEMIA AND PHOTOSENSITIZATION

An inherited photosensitization with hyperbilirubinemia has been observed in Southdown sheep in New Zealand and the United States, and in Corriedales in California.1 It is inherited as an autosomal recessive trait.

Liver insufficiency is present but the liver is histologically normal. Phylloerythrin and bilirubin excretion by the liver is impeded and the accumulation of phylloerythrin in the bloodstream causes the photosensitization. There is also a significant deficiency in renal function. Symptomatic treatment of photosensitization and confining the animals indoors may enable the lambs to fatten to market weight. The persistent hyperbilirubinemia is accompanied by an inability of the kidneys of these sheep to concentrate urine and the eventual death of the sheep from renal insufficiency.

Affected sheep live for several years if they are protected from sunlight and tend to die from renal failure associated with progressive fibrosis of the kidney.

A similar disease in Corriedes sheep in California is inherited as an autosomal recessive trait.1 The functional defect is not in the uptake of unconjugated bilirubin and phylloerythrin, but rather its excretion from liver into bile. It affects lambs as they begin to eat pasture. Lambs live until 6 months of age if provided with shade. There is also marked melanin-like pigmentation of the liver.

These two diseases are examples of the involvement of external environmental disease factors with a genetic disease: a diet of green forage (chlorophyll) and sunlight, working in concert with the inborn error of metabolism to induce photosensitization.1

INHERITED CONGENITAL ICHTHYOSIS (FISH-SCALE DISEASE)

Congenital ichthyosis is a disease characterized by alopecia and the presence of plates of horny epidermis covering the entire skin surface. It has been recorded only in Holstein and Norwegian Red Poll and probably in Brown Swiss calves among the domestic animals, although it occurs also in humans.

The newborn calf appears to be either partly or completely hairless and the skin is covered with thick, horny scales separated by fissures which follow the wrinkle lines of the skin.2 These may penetrate deeply and become ulcerated. There are plenty of normal hair follicles and normal hairs but these are lost in the areas covered by the growth of scales. A skin biopsy section will show a thick, tightly adherent layer of keratinized cells. The disease is incurable and, although it may be compatible with life, most affected animals are disposed of for esthetic reasons. The defect has been shown to be hereditary and to result form the influence of a single recessive gene.

INHERITED DERMATOSIS VEGETANS

This disease appears to be conditioned by the inheritance of a recessive, semilethal factor. Affected pigs may show defects at birth but in most instances lesions appear after birth and up to 3 weeks of age. The lesions occur at the coronets and on the skin.3 Those on the coronets consist of erythema and edema with a thickened, brittle, uneven hoof wall. Lesions on the belly and inner surface of the thigh commence as areas of erythema and become wart-like and covered with gray-brown crusts.

Many affected pigs die but some appear to recover completely. Many of the deaths appear to be due to the giant-cell pneumonitis which is an essential part of the disease. The pathology of the disease indicates that it is the result of a genetic defect which selectively affects mesodermal tissue. It is known to have originated in the Danish Landrace breed.

REFERENCES

DERMATOSPARAXIS (HYPERELASTOSIS CUTIS)

This is an extraordinary fragility of skin and connective tissue in general, with or without edema. It is probably inherited as a recessive character. It occurs in cattle, horses, in Finnish and White Dorper sheep, and a mild form is seen in Merino sheep. The latter is inherited as a simple autosomal recessive. The skin is hyperelastic, as are the articular ligaments; marked cutaneous fragility, delayed healing of skin wounds, and the development of pappaceous scars are also characteristic.

Pieces of skin may be ripped off when affected sheep are being handled.

In horses the skin in some parts of the body is thinner than elsewhere, e.g. the skin of the ventral abdomen and the collagen bundles in the area are more loosely packed and are curved rather than straight. The proportion of acid-soluble collagen is also much higher in this abnormal skin. The disease involves a molecular defect of a collagen-binding protein, and is related to a recognized problem in dogs and cats identified as ‘dominant collagen packing defect’.3

Hereditary equine regional dermal asthenia has been recorded in Quarter horses in Brazil similar to that reported in the United States.4 Reported cases of horses with hyperextensible skin have involved Quarter Horses.5 Clinically there were bilateral asymmetrical lesions of the trunk and lumbar regions, where the skin was hyperextensible. Handling of the skin elicited a painful response and superficial trauma led to skin wounds. The skin was thinner than normal in affected areas, with thickened borders and harder fibrotic masses. Histologically, the collagen fibres were thinner and smaller, which created a loose arrangement of collagen fibers within the deep dermis. The deep dermis contains a distinctive horizontal linear zone in which separation of collagen bundles results in formation of large empty cleft-like spaces between the upper and lower regions of the deep dermis ‘zonal dermal separation’.5 Pedigree analysis indicates an autosomal recessive type of inheritance.

The Ehlers–Danlos syndrome, recorded in Charolais and Simmental cattle, and Rippolese sheep,6 is also characterized by extreme fragility of skin and laxness of joints in the newborn. There is a defect in collagen synthesis, and histopathological findings include fragmentation and disorganization of collagen fibers.

The syndrome has also been recorded in lambs.7 The skin was loose and present in excessive amounts, with folds over the carpal joints and lower regions of the legs. In some lambs, there may be separation of epidermis from dermis with blood-filled cavitations and intact skin which can be easily torn.

INHERITED MELANOMA

Inherited cutaneous malignant melanoma are found in National Institute for Health (NIH miniature) and Sinclair miniature swine. Its expression is associated with two genetic loci, one of them associated with the swine major histocompatibility complex. Familial melanoma have also been recorded in members of successive litters from an individual Duroc x Slovak White sow.

REFERENCES

INHERITED HYPERHYDROSIS

A condition characterized by excessive sweating, and thought to be inherited, is recorded in beef Shorthorn calves. The syndrome includes conjunctivitis, some cases progressing to complete opacity of the cornea, heavy dandruff, and persistent wetness of the hair coat.

Miscellaneous inherited defects

INHERITED EYE DEFECTS

An inherited, congenital corneal opacity occurs in Holstein cattle. The cornea is a cloudy blue color at birth and both eyes are equally affected. Although the sight of affected animals is restricted they are not completely blind, and there are no other abnormalities of the orbit or the eyelids. Histologically there is edema and disruption of the corneal lamellae.

With lens dystrophy Brown Swiss cattle are affected by an inherited congenital blindness with a cloudy shrunken lens as the cause. Japanese Black cattle also suffer from an inherited blindness caused by defects in the pupil, retina, and optic disk.

Bilateral cataract has been observed to be an inherited defect in Romney sheep. It is inherited as an autosomal dominant and can be eradicated easily by culling.

Complete absence of the iris (aniridia) in both eyes is also recorded as an inherited defect in Belgian horses. Affected foals develop secondary cataract at about 2 months of age. Total absence of the retina in foals has also been recorded as being inherited in a recessive manner.

Microphthalmia is reported to be an inherited defect in Texel sheep but the incidence is low. It is a well-recognized genetic defect of Texel sheep in Europe. Following importation and 'breeding up' of the breed in New Zealand in the 1990s, animals were released from quarantine for further expansion of the breed. The abnormality has occurred in a number of flocks in New Zealand and an experimental breeding flock is maintained to study the molecular genetics. It is inherited as an autosomal recessive trait. An outbreak in Texel sheep in New Zealand has been recorded. The optic globes are approximately one half normal size and the optic nerves at the chiasma are approximately one half normal size. No other lesions are present in any organs. The retina is composed of an irregular mass attached to and continuous with the ciliary apparatus at one pole, and connected to the optic nerve posteriorly by a short stalk. The morphology and morphogenesis of the defect has been followed in embryos at different ages from eyes known to be carriers of the microphthalmia factor. The primary event was abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 of gestation and in newborn lambs appeared to be remnants of the epithelial lens vesicle.

Typical colobomata, ophthalmoscopically visible defects of one or more structures of the eye, caused by an absence of tissue, have assumed a more prominent position than previously because of their high level of occurrence in Charolais cattle. The lesions are present at birth and do not progress beyond that stage. They affect vision very little, if at all. However, because they are defects they should be named in certificates of health for all purposes. The defects include iridal heterochromia, tapetum fibrosum, and colobomas. Congenital blindness is also seen in cattle with white coat color, especially Shorthorns. The lesions are multiple and include retinal detachment, cataract, microphthalmia, persistent pupillary membrane, and vitreous hemorrhage. Internal hydrocephalus is present in some, and hypoplasia of optic nerves also occurs.

A combination of iridal hypoplasia, limbic dermoids and cataracts was recorded in the eyes of progeny of a Quarter Horse stallion, presumably as a result of a mutation in the stallion and transmission to the foals via an autosomal, dominant gene. The inheritance is a simple autosomal recessive.

Iridiremia (total or partial absence of iris), microphakia (smallness of the lens), ectopia lentis and cataract have been reported to occur together in Jersey calves. The mode of inheritance of the characters is as a simple recessive. The calves are almost completely blind but are normal in other respects and can be reared satisfactorily if they are hand-fed. Although the condition has been recorded only in Jerseys, similar defects, possibly inherited, have also been seen in Holsteins and Shorthorns.

Inherited night blindness occurs in Appaloosa horses which have otherwise normal sight. No defect has been described in the eyes.

REVIEW LITERATURE

REFERENCE
INHERITED PROLONGED GESTATION (ADENOHYPOPHYSEAL HYPOPLASIA)

Prolonged gestation occurs in cattle and sheep in several forms and is usually, although not always, inherited. The two recorded forms of the disease are prolonged gestation with fetal giantism and prolonged gestation with deformed or normal or small size fetuses.

Prolonged gestation with fetal giantism

The inherited disease is recorded in Holstein, Ayrshire, and Swedish cattle with prolongation of pregnancy from 3 weeks to 5 months. The cows may show marked abdominal distension but in most cases the abdomens are smaller than one would expect. Parturition, when it commences, is without preparation. Udder enlargement, relaxation of the pelvic ligaments, and loosening and swelling of the vulva do not occur and there is also poor relaxation of the cervix and a deficiency of cervical mucus. Dysostia is usual and cesarean section is advisable in Holstein cattle but the Ayrshire calves have all been reported as having been born without assistance. The calves are very large (48-80 kg body weight) and show other evidence of postnatal growth, with a luxuriant hair coat and large, well-erupted teeth which are loose in their alveoli, but the birth weight is not directly related to the length of the gestation period.

The calves exhibit a labored respiration with diaphragmatic movements more evident than movements of the chest wall. They invariably die within a few hours in a hypoglycemic coma. At necropsy there is adeno-hypophyseal hypoplasia and hypoplasia of the adrenal cortex and the thyroid gland. The progesterone level in the peripheral blood of cows bearing affected calves does not fall before term as it does in normal cows.

Prolonged gestation with craniofacial deformity

This form of the disease has been observed in Guernsey, Jersey, and Ayrshire cattle. It differs from the previous form in that the fetuses are dead on delivery, show gross deformity of the head, and are smaller than the normal calves of these breeds born at term. In Guernseys the defect has been shown to be inherited as a single recessive character and it is probable that the same is true in Jerseys. The gestation period varies widely with a mean of 401 days.

Clinical examination of the dams carrying defective calves suggests that no development of the calf or placenta occurs after the seventh month of pregnancy. Death of the fetus is followed in 1-2 weeks by parturition unaccompanied by relaxation of the pelvic ligaments or vulva or by external signs of labor. The calf can usually be removed by forced traction because of its small size. Mammary gland enlargement does not occur until after parturition.

The calves are small and suffer varying degrees of hypotrichosis. There is hydrocephalus and in some cases distension of the gut and abdomen due to atresia of the jejunum. The bones are immature and the limbs are short. Abnormalities of the face include cyclopaic eyes, microphthalmia, absence of the maxilla, and the presence of only one nostril. At necropsy there is partial or complete aplasia of the adenohypophysis. The neural stalk is present and extends to below the diaphragm sellea. Brain abnormalities vary from fusion of the cerebral hemispheres to moderate hydrocephalus. The other endocrine glands are also small and hypoplastic.

The disease has been produced experimentally in ewes by severe ablation of the pituitary gland, or destruction of the hypothalamus, or section of the pituitary stalk in the fetus and by adrenalectomy of the lamb or kid. Infusion of ACTH into ewes with prolonged gestation due to pituitary damage produces parturition but not if the ewes have been adrenalec tomized beforehand.

Prolonged gestation with arthrogryposis

A form of prolonged gestation, which occurs in Hereford cattle and is thought to be inherited, is accompanied by arthrogryposis, scoliosis, torticollis, kyphosis, and cleft palate.

REFERENCE

INHERITED COMBINED IMMUNODEFICIENCY (CID) IN FOALS OF ARABIAN BREEDING

Syndrome

Etiology Inherited immunodeficiency in foals of Arabian parentage caused by a mutation in the gene coding for DNA-dependent protein kinase catalytic subunit.

Epidemiology Familial pattern of occurrence with autosomal recessive inheritance. Approximately 8% of Arabian horses are heterozygous for the mutation (carriers). Random mating results in approximately 1 in 600 foals being affected, but not all matings are random and the incidence of the disease is less than this number.

Clinical findings Foals normal at birth but succumb to systemic infection soon after birth and die before 3 months of age.

Death from acute septicemia, or recurrent or chronic continuous infection, usually of respiratory tract. Poor response to normally effective antibiotic therapy.

Clinical pathology Lymphopenia, hypogammaglobulinemia. PCR test detects animals heterozygous (carriers, parents of affected foals) or homozygous (affected foal) for the mutated gene.

Necropsy findings Thymic, lymph node, and splenic hypoplasia and a marked reduction in the numbers of splenic and lymph node lymphocytes. Diagnostic confirmation. PCR detection of mutated gene (homozygous in affected foals). Lymphopenia and agammaglobulinemia in a foal of Arabian breeding. Treatment Nil.

Control Ideally, elimination of the mutated gene by not breeding carrier animals. The disease can be prevented by not breeding a carrier animal to another carrier.

ETIOLOGY

The fundamental defect is a 5 base-pair deletion in the specific gene that codes for DNA-dependent protein kinase. The gene is located on chromosome BCA9. This mutation causes a lack of activity of the catalytic subunit of DNA-dependent protein kinase. The deficiency of protein kinase activity, which is absolute in affected foals, results in the inability to join DNA strands that have been broken as part of the normal process of creation of V (variable) regions of T cell and B cell antigen receptors on lymphocytes. Without these receptors the lymphocytes are unable to respond to antigens and thus the foal is not capable of mounting adaptive, either cellular or humoral (antibody), immune responses.

EPIDEMIOLOGY

The immunodeficiency is inherited as an autosomal recessive defect. The disease occurs in purebred and part-Arabian horses. It has also occurred in an Appaloosa foal that had an Arab stallion in the fifth past generation of its mother’s pedigree. In one survey of Arabian foals in the United States, the prevalence rate of affected foals was 2.3% of 257 foals of Arabian breeding, and 25.7% of the parents of affected foals were estimated to be carriers of the genetic defect. However, this likely represents an overestimation of the incidence of the disease and prevalence of the mutation in the population of Arabian horses because of selective testing. The frequency of carriers of the mutation for severe combined immunodeficiency is approximately 8%, with an estimated 0.2% (1 in 600) of foals of random matings between Arabian horses affected with the disease, based on...
a survey of 250 horses. Approximately 17% of Arabian horses are heterozygous for the mutation and 0.3% of foals are homozygous among > 6000 horses tested by a commercial laboratory.7 Affected foals usually appear normal at birth, but are highly susceptible to infections from 2 to 65 days after birth and usually die from one or more infections by 3 months of age. The sires and dams of affected foals are clinically normal and have normal lymphocyte counts and serum immunoglobulin concentrations.

PATHOGENESIS
Affected foals are born with a combined immunodeficiency associated with a deficiency in both B-lymphocytes (which produce immunoglobulins) and T-lymphocytes (which provide cellular immunity). There is a marked lymphopenia and failure of immunoglobulin (Ig) synthesis and absence of delayed hypersensitivity of skin responses. Foals that receive immunoglobulins from the dam’s colostrum derive passive immunity and can survive for as long as 4 months. Foals that do not receive colostrum die much earlier. The cause of death is infectious disease.

Affected foals are susceptible to infections of all kinds, but mostly of the respiratory tract. Adenoviral pneumonia is considered to be the most common secondary complication, probably because adenovirus infection is so widespread in the horse population. Affected foals may also die from hepatitis, enteritis, or infection of other organs without pulmonary involvement. While adenoviral pneumonia is the most common complication, infections with bacteria and Pneumocystis carinii also occur. Cryptosporidium sp. has also been recorded in a number of foals with diarrhea, which is also a common complication.

CLINICAL FINDINGS
Affected foals usually become ill from 10 to 35 days of age. Commonly there is a history suggesting a mild disease of the respiratory tract, especially the appearance of a bilateral nasal discharge, which often becomes sufficiently thick to interfere with sucking. The foal is unthrifty, lethargic, and tires easily but still nurses and eats solid feed. A deep dry cough and a serous to mucopurulent ocular and nasal discharge are common when pneumonia is present. There is moderate fever (39.5°C, 103°F) and an increase in the heart and respiratory rates. The depth of respirations is increased and a double expiratory effort is common. On auscultation, loud bronchial tones and moist and dry crackles are common over the anterior ventral aspects of both lungs. A chronic diarrhea is present in some foals, and alopecia and dermatitis, commonly associated with an infection by Dermatophilus congolensis, also occur. An important clinical feature is that affected foals do not respond favorably to treatment with antimicrobial agents. The course of the illness will vary from a few days to a few weeks and probably depends on the degree of immunodeficiency and the nature of the infection. Most affected foals become progressively worse over a period of 2–4 weeks, and death by 3 months of age is the usual outcome.

CLINICAL PATHOLOGY
Lymphopenia is a constant finding with counts often less than 1000/mL and there is a concurrent hypogammaglobulinemia in foals that have not received colostrum. There is no IgM in precolostral serum of the foal. Following ingestion of colostrum, all subclasses of immunoglobulin will be present but in affected foals the level of IgM will steadily decrease weekly until about 36 days when IgM is detectable. The lack of IgM is because of lack of synthesis and the shorter half-life of this isotype of immunoglobulin in foals – serum IgG concentrations decline more slowly. Until the development of the PCR test for detection of homozygous foals and confirmation of the disease, the measurement of serum Ig concentrations was considered essential for a definitive diagnosis. Additional tests include enumeration of B-lymphocyte and T-lymphocyte responses to phytolectin stimulation and other tests of lymphocytic immunological function, but these tests are no longer required for diagnostic confirmation of the disease.

NECROPSY FINDINGS
The lymph nodes are small and splenic follicles are not visible. A viral interstitial pneumonia and a secondary bacterial bronchopneumonia are common. The thymus gland is usually hypoplastic. Histologically the lymph nodes and spleen are depleted of lymphocytes, and germinal centers are absent. In some foals there are foci of necrosis of the intestinal epithelium but with minimal infiltration of inflammatory cells. Inclusion bodies of adenovirus may be present in the cells of several different body systems. In Australian foals Rhodococcus equi can be commonly isolated from pulmonary abscesses. Additional histological findings include a severe adenoviral pancreatitis and adenitis of the salivary glands.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation in an apparently chronic case of pneumonia in a young foal depends on the identification of the characteristic lymphopenia.

The differential diagnosis list includes:
- Septicemia and pneumonia of foals, caused by Rhodococcus equi
- Agammaglobulinemia due to failure of transfer of maternal immunoglobulins from colostrum.
- In many foal populations as many as 20% of foals are immunodeficient for this reason
- Other immunodeficiencies

TREATMENT
There is no satisfactory treatment for CID in foals. Hyperimmune serum, whole blood transfusions, and broad-spectrum antibiotics are all used without more than a temporary response. Affected foals may be kept alive by twice-weekly injections of hyperimmune serum and a constant antibiotic cover. Immunotherapy using a transplant of bone marrow and a fetal thymus transplant has been attempted without success. Corticosteroids are contraindicated.

CONTROL
Horses heterozygous for the mutation can be detected using a commercial PCR assay.6 These horses have normal serum immunoglobulin concentrations and lymphocyte counts. Detection of heterozygous animals, which is required by some national breed organizations, is
useful for several reasons. Firstly, it should, ideally, permit elimination of the disease from the population by breeding of only homozygous normal animals. However, this approach has not met with success because of the financial and emotional value of some heterozygous animals. Secondly, identification of the status of an animal permits controlled breeding such that the risk of producing homozygous affected foals is eliminated. This is achieved by mating only pairs of homozygous normal animals, in which case none of the off-spring will carry the mutated gene, or by mating a heterozygous animal with a homozygous normal animal. In this instance 1 in 4 of the progeny will carry the mutated gene, but none of the progeny will be homozygous for the mutated gene and, therefore, afflicted with the disease. This second approach, if applied consistently, should almost eliminate the disease.

Introduction

It was anticipated that, with time, this chapter would shrink in succeeding editions and, eventually, disappear. As the causes of individual diseases are demonstrated they are removed to other chapters but in the past newly identified diseases have been added at almost the same rate so that the net effect on the chapter has been small. The process could have been hastened by moving diseases when the consensus of opinion, short of proof, was that the cause had been identified. We have thought it preferable to leave those diseases here, together with those in which the combination of causes is complex, such as ‘weaner illthrift’.

Diseases characterized by systemic involvement

UNTHRIFTINESS IN WEANER SHEEP (WEANER ILLTHRIFT)

ETIOLOGY

A number of different diseases have been associated with this syndrome in both lambs and calves. In many cases an association has been established by a response trial but in others the association has not been established as causal. These include...
intestinal parasitism, coccidiosis, infection with hemoplasma (eperythrozoonosis), deficiencies of copper, cobalt, selenium, zinc, thiamin, vitamin A, and vitamin D. A combination of these deficiencies has also been suspected.

Palatability of pasture appears a cause of illthrift in some instances, or at least associated with it, and moving the animals to a different pasture will sometimes alleviate the condition. This has been observed with perennial ryegrass (Lolium perenne), setaria grass (Setaria sphacelata), tall fescue (Festuca arundinacea), and turnips (Brassica rapae). Infestation of grass species with endophyte fungi may prove an important cause of illthrift and poor growth rates occur in calves with the 'summer syndrome' associated with the endophyte Acremonium coenophialum in tall fescue pastures. Infection of pasture species with toxigenic Fusarium spp. has been associated with illthrift in lambs in South Africa, New Zealand, and Australia. Pasture and soil fungi have also been suspected of being associated with illthrift in sheep in eastern Canada.

EPIDEMIOLOGY

- The problem has seemed to be most severe in the southern hemisphere but this may be because sheep are so prevalent there.
- It may also be due partly to the predominance of Merino and Merino-type sheep; the disease is most common in these breeds which have their own particular timorous nature which makes weaning and the need to shift for themselves more traumatic than in most other breeds.
- This trait is particularly noticeable if there is overcrowding on pasture.
- Lambs that are weaned at light weights are more prone to illthrift following weaning and ideally they should be 45% of mature weight when weaned.
- Merino ewes have a low persistency of milk production and consequently management of the flock and the pastures is critical for effective weaning weights.
- Other management factors likely to lead to low weaning weights and subsequent unthriftness are multibirth lambs, small ewes, ewes with little milk, and lambs born late in the season.

Weaner illthrift does occur in breeds other than Merino and is also reported from several countries in the northern hemisphere. Weaner illthrift has been reported on a variety of different pastures and under a variety of different management systems.

In bad years there may be many deaths; in any circumstance there is a gross delay in maturation so that maiden lambing may be delayed to as late as 3 years of age. The economic effects can be disastrous. Illthrift syndromes are also recorded in calves although with less frequency.

CLINICAL AND NECROPSY FINDINGS

As the name indicates the disease in weaned sheep is manifest primarily by poor body condition and failure to thrive. Within an affected group not all lambs are equally affected and there will be a range of conditions. Those lambs in very poor condition are usually anemic, frequently have diarrhea, and there is a sporadic but continuing death loss amongst them. Commonly the sheep have been treated with anthelmintics with no response. There are usually no abnormal findings at post-mortem other than those associated with emaciation but villous atrophy is often found on histological examination of the small intestine.

This lack of significant findings is probably the defining factor for placing a problem in this disease category.

DIFFERENTIAL DIAGNOSIS

When faced with this problem the initial approach should be to examine for the most likely cause which is a deficiency in energy or protein intake. An examination of the teeth to insure that there is no excessive attrition of the teeth, or even breaking of the incisors if the sheep are being fed roots, is also a logical preliminary step in any investigation of an illthrift problem.

The Parasite Status of the group should be examined by techniques appropriate to their detection as outlined in previous chapters. Clinical or subclinical infestations with nematodes are common; Occurrences at this time in the sheep's life, before immunity is properly developed and when pasture contamination can be high. Infections with coccidia, cryptosporidia, or Mycoplasma (Eperythrozoon) ovis are significant causes of illthrift and should be examined as outlined in previous chapters.

The Trace Element Status of the group should be examined if the cause cannot be found with the above examinations. Many trace element deficiencies are area deficiencies or in an area are strongly associated with certain soil types. If trace element deficiency is a cause it is likely that there will be some prior history of this problem in the area. Diagnosis by response to supplementation is a common approach and the diagnostic aspects of the trace element deficiencies are outlined under their specific headings in this text.

Examination of the above-mentioned possible causes is time-consuming and costly and, if there is a residuum of unsolved cases, they are likely to remain undiagnosed.

Infectious Agents can produce enteric lesions and illthrift (e.g. coronavirus and yersiniosis) and the malabsorption which results may be manifested by weight loss and by chronic diarrhea. They are differentiated on the initial postmortem examinations.

**BULLER STEER SYNDROME**

**Synopsis**

**Etiology** Unknown. Behavioral problem of steers in feedlots

**Epidemiology** Prevalence varies and increases with increasing age and weight at entry.

**Clinical Findings** Areas of denuded hair, subcutaneous hematomas, other traumatic injuries

**Treatment** Symptomatic

**Control** Removal from pen

**ETIOLOGY**

The buller steer syndrome is a behavioral problem in cattle confined in feedlots of unknown etiology. Within a pen of cattle, one or more cattle persistently ride a particular individual or individuals of the group. The ridden animals are referred to as bullers. There have been several suspect etiologies. Improper placement of hormonal growth implants has been suspected as being associated.

**EPIDEMIOLOGY**

**Occurrence**

The syndrome occurs only in cattle in feedlots. The prevalence varies, but in one study ranged from 0 to 11% with a mean of 2.7%. The prevalence increases with increasing weight and age. The case fatality has been estimated at 1%. The incidence of occurrence is higher in the summer and the fall and during the first 30 days of the feeding period.

Epidemiological studies indicate that bullers occur as a point source epidemic with the cause occurring soon after cattle arrive in the feedlot and mingle into pen groups. The peak incidence of bullers occurs much sooner after arrival and declines much quicker in older cattle. Bullers occur significantly sooner after mixing in older cattle than in younger cattle. The pen prevalence also increases as cattle become older on arrival at the feedlot and are more aggressive. As the prevalence of intact bulls increases in pens of cattle, so does the prevalence of bullers, presumably due to more aggressiveness in the bulls.

**Risk factors**

Postulated causative and risk factors include the incorrect timing and administration of hormonal growth implants, reimplantation and double dosing, estrogenic substances in feeds, pheromones in the urine of certain cattle, improper or late castration of young cattle, weather and seasonal factors, disease, group size, and dominance behaviour. However, these factors have not been well substantiated and controlled studies have found little influence of
Economic importance

The syndrome has been ranked along with acute undifferentiated bovine respiratory disease and footrot as one of the three most important disease syndromes in beef feedlots in North America. In addition to the economic loss from decreased weight gain, injury, treatment, death, and carcass condemnation, there is economic losses associated with extra handling necessary to accommodate affected cattle, the disruption of uniform marketing of cattle, especially in custom feedlots, and the need for extra pens in which to house the bullers. The importance of the syndrome includes the animal welfare aspects.

Bullers may be at significantly greater risk of illness and mortality (from bacterial pleuropneumonia) than other steers. The association between illness, mortality, and bullers among individuals was greatest among the oldest yearlings. 

CLINICAL FINDINGS

Two types of bullers are identified. Type 1 true bullers stand as if they were a heifer in estrus and do not move away or show agonistic behaviour when being mounted by rider cattle. There can be several rider cattle in a pen and type 1 bullers are rapidly damaged. Type 2 bullers are animals that appear low in social dominance. They use aggression to discourage riders and will lie down to avoid being ridden.

Affected animals show areas of denuded hair and have extensive subcutaneous hemorrhage. The hematomas may become large. In addition, there can be lacerations of the skin caused by the riders. In some cases, the hematomas may become so large that they can be seen under the skin. In other cases, the hematomas may be so large that they can be palpated. In some cases, the hematomas may be so large that they can be palpated. In some cases, the hematomas may be so large that they can be palpated. In some cases, the hematomas may be so large that they can be palpated. In some cases, the hematomas may be so large that they can be palpated.

HISTORICAL ASPECTS

A disease of newborn calves called the "weak calf syndrome" was first recognized in Montana in 1964. It has been recognized throughout the US and other countries since then, and is considered a major economic loss in beef cattle herds. In the earlier descriptions of the syndrome, calves were affected by 10 days of age, and approximately 20% were affected at birth. Morbidity ranged from 6% to 15%. In some herds, sporadic abortions occurred before calving season of the herd began. In some cases, affected calves died within minutes after being born with varying degrees of obstetrical assistance.

In calves which survived for a few days, clinical findings included lassitude, depression, weakness, variable body temperature, a reddened and crusty muzzle, lameness, and reluctance to stand, enlargement of the carpal and tarsal joint capsules along with pericardial subcutaneous swellings, and a hunched-up back if they stood. Diarrhea occurred in some calves after a few days of illness but was not a major clinical finding. Treatment was ineffective and the case fatality rates ranged from 60 to 80%.

At necropsy, the prominent lesions were hemorrhage and edema of the subcutaneous tissues over the carpal and tarsal joint regions and extending distally. Polysynovitis with hemorrhagic synovial fluid often containing fibrin was also common. Erosive and hemorrhagic lesions of the forelimbs and abomasum also occurred. Several different pathogens were isolated from these calves but no consistent relationship between the pathogens and the lesions was ever determined.

In retrospect, the case definitions were not well described and it is possible that several different diseases of newborn calves were lumped into the remnant of the weak calf syndrome. As more detailed clinical and laboratory examinations of sick newborn calves have been done over the years, some of the causes of the original syndrome have been identified as certain diseases of newborn calves which are characterized by such non-specific signs as lack of desire to suck, weakness, and failure to respond to therapy.

A wide spectrum of clinical and pathological findings has been associated with the weak calf syndrome. In the common situation, which is a major diagnostic challenge, calves are born weak and die within 10–20 minutes after birth; sometimes they live for up to a few days. At necropsy there are no obvious or only few lesions to account for the illness. Calves which are weak after birth due to traumatic injuries associated with dystocia or other significant lesions can be accounted for according to the nature and severity of the lesions. Reports from Northern Ireland in recent years indicate that in dairy herds the incidence of the weak calf syndrome has ranged from 10 to 20% of all calves born. Field observations in problem herds found that the gestation period is of normal duration but parturition is usually prolonged with the first and second stages of labor lasting 24 hours. Affected calves usually are born alive but are unable to sustain breathing following birth. Despite resuscitation efforts, they commonly die within 10 minutes often accompanied by prominent incoordinated movements of the limbs. Some calves are stillborn and whether or not this is a variation of the syndrome is uncertain. In a report from the UK, the syndrome occurred in calves born from heifers and was characterized...
by failure to breathe at birth, or breathing with difficulty, and/or failing to move after birth, and failure to suck. The term stillbirth/perinatal weak calf syndrome has been suggested as more appropriate.

**Dummy calf syndrome**

A variation of the weak calf syndrome is the dummy calf syndrome reported from the southern US. Affected calves appear normal at birth, are generally alert, but lack the instinct or the desire to seek the teat or suck after birth and for up to several hours later. The syndrome may occur in calves of any birth weight. The incidence has been highest in purebred Brahman females but it has also occurred in Aberdeen Angus, Hereford, Chianina, and Brown Swiss breeds of cattle. Field observations indicate that affected calves did not stand for up to 1-2 hours after birth to initiate teat-seeking. Dummy calves appear to lack the sensitivity to teat-seek and if they fail to locate a teat by about 4-5 hours after birth they commonly lose the sucking reflex and then require intensive nursing care by bottle feeding to initiate sucking. In calves which fail to suck and ingest colostrum, hypothermia, hypoglycemia, and neonatal infections are common complications. Concurrently, the dam loses interest in the calf and may abandon it. The cause is unknown but is thought to be a behavioral disorder inherent in some breeds; this has not been supported with any scientific evidence.

**ETIOLOGY AND EPIDEMIOLOGY**

The etiology of the weak calf syndrome is unclear, but several epidemiological observations have suggested some possible causes. These include:

- Fetal infection near term
- Underdevelopment because of nutritional inadequacy of the maternal diet during pregnancy
- Placental insufficiency
- Maternal dietary deficiencies of selenium and vitamin E
- Hypothyroidism
- Traumatic injuries associated with dystocia and excessive force during obstetrical assistance
- Fetal hypoxia from prolonged parturition.

**Fetal infections**

Fetal infections in the last few days before term can result in stillbirth or weak calves which may die within hours or days after birth. In one series of 293 weak calves in Northern Ireland, leptospiral infection was present in 25% of them. Calves in which leptospirosis antigen was detected in the placenta were significantly lighter by an average of 6 to 10 kg than calves with no antigen in the placenta. Calves infected with *Leptospira* in the uterus were more likely to be infected by *Arcanobacterium pyogenes* or *Bacillus* species, and infection of the placenta is associated with a lower bodyweight. The adrenal gland, lung, and placenta are most useful tissues to examine for leptospiral antigen.

There is some evidence that an immune inadequacy based on T lymphocyte function may be associated with the weak calf syndrome in Japanese Black calves but the data are not compelling.

An unidentified type of adenosavirus has been associated with the weak calf syndrome on a large dairy farm in Israel. At birth the calves were reluctant to suck or drink colostrum and were force fed colostrum with a gastric tube. Affected calves were weak at birth, unable to rise without assistance and when forced to move, walked stiffly, suggestive of polyarthritis. An adenosavirus was detected in the feces, synovial fluid, and aqueous humor of affected calves.

**Maternal nutritional deficiency causing fetal underdevelopment**

**Hypothyroidism due to iodine deficiency**

In the pregnant dam has been considered on the basis of thyroid hyperplasia in some calves. Analysis of the laboratory data from 365 calves which died from the stillbirth/perinatal weak calf syndrome in Ireland, found some differences between calves with an abnormal and normal thyroid gland. Abnormal thyroid glands had a lower selenium concentration in the kidneys.

However, the experimental reproduction of iodine deficiency in pregnant heifers by feeding an iodine deficient diet over the last 4 to 5 months of pregnancy resulted in clinical, pathological changes and pathological changes in the thyroid glands of both the heifers and their calves, but all calves in the iodine deficient group were born clinically normal.

**A maternal dietary deficiency of selenium**

in pregnant cattle has also been examined but field trials have failed to show any protective effect from the parenteral administration of pregnant cattle with selenium. The parenteral administration of both selenium and iodine to pregnant cattle did not have any effect on the incidence of the syndrome between treated and untreated herds where the incidences were 7.9% and 7.4%, respectively. A general nutritional inadequacy in the maternal diet can result in underdevelopment of the fetus and the birth of smaller than normal calves but the deficiency usually must be grossly inadequate. Radiographic examination of affected calves found that intrauterine growth retardation is not a common feature in calves dying with the syndrome.

**Placental insufficiency**

Intrauterine growth retardation associated with feto-placental dysfunction has been described in Japanese Black beef calves. Affected calves were weak when born at term and were underweight compared to normal calves. Anemia due to bone marrow dysfunction was present in affected calves and presumably was associated with intrauterine growth retardation. Dams delivering weak calves had lower serum concentrations of estrone sulfate during late pregnancy than those of normal calves suggesting a feto-placental dysfunction. The dysfunction was influenced by sires and maternal families.

**Fetal hypoxemia**

Fetal hypoxemia due to a prolonged parturition or dystocia may be a cause of the weak calf syndrome. While asphyxia is not an integral part of normal delivery, it is still an important cause of fetal death during abnormal parturitions. Various predisposing factors can cause prolonged interference with fetal blood or oxygen supply, which results in death during delivery or shortly after.

In newborn mammals subjected to anoxia, initially there is a period of struggling and rapid gasping during which blood pressure rises and bradycardia becomes profound. A relatively short period of primary apnea follows, after which there is a period of more regular and deeper gasping, which may become more frequent terminally. This is followed by a period of secondary apnea, the heart rate continues to beat at a slowly declining rate, and blood pressure falls slowly. The brain lesions begin in lower brainstem nuclei and, as asphyxia becomes prolonged, progress to involve the cerebellar and thalamic nuclei and the cerebral cortex. Examination of blood gas values on newborn calves has shown that a prolonged parturition or delivery terminated by forced extraction may result in a severe acidosis due to oxygen deprivation. As blood pH drops, first vitality is reduced, subsequently vital organs like the brain are damaged and ultimately the fetus dies.

The bovine fetus appears relatively susceptible to anoxia which has been studied experimentally by clamping the umbilical cords of fetuses for 4-8 minutes, at 24-48 hours before expected birth, followed by a cesarean section 30-40 minutes later. Calves born following this procedure may die in 10-15 minutes after birth or survive for only up to 2 days. Under these experimental conditions, fetuses can survive anoxia for 4 minutes.
but most will die following 6 or 8 minutes of anoxia. During the clamping of the umbilical cord, there is a decline in the blood pH, PO$_2$, and standard bicarbonate levels and an increase in the PCO$_2$ and lactate levels. Hypoxia in neonatal calves can result in high plasma lactate concentrations, which contributes to a progressive primary metabolic acidosis.

During the clamping there is also increased fetal movement and a release of meconium which stains the calf and the amniotic fluid. Those which survive for a few hours or days are dull, depressed, cannot stand, have poor sucking and swallowing reflexes, and their temperatures are usually subnormal. They respond poorly to supportive therapy.

Some calves whose umbilical cords were clamped for 4 minutes were born weak, and made repeated efforts to raise their heads and move onto their sternum but were unable to maintain an upright position for long. These calves become hypothermic, dull, and their sucking and swallowing reflexes are present but weak. These calves are usually too weak to suck the cow even when assisted, and commonly develop diarrhea and other complications.

Dystocia and traumatic injuries at birth

Dystocia is a major cause of neonatal mortality in range beef cattle and may be a cause of the weak calf syndrome because of fetal hypoxia or traumatic injuries associated with obstetrical assistance. In a study of 13,296 calvings over a period of 15 years in two research herds in Montana, calf mortality due to dystocia accounted for the single largest loss category through the first 96 hours postpartum. Dystocia accounted for 51% of calf deaths and 53% of dystocia deaths occurred in calves which were born without assistance. Calf deaths from primiparous 2- and 3-year-old dams accounted for 41% of total mortality. Necropsies done on 796 of 899 calves found that 77.7% were anatomically normal and 22.3% abnormal. At necropsy of the calves which died associated with dystocia the findings included a froth-filled trachea, non-functional lungs, bruises, contusions, hemorrhages, bone fractures, and joint dislocations. It was concluded that the provision of adequate obstetrical assistance at the right time could have reduced the mortality associated with dystocia.

Similar reports of weakness following dystocia have been reported; in some cases a collapsed trachea is present. In a study of parturient calf mortality in Australia, death rates as high as 44% from heifer groups have been reported. The death rate was significantly higher in male calves than female calves. Pathological changes in many of the dystocia-related deaths were minimal but a congested swollen tongue was a definitive lesion.

Traumatic injuries of calves at birth are caused primarily by the mechanical influence of traction during delivery and can result in asphyxia and a high perinatal mortality rate. Excessive traction is the most important cause of rib and vertebral fractures in the calf during dystocia. A series of 235 calves which died perinatally were examined by necropsy to determine the possible causes of death related to dystocia. Most of the parturitions were protracted and needed veterinary assistance, and 58% of the calves had pathological evidence of asphyxia. Calves delivered by extraction had pathological evidence of asphyxia more often than those born unassisted or delivered by cesarean section. Intrapulmonary amniotic material may be present in the lungs and represent evidence of perinatal respiratory distress. The aspiration of small amounts of amniotic fluid with or without meconium is common in calves and is not associated with hypoxemia, respiratory acidosis, or failure of passive transfer.

Premature expulsion of placenta

Premature expulsion of the placenta has been associated with perinatal calf mortality. Field observations indicate that the majority of affected fetuses die from fetal hypoxia during stage two of calving. The most significant risk factor associated with premature expulsion of the placenta was fetal malpresentation and malposition. Prolongation of the second stage of parturition allows for sufficient detachment of the placenta for it to occupy the posterior part of the genital tract. The placenta is frequently expelled together with the calf. In one series of cases, there was no significant relationship between the occurrence of premature expulsion of the placenta and parity, calving difficulty, previous calving history, or sex of the calf.

Necropsy findings

All calves which die should be examined by necropsy to identify possible causes. It is important to establish if there is one disease complex or several different diseases of newborn calves. In the weak calf syndrome described in Northern Ireland, at necropsy, many calves had petechial hemorrhages in the thymus gland, on the ventricular epicardium and the parietal pleura and endocardium. These lesions were similar to those present in animals which died of acute terminal asphyxia. The gasps made in response to asphyxia in utero result in amniotic fluid being inhaled into the respiratory tract. In one study, 84% of stillborn calves had these lesions of asphyxia. It is well established that asphyxiation during birth is a major factor in intrapartum stillbirth in piglets and contributes to early postnatal mortality. Froth may be present in the caudal trachea of some calves which die within 10–20 minutes after birth.

Varying degrees of subcutaneous edema of the head and/or bruising of the rib cage are also common. Fractures of the ribs are common, accompanied by intrathoracic hemorrhage. Vertebral body fractures occur commonly at the thoracolumbar region and may be accompanied by intra-abdominal hemorrhage. The lungs may be inflated normally, partially inflated, or not inflated. Severe bruising and hemorrhage occur around the costochondral junctions, the sternal extremities of the costal cartilages, and over the sternum and shoulder regions. In some cases, the traumatic lesions are severe and may involve primarily the right side of the rib cage. Severe subcutaneous hemorrhage and edema may be present over the carpal and fetlock joints due to the pressure applied by the obstetrical chains or ropes.

In the syndrome described in the US, the lesions either appeared at birth or developed in the first few weeks of life. At necropsy the prominent lesions are marked edema and hemorrhages of the subcutaneous tissues over the carpal and tarsal joints and extending distally down the limbs. The synovial fluid may be blood-tinted and contain fibrinous deposits. Erosions or ulceration of the gastro-intestinal tract, petechial hemorrhage of internal organs, involution of the thymus gland, and hemorrhages in skeletal muscle have also been present.

Samples for confirmation of diagnosis
- Bacteriology – fetal liver, lung, stomach content, adrenal gland, placenta (CULT). Special detection techniques for Leptospira antigens.
- Histology – fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (LM, IHC)

Differential diagnosis

Determination of the cause of the weak calf syndrome in a herd is often difficult because the limits of the case definition cannot be determined. Several risk factors may interact to contribute to the disease. The most common definition is a calf that is alive at birth, appears normal otherwise, but either fails to breathe or breathes for less than about 10 minutes and then dies. If they survive for several hours or a few days, affected calves are usually in sternal recumbency, depressed, reluctant to stand unassisted, reluctant to walk, and not interested in sucking. They may not respond favorably to supportive therapy.

Case definition

When an epidemic of the disease is encountered, an epidemiological investigation of the herd is necessary in an attempt to identify possible risk factors.
The patterns of occurrence should be determined:
- Is the problem more common in calves born to heifers than cows? In some situations, the owner may provide more surveillance for the calving heifers and less for the mature cows with a consequent greater incidence of weak calves born from the cows.
- Is there any evidence that parturition is prolonged in the heifers or the cows and what are the possible reasons?
- How long are heifers and cows in the herd allowed to calve unassisted before obstetrical assistance is provided?
- Is it possible that some nutritional, management or environmental factor is interfering with normal parturition?
- Is the condition more common in male or female calves and what are the relative birth weights?
- How soon after birth are the calves affected?
- What is the cause of the illness after the first clinical abnormalities are noted?
- What level of calving surveillance and assistance is being provided by the attendants?
- The veterinarian should make every effort to clinically examine a representative number of affected calves.

TREATMENT
Calves born weak, unable to stand, lacking the instinct to seek the teat or lacking a suck reflex, need intensive care including force-feeding of colostrum and the provision of warm surroundings to prevent hypothermia and other complications.

CONTROL AND PREVENTION
Control and prevention of the weak calf syndrome is based on empirical observations beginning with insuring adequate nutrition of the dam to avoid any possible nutritional factors affecting neonatal calf vitality. The provision of adequate calving time and competent obstetrical assistance when necessary is also crucial to avoid prolonged parturition and fetal hypoxia in calves.

When epidemics of the disease are occurring, the surveillance of calving must be intensified, and it may be necessary to intervene with obstetrical assistance earlier than usual. Determination of the cause may require that the veterinarian attend several calvings, make detailed clinical examinations of the length of parturition and observe the parturition process and the health of the calves at birth.

WATER MOUTH OF LAMBS (RATTLE BELLY, SLAVERS)

**Synopsis**

**Etiology**
Non-enteropathogenic *E. coli* endotoxemia predisposed by failure of passive transfer

**Epidemiology**
Higher risk with intensive housing with poor hygiene

**Clinical findings**
Loss of sucking reflex, retention of meconium or feces, excessive mucoid saliva, abomasal distension

**Lesions**
None specific

**Diagnosis**
No pathognomonic

**Treatment**
Fluids and energy via stomach tube. Antimicrobials.

**Control**
Antimicrobials at birth, pen hygiene, ensure adequate colostral transfer

**Etiology**
This disease is believed to be the result of endotoxemia in young lambs. It is postulated that the neutral pH of the abomasum in newborn lambs, coupled with low concentrations of colostral immunoglobulin in the gut, allow rapid multiplication of non-enteropathogenic strains of *Escherichia coli* in the gut, and to some extent systemically, to result in endotoxemia.

**Epidemiology**

**Occurrence**
The syndrome is primarily reported in lambs in Great Britain but has also been reported in New Zealand and in goat kids in Spain and North America.

**Animal and environmental risk factors**
Lambs 12 to 72 hours of age are affected. The disease is seen under all management systems but is rare in pastured flocks and occurs most commonly in lambs kept in intensive housing where there is poor hygiene of the lambing environment. Lambs from prolific ewes are at risk and the disease is more common in triplets than twins or singles.

**Delayed or poor colostral intake** is a major risk factor and situations that predispose this may lead to outbreaks. A high prevalence has occurred in ram lambs castrated by the use of an elastic band at a very young age and the resulting pain may have dissuaded them from feeding.

Other risk factors, all of which reduce sucking by the lamb, are inclement weather, misthinking, maternal agalactia, competition between twins or triplets, low vitality, and ewes in poor condition.

**Experimental reproduction**
An equivalent clinical syndrome is reproducible by administering non-enterotoxigenic strains of *E. coli* by mouth to colostrum-deprived lambs, all of whom died within 24 hours.

**Economic importance**
Watery mouth disease is a major cause of mortality of housed newborn lambs in Great Britain and is reported to be the cause of approximately 25% of all deaths of lambs in indoor intensive lambing systems. Where conditions allow morbidity rates may approach 24% and without early treatment case fatality rates are high.

**Pathogenesis**
Gram-negative bacteria, non-enterotoxigenic and non-enteropathogenic *E. coli* in the environment, are ingested as a result of a contaminated environment, or from a contaminated fleece, and survive passage through the neutral pH of the abomasums to be absorbed into the systemic circulation by the natural pinocytosis that occurs in the intestinal epithelium of newborn ruminants, to produce an endotoxemia.
CLINICAL FINDINGS
Affected lambs are normal at birth but become sick at 24–48 hours and up to 72 hours old. The disease is characterized by dullness, a complete failure to suck, and excessive mucoid saliva around and drooling from the mouth. As the disease progresses there is hypothermia, failure to pass faeces, cold extremities, depression to the point of coma, anorexia and, in the late stages, abdominal distension and recumbency, but rarely diarrhea. The alimentary tract is full of fluid and the lamb rattles when it is shaken. Some lambs are hypothermic but the temperature is normal at the onset of the condition and falls to subnormal as the disease progresses. Progress is rapid with death 6–24 hours after the first signs of illness.

CLINICAL PATHOLOGY
Total protein concentrations and base excess values are significantly elevated compared to normal lambs. Blood glucose concentrations are normal but may be low in the terminal phase of the disease.

NECROPSY FINDINGS
There are no findings specific to the syndrome. The abomasal contents are fluid and mucoid, and contain small milk curds and the intestine is gas filled.

TREATMENT
Treatment with intramuscular amoxycillin and clavulanic acid, intravenous flunixin meglumine, and oral rehydration fluid, when administered early in the clinical course, has resulted in a high recovery rate in field cases. Dextrose solution should also be given to those lambs that are hypoglycaemic and external warming should be provided. Other recommended treatments include emptying the alimentary tract by purgation or enema.

DIFFERENTIAL DIAGNOSIS
Most neonatal disease of lambs is manifest with diarrhea which is not present in warty mouth. The early stages of Colisepticaemia and Clostridium perfringens type B or C present with similar clinical signs but are easily differentiated later in the clinical course or at post mortem examination. Hypothalamic/thyrohypophyseal stress can present with similar clinical findings but the history and environmental circumstances of occurrence differ.

CONTROL
In outbreaks the administration of antibiotics to all newborn lambs within 15 minutes to 2 hours of birth dramatically reduces the occurrence of further cases. Fresh or frozen sheep or cow colostrum should be supplemented to lambs at risk. The provision of ewe colostrum at 50 mL/kg body weight within 6 hours of birth prevents the disease.

Lambing areas and associated pens and yards should be kept clean and fresh bedded. Contaminated fleece should be removed from around the udder of the ewe prior to lambing and every effort should be made to insure early and adequate colostral intake by newborn lambs, especially for twins and triplets.

REVIEW LITERATURE

COLD COW SYNDROME
This is a herd disease problem reported from the UK in cows freshly turned out onto lush pasture with a high (27–43%) soluble carbohydrate content. There is a high morbidity (up to 80%) and a large number of outbreaks in an area. The syndrome includes hypothermia, dullness, inappetence, agalactia, and profuse diarrhoea. Affected cows feel cold to the touch. Some have perineal edema, some collapse. The herd milk yield falls disastrously but is regained if the cows are returned to the same pasture. There is no obvious clinical syndrome, especially if nutrition is inadequate.

THIN SOW SYNDROME

Syndrome
The syndrome is the result of inadequate nutrition and unbalanced nutrition in pregnancy and lactation but can also result from parasitic or chronic infectious disease. The syndrome is characterized by anorexia, inappetence, and failure to gain weight as a problem in the 1970s as a result of poor understanding of the inter-relation between feed intake in pregnancy and that in lactation, combined with the move to intensive indoor housing of pregnant sows. Feeding of sows exacerbated social dominance/submissive relationships. The voluntary intake of food by sows during lactation is inversely related to the intake in pregnancy. Consequently sows that are fed at high levels during pregnancy will gain excessive weight during pregnancy but will voluntarily restrict feed intake during lactation and lose excessive weight during lactation. In contrast sows that are fed what is basically a maintenance ration 2.0–2.5 kg (4.5–5.5 lbs) of a balanced sow ration during pregnancy will gain adequate weight for conceptus and body growth and during lactation will consume adequate feed for lactation requirements and lose minimal weight in this period. Knowledge of sow nutrition has improved such that major problems with this syndrome should not occur but there is still a risk of

ETIOLOGY

The thin sow syndrome is characterized by a failure of voluntary feed intake during lactation in the presence of an adequate energy and protein source. This syndrome is characterized by a failure of voluntary feed intake during lactation in the presence of an adequate energy and protein source. This syndrome is characterized by a failure of voluntary feed intake during lactation in the presence of an adequate energy and protein source.
inadequately feeding sows selected for lean genotype and high litter size and weaning weights. First and second litter gilts may require more feed to provide for body growth.

**CLINICAL FINDINGS**

Within a herd the thin sow syndrome develops over a period of months and often one or two pregnancy cycles, with a gradually declining body condition of the group until 20% to 30% of sows have a low body condition score. No abnormalities are evident on clinical examination but the sow fails to regain weight after weaning, particularly sows after their first litter. The most critical period for weight loss is the first 2 weeks after weaning. Affected sows have a poor appetite but often show pica and excessive water intake and may be anemic.

**CONTROL**

**Feeding during pregnancy**

Currently the risk for the thin sow syndrome exists where it is assumed that all pregnant sows can be fed a standard amount of ration. Problems are likely to occur when sows are run in groups and fed as a group where timid sows are likely to be bullied out of their required share of food.

Individual feeders or stall feeding will prevent this.

**Feeding during lactation**

The critical issue is to ensure adequate feed and energy intake during lactation. This can be achieved by:

- not feeding to excess during pregnancy
- restricting the feed intake of sows in the first few days after farrowing to encourage better feed intake in later lactation
- ensuring an adequate and constant supply of water
- ad lib feeding during lactation
- a high-energy-density lactation diet enclosing the creep with heat for the piglets so that the farrowing house can be kept at a lower temperature 65°F (6°c) for the sow control of parasitic disease.

**Condition scoring** is a valuable guide to the feeding of individual sows and for a judgement of feeding practices in the herd as a whole. On a score of 1 to 5 it should be very rare to find sows with condition scores of 1 or 5. The optimum is to have sows entering the farrowing house between condition score 3 and 4 and not less than 2.5 at weaning. First and second parity sows in poor condition at weaning are best ‘skipped’ at the first heat and mated on the second heat. Methods for condition scoring and guidelines can be found at http://www.defra.gov.uk/animalh/welfare/farmed/pigs/p3480/pigscotorc.htm

**ACUTE HEPATITIS (POSTVACCINIAL HEPATITIS) OF HORSES (THEILER’S DISEASE, SERUM HEPATITIS)**

An acute hepatopathy of horses often associated with administration of equine biological products such as tetanus antitoxin.

**ETIOLOGY**

Etiology is unknown, although an infectious agent is suspected.

**EPIDEMIOLOGY**

The disease occurs in horses administered equine serum or tissue products. The first reports of the disease were in horses in South Africa administered equine serum as prophylaxis for Africa Horse Sickness. Outbreaks of the disease have occurred in horses in Africa, Europe, and North America administered equine serum as prophylaxis for a variety of diseases including African horse sickness, encephalomyelitis, botulism, *Strep. equi* infection, tetanus, and influenza and in mares given pregnant mare serum. Most sporadic cases of the disease appear to be associated with administration of tetanus antitoxin.

The disease is reported only from adult horses (>1 year of age) and most cases are reported in the summer and autumn. There is a suspicion that pregnant mares are at increased risk.

The morbidity rate in outbreaks among horses administered equine serum ranges between 2 and 18%, although the rate among horses administered tetanus antitoxin as prophylaxis following injuries is clearly much lower. Acute hepatitis developed in 4 (0.4%) of 1260 horses >1 year of age administered commercial equine plasma at one institution in the United States over a 6-year period. The disease can occur after intrauterine infusion of equine serum to mares.

The case fatality rate is between 50 and 90%.

The disease occurs sporadically in horses that have not been administered equine biological products. There are reports of in-contact, non-treated horses developing the disease.

**PATHOGENESIS**

 Destruction of hepatocytes results in hepatic dysfunction. Hepatoencephalopathy develops in severely affected horses.

**CLINICAL FINDINGS**

The disease usually occurs after an incubation period of 40-70 days (range 27-165 days). Depression, anorexia, and icterus are evident in mildly affected cases. There may be mild to moderate colic. Body temperature and heart rate are usually normal. Acutely affected, or horses observed infrequently, can die unexpectedly. Signs of hepatoencephalopathy include restlessness, excitement, compulsive walking and head pressing, abnormal head position, seizures, apparent blindness, muscle tremors, and ataxia. Affected horses often injure themselves by walking into fences and troughs.

**CLINICAL PATHOLOGY**

Leukocytosis with neutrophilia and mild lymphocytopenia is common. The hematocrit and plasma total protein concentrations may be mildly increased. Hyperbilirubinemia and an increase in direct (conjugated) bilirubin concentration are present and serum bile acid concentration is increased, as is serum activity of liver specific enzymes aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), and sorbitol dehydrogenase (SDH). Increases in serum GGT activity is often less than expected for the increases in serum AST, SDH, and bile acid concentrations, likely reflecting the primary insult to hepatocytes.

Hypoglycemia (<2 mmol/L, 40 mg/dL) and hyperammonemia (>150 µmol/L) may be severe. Clotting time, especially the one stage prothrombin time, may be prolonged.

**NECROPSY FINDINGS**

The liver may be enlarged, normal or shrunken and discolored slightly yellow to green. There is severe centrilobular necrosis of hepatocytes with mild infiltration of lymphocytes and plasma cells. Alzheimer type II astrocytes are present in the brains of horses with encephalopathy.

**Differential diagnosis**

Diagnostic confirmation antemortem is achieved by examination of a liver biopsy, although this should not be performed in animals with coagulation abnormalities.

**Differential diagnosis list:**
- Acute aflatoxicosis
- Rubratoxocosis (Penicillin rubrum)
- Pyrodoxine alaid shocked intoxication
- Dioxin intoxication
- Idiopathic hyperammonemia.

**TREATMENT**

Treatment is essentially supportive and consists of correction of metabolic and acid-base abnormalities, reduction of plasma ammonia concentration, and preventing horses with hepatoencephalopathy from injuring themselves.

Hypoglycemia and dehydration can be corrected by intravenous administration of
5% dextrose and isotonic electrolyte solutions. Metabolic acidosis can be corrected by infusion of sodium bicarbonate. Plasma transfusions may be necessary to correct coagulation abnormalities.

Hyperammonemia can be treated by giving neomycin (20 mg/kg, orally, every 6 hours for 4 doses) or lactulose (0.25 mL/kg, orally every 8 hours) to decrease absorption of ammonia from the gastrointestinal tract.

Sedation with xylazine or similar compounds may be necessary to prevent the animal injuring itself. The affected horse should be housed in an area where it has the least opportunity to injure itself, and may need to be fitted with a padded helmet.

CONTROL
Minimal use of biologics, including plasma, of equine origin is prudent.

REFERENCES

GRANULOCYTOPENIC DISEASE OF CALVES
A fairly widespread disease of recent origin, granulocytopenic disease of calves is commonly ascribed to poisoning with furazolidone. Affected calves are those reared on milk replacer and sometimes, but not always, receiving prophylactic antibiotics.

Affected calves show persistent fever, increased salivation and nasal discharge, and there are hemorrhages and necrotic lesions in the mouth and lower alimentary tract. The disease is characterized by decreased myelopoiesis in bone marrow, neutropenia, and thrombocytopenia. The course varies from 2 to 5 days, and the mortality rate is high, apparently from bacterial invasion. Pneumonia, peritonitis, and enteritis are common accompaniments. Fusobacterium necrophorum can be isolated from necrotic lesions. These clinical, pathological, and hematological findings resemble those of radiation sickness, and poisoning by bracken fern.

The disease has been related to long-term feeding of furazolidone (2 mg/kg BW daily), either in the milk replacer or as a specific therapy, and the disease can be reproduced by this means. At higher dose rates (20–30 mg/kg BW) nervous signs, including convulsions, and death follow within a few days; both syndromes may occur at the same time in a group of calves.

SWEATING SICKNESS (TICK TOXICOSIS)

ETIOLOGY
Unknown, associated with bites of Hyalomma truncatum.

EPIDEMIOLOGY
Reported in Africa, India, and Sri Lanka affecting calves 2 to 6 months of age.

CLINICAL FINDINGS
Fever, salivation, lacrimation, hyperemia of mucous membranes, epistaxis, and severe dermatitis, necrosis of oral epithelium.

Lesions
Dermatitis and necrotic stomatitis, disseminated intravascular coagulopathy.

Treatment
Symptomatic and use of hyperimmune serum.

Control
Tick control.

ETIOLOGY
The cause has not been identified, but it behaves as though it were an epitheliotropic toxin produced by the salivary glands of certain strains of the tick Hyalomma truncatum. Not all strains of H. truncatum have the ability to produce the disease and antigens unique to sweating sickness-inducing strains are described.

EPIDEMIOLOGY
Attempts to transmit the disease between animals by mediate or immediate contact and by injections of tissue or blood are unsuccessful. The disease occurs in Central, East and South Africa, Sri Lanka, and probably southern India. Only calves 2–6 months of age are affected as a rule but rare cases occur in adults. Sheep, pigs, and goats are susceptible, although the disease does not naturally occur in them, and the disease has been produced experimentally in dogs. Sweating sickness occurs at all times of the year but is most prevalent during the wet season when ticks are more plentiful. The morbidity rate varies with the size of the tick population but is usually 10–30%. The case fatality rate is up to 30%.

PATHOGENESIS
The clinical signs begin 4–7 days after the ticks attach, probably 3 days in experimental infestations. The effects are dose-specific; if the ticks are removed very early there is no clinical response and the animal remains susceptible; with a longer exposure before the ticks are removed the animal becomes immune but shows no clinical signs. With longer exposure of more than 5 days the subject develops the full-blown clinical disease and may die. If it recovers it has a solid and durable immunity.

CLINICAL FINDINGS
There is a sudden onset of fever up to 41°C (106°F), anorexia, hyperemia of the mucous membranes, and hyperesthesia. The animal is lethargic, depressed, dehydrated, and has a serous then mucopurulent ocular discharge, an arched back, and a rough coat. There is an extensive, moist dermatis commencing in the axilla, groin, perineum, and at the base of the ears which extends to cover the entire body in bad cases. ‘Sweating’ refers to this moist dermatitis. The hair is matted together by exudate and moisture collects in the form of beads on the surface. The eyelids may be stuck together. Subsequently patches of the skin and hair are rubbed off or can be pulled off to leave raw, red areas of subcutaneous tissue exposed. The tips of the ears and tail may slough.

Affected calves seek shade and their skin is very sensitive to touch. Later it becomes dry and hard, and cracks develop. Secondary bacterial infection and infestation with blowflies or screw-worm larvae are common sequelae. The oral mucosa is hyperemic at first and then becomes necrotic with the formation of ulcers and diphtheritic membranes. The calf salivates profusely, cannot eat or drink, and becomes emaciated and rapidly dehydrated. There are similar mucosal lesions in the vagina and nasal cavities, the latter causing dyspnea. The severity of the mucosal lesions appears to vary with different strains of the toxin. There may be abdominal pain and diarrhea in some calves.

The course may be as short as 2 days but is usually 4 or 5 days. In recovered animals the skin may heal and the hair may regrow, but there may be permanent, patchy alopecia and the calves may remain stunted and unthrifty.

CLINICAL PATHOLOGY
There is a severe neutropenia and eosinopenia and a degenerative left shift. a-globulin and beta-globulin levels are raised. Urinalysis indicates the existence of nephrosis but serum creatinine levels are normal. Dermatological examination fails to reveal the presence of any of the usual infectious causes of dermatitis.

NECROPSY FINDINGS
The lesions are essentially those seen clinically. There is also evidence of severe toxemia, dehydration, emaciation, and hyperemia of all internal organs and disseminated intravascular coagulation. The necrosis of the oral epithelium extends into the esophagus and may reach the forestomachs.
### Differential Diagnosis

The combination of extensive dermatitis and mucosal necrosis is unusual. Mucosal disease and bovine malignant catarrh may bear some resemblance and there could be difficulty in differentiation in areas where the tick *Hyalomma truncatum* occurs.

### Treatment

There is no specific treatment; efforts should be directed at relieving the severity of the dermatitis and mucosal loss. Non-steroidal anti-inflammatory drugs (NSAIDs) and broad-spectrum antibiotic cover is a logical regimen. Hyperimmune serum, produced in sheep and cattle by infesting them with *Hyalomma truncatum* at 6-week intervals for 2–5 occasions, is an effective treatment in pigs, sheep, and to a less extent calves.

### Control

Control is limited to control of the causative tick. No vaccine is available.

#### Equine grass sickness (Equine dysautonomia, grass disease, mal seco)

<table>
<thead>
<tr>
<th><strong>Synopsis</strong></th>
<th><strong>Etiology</strong> Unknown</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Etiology</strong> Unknown</td>
<td></td>
</tr>
</tbody>
</table>

#### Etiology

The cause is unknown but is suspected to be a neurotoxin, possibly *Clostridium botulinum* toxin, based on epidemiologic data.

Evidence supporting a role for *Cl. botulinum* in the etiology of the disease included the isolation of toxin (BoNT/c) producing strains of *Cl. botulinum* type C from the ileum of 45% of horses with grass sickness and 4% of clinically normal control horses.

In addition to preventing the release of acetylcholine at cholinergic nerve terminals and thereby causing paralysis, a function that it shares with other botulinum toxins, BoNT/c is neurotoxic. Other studies have demonstrated increased numbers of bacterial organisms, including anaerobes, and a number of species of clostridia in feces of horses with grass sickness compared with normal horses.

Whether these findings represent a causative role of *Cl. botulinum* in grass sickness, or an effect of the modified gastrointestinal motility and on intestinal flora remains to be determined. Further evidence to support a role for *Cl. botulinum* in the etiology of grass sickness include the observations that low serum concentrations of antibodies to *Cl. botulinum* are associated with increased risk of the disease.

However, the hypothesis of a role for toxico- infectious botulism in grass sickness of horses does not explain the geographic distribution of the disease given that botulism occurs worldwide in horses and grass sickness does not.

#### Epidemiology

**Occurrence**

Grass sickness is not common and appears to be restricted in its distribution to all parts of Great Britain (including possibly Ireland), Sweden, and the northern and western coasts of Europe. A clinically and histologically indistinguishable disease, mal seco occurs in the Patagonia region of Argentina, southern Chile, and in the Falkland (Malvinas) Islands.

Horses, ponies, donkeys, zebra, Przewalski's horses, rabbits, and hares are the predominant species affected. The morbidity and mortality rates are not reported, but the incidence on farms with a history of the disease ranges between 0.4 and 16% per year or 2.1 grass sickness cases per 100 horses per year.

The case fatality rate for acute grass sickness is 100%, while that for the chronic form of the disease in horses treated at a referral hospital is 60–70%. Horses that survive the chronic form of the disease are often destroyed because of weakness and emaciation, although make complete recoveries. However, given the difficulty in establishing an antemortem diagnosis, it is unclear whether horses that fully recovered actually had chronic grass sickness.

#### Risk factors

**Animal risk factors**

The risk of disease is greatest in 4–5 year old horses (adjusted odds ratio of 1.9 compared with 0–3 year olds) and then declines such that the risk of disease is lowest in horses >12 years old (odds ratio 0.02 compared to that of 0–3 year olds). Cases in horses 10 months to 20 years of age have been encountered. Foals born of affected mares are clinically normal, there is no apparent breed predilection.

Horses at pasture are at increased risk (hence the colloquial name of the disease), although the disease does occur rarely in stabled horses. A recent (<14 day) change of pasture carries an increased risk (odds ratio 24) of development of the disease.

Horses that have been on the farm for less than 2 months are at increased risk of developing the disease. Horses on farms with previous cases of the disease are at increased risk (odds ratio 2.2–45) of the disease, although horses that have been in contact with animals with the disease are at reduced risk (odds ratio 0.1) of developing the disease.

**Environmental risk factors**

There is a marked seasonal distribution of cases, with the peak incidence occurring in early summer in the British Isles. Outbreaks of the disease are associated with the occurrence of cooler and drier weather than normal during the 2 weeks preceding the outbreak, although this is not consistently reported.

#### Farm or premise risk factors

As mentioned, farms with a history of horses with the disease are at increased risk of having further cases. For premises with previous cases of grass sickness there is an increased risk of the disease developing as the number of horses on the farm increases, with the presence of young horses, on stud farms and livery/riding schools, on farms having sand or loamy
Diseases characterized by alimentary tract involvement

soil, and those rearing of domestic birds and using mechanical fecal removal. The risk of recurrence of disease on a farm decreased with presence of chalk soil, cograzing ruminants, grass cutting of pastures, and manual removal of feces. There is no association between the disease and the type of pasture, nor with provision of supplementary feeds. Feeding hay or haylage is associated with a decreased risk of the disease. Any disturbance of the soil, such as by ploughing, increases the risk of disease.

Transmission

The disease is not contagious. Injection of normal horses with serum of affected horses causes lesions, but not clinical signs, consistent with the disease.

PATHOGENESIS

The clinical signs are attributable to widespread damage to the autonomic nervous system, resulting in sympathetic and parasympathetic dysautonomia that is most clearly evident in the gastrointestinal tract. Coincident with damage to the autonomic nervous system are increases in plasma concentrations of dihydroxyphenylalanine, epinephrine, norepinephrine, and dopamine, possibly because of increased secretion of these compounds from affected sympathetic ganglia and neurons. Lesions in the cranial nerves and brain stem are probably responsible for dysphagia and drooling evident in most cases. Rhinitis is associated with diminished nonadrenergic, noncholinergic (NANC) innervation, greatest in neurons positive for substance P or calcitonin gene-related peptide, of the nasal mucosa in subacute cases.20

Electrocardiographic examination of affected horses reveals evidence of loss of parasympathetic innervation of the heart, which is consistent with lesions in the terminal cardiac ganglia.21 Splanchic lesions are most severe in the myenteric and submucosal plexuses of the ileum, with less severe changes in the large colon and celiacomesenteric ganglia.33 There is also a reduction in interstitial cells of Cajal (cells involved in pacemaker activity and autonomic transmission within the gut).23 These neuronal changes are associated with a marked impairment of cholinergic activity in ileal tissue of affected horses.24 Because of the altered autonomic activity, peristalsis decreases (in chronic cases) or ceases (in acute cases) with subsequent accumulation of ingesta in the small intestine, stomach, and large colon. Death is due to emaciation in chronic cases or rupture of the stomach or intestine in acute cases.

CLINICAL FINDINGS

The clinical signs of grass sickness are varied, and accurate diagnosis on clinical signs alone is very difficult. The incubation period of the disease is approximately 10–14 days.35 Acute, subacute, and chronic forms of the disease are recognized, although some authorities use a designation of acute and chronic.26 In all cases, there is some dysphagia, resulting in drooling of saliva and trickling of ingesta from the nose. Dried food is impacted between the cheeks and the teeth and the animal plays at drinking. These signs are attributable to lesions in the cranial nerves. Most animals are depressed.

Acute cases the onset is sudden and the course of the disease is 1–4 days. Abdominal pain may be severe but also may be absent even in the presence of severe tachycardia. There is tachycardia (80–90/min may be >100), decreased to absent gut sounds, lack of defecation, and abdominal distension. On rectal examination, there are hard, dry pellets of feces, the large colon contains farm ingesta which has a corrugated feel that is quite distinct to the smooth surface of a primary colonic impaction. The small intestine is distended with fluid and readily palpable in the caudal abdomen. Nasogastric intubation yields a large (20 L) quantity of fluid. Uribination is frequent and may be accompanied by tenesmus. Affected horses may wander about in a restless manner and a fine muscle tremor occurs constantly, especially in the upper forelimb. Periodic attacks of patchy sweating occur commonly. There is noticeable salivation. Esophageal endoscopy reveals linear ulcerations resulting from reflux esophagitis.

Subacute cases have signs of mild colic, or may not have any signs of colic, in the presence of tachycardia, depression, reduced gastrointestinal sounds, and impaction of the large colon with characteristic corrugated appearance.25 The clinical course is 2 to 7 days and death is inevitable. Esophageal endoscopy reveals the presence of linear erosions in many affected horses.

Chronic cases the course is usually >7 days and is characterized by weight loss, patchy sweating, and intermittent colic. Horses stand with all four feet close together under them ('elephant on a tub stance') and have a tucked up abdomen. Dysphagia is evident and the gut is empty except for the colon and rectum which contain dry, hard feces. In the late stages the patient snores, the penis droops, and attempts are made to eat abnormal materials. Most cases of the chronic form have rhinitis, characterized by crusting of mucopurulent material on the turbinates and this is considered, in the presence of appropriate history and other clinical signs, almost pathognomonic for grass sickness. Application of phenylephrine (0.5 mL of a 0.5% solution) into one eye causes a dorsal deviation of the eyelashes of the upper eyelid in horses with grass sickness, but not in normal horses.27 There is a radiological discernible defect in esophageal motility in horses with grass sickness.28

Recurrent of the disease in a horse is exceedingly rare.

CLINICAL PATHOLOGY

Serum biochemical profiles and hematological examinations do not demonstrate pathognomonic changes.29 Signs of dehydration, electrolyte imbalances, hyperbilirubinemia, and elevations of serum activity of liver derived enzymes are all secondary to the disease.30 Urine from horses with grass sickness has higher specific gravity, protein and creatinine concentrations, and lower pH than that from unaffected horses,31 consistent with dehydration and electrolyte imbalances that occur with the disease. Peritoneal fluid is often abnormal, having an increased protein concentration and leukocyte count but, because of the considerable overlap with values in horses with lesions of the gastrointestinal tract requiring surgery, is of limited diagnostic value.32 Antemortem diagnostic confirmation can only be achieved by examination of biopsy specimens of the ileum,33 although biopsy of nasal mucosa has been suggested as an alternative.34 Examination of rectal biopsy is specific, but not sensitive, for the disease.

NECROPSY FINDINGS

In cases of short duration, the stomach and small intestines are distended with an excess of fluid and gas, and the colon is often impacted with corrugated ingesta coated with black material. In chronic cases, the alimentary tract is empty.

Histologically there is extensive degeneration of neurons of the autonomic nervous system without evidence of inflammation.35 These neurons include those of the ganglia (cranial cervical, stellate, coeliacomesenteric, etc.) and those of the myenteric and submucosal plexi of the intestines. Degenerative neuronal changes may also be observed in the central nervous system, including the oculomotor, facial, lateral vestibular, hypoglossal and vagal nuclei, the ventral horns of spinal cord and the dorsal root ganglia. This neuropathy is difficult to confirm unless fresh, well-fixed samples are submitted for histological examination. Immunohistochemical staining for synaptophysin aids in the differentiation between autolytic tissue and tissue from horses with grass sickness.34
GRANULOMATOUS ENTERITIS OF HORSES

The etiology of granulomatous enteritis is unknown. Infection with Mycobacterium spp. is suggested as a cause but demonstration of acid fast bacteria in tissue sections or by culture of gut or mesenteric lymph nodes of affected horses is rare and inconsistent. The disease occurs with greatest incidence in Standardbred horses between 1 and 6 years of age, although it does affect other breeds of horses. The disease is usually sporadic, although it has been recorded in siblings raised on the same farm. Estimates of incidence are not available. The disease has an almost 100% case fatality rate.

Accumulation of lymphocytes and multinucleated giant cells in the lamina propria is associated with villous blunting in the small intestine. There is malabsorption of carbohydrates and fats and excessive loss of protein in feces with subsequent hypoalbuminemia, edema, and weight loss. Weight loss and anorexia are the most common presenting signs. Fever is uncommon. Approximately one-third of horses have diarrhea or a history of abdominal pain. Affected horses may have a diffuse, scaling alopecia and excoriations especially of the coronary band. Rectal examination may reveal enlarged, soft mesenteric lymph nodes. Exploratory laparotomy in horses with signs of colic attributable to inflammatory bowel disease often reveals constricting circumferential bands in the large or small intestine.

Hematological and serum biochemical evaluation reveals:

- A mild, macrocytic anemia (hemoglobin <100 g/L, hematocrit <30%) with a normal leukogram
- Hypoalbuminemia is a consistent finding (<25 g/L, <25 g/dL) while the globulin concentration may be normal, low, or more commonly, high (>50 g/L, >5.0 g/dL)
- Plasma fibrinogen concentration is usually increased (>4 g/L, 400 mg/dL)
- There are no characteristic changes on serum biochemical analysis
- Peritoneal fluid is normal.

Absorption tests using (D(+)-xylose, glucose, or starch) may indicate diminished absorption of carbohydrate by the small intestine. The D(+)-xylose absorption test is performed by administering D(+)-xylose at a dose of 0.5 or 1 g/kg as a 10% solution by nasogastric intubation after an overnight fast. The concentration of D(+)-xylose in blood samples collected at 0, 1, 2, 3, 4, and 5 hours after dosing is determined. An abnormal test is one in which there is not an obvious peak in the D(+)-xylose curve and in which the peak concentration is lower than expected for a normal horse on a similar diet. Administration of a 10% glucose solution orally at a dose of 1 g/kg body weight results in an increase in plasma glucose concentration of >85% the baseline values in horses with normal small intestine. An increase of <15% over baseline is found in horses with small intestinal disease that impairs absorption.

DIFFERENTIAL DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differential diagnosis list:
- Acute grass sickness
- • Small intestinal strangulation or volvulus
- • Large colon torsion
- • Anterior enteritis
- • Peritonitis
- • Terminal ileal impaction
- • Ileocecal intussusception.

Subacute or chronic grass sickness
- • Impaction of the large or small colon
- • Hemorrhage
- • Mesenteric abscessation or other chronic inflammatory disease
- • Gastric squamous cell carcinoma
- • Alimentary lymphosarcoma or other neoplasia
- • Inadequate diet
- • Poor dentition
- • Equine motor neuron disease.

TREATMENT

Acute cases respond transiently to gastric decompression and intravenous fluid administration, but death is inevitable. Selected chronic cases may benefit from careful nursing care and the administration of the promotility, indirect acting choliner­gic agent, cisapride (0.5–0.8 mg/kg orally every 8 hours for 7 days). Administration of brotizolam (a putative appetite stimu­lant), acetlycysteine (antioxidant and neuroprotectorant), and aloe vera gel (anti­oxidant, anti-inflammatory and laxative) was without beneficial effect in 29 cases.

CONTROL

Successful measures have not been satisfactorily established and no definitive recommendation can be made. However, consideration should be given to the factors identified as increasing the risk of disease, such as pasturing, movement to new properties and especially those on which previous cases of this disease have occurred, and the disturbance of soil. Feeding of hay and haylage is associated with a reduced risk of developing the disease. Although administration of ivermectin is associated with an increased risk of the disease, appropriate parasite control should not be ignored in horses in areas in which grass sickness is endemic.

REVIEW LITERATURE

LYMPHOCYTIC-PLASMACYTIC ENTEROCOLITIS

This is an uncommon disease of horses, in contrast to dogs, affecting horses of any age and without discernible breed or sex predilection. The etiology is unknown. Presenting signs include weight loss, diarrhea, and lethargy. Clinopathologic abnormalities include hypoproteinemia and hypoalbuminemia in approximately one-half and three-quarters of cases, respectively. Results of an oral glucose tolerance test are abnormal in approximately 75% of cases. Histologic examination of a rectal mucosal biopsy reveals abnormal tissue suggestive of the disease in about one-half of cases. The diagnosis is confirmed by biopsy of ileum or necropsy examination. Differential diagnoses are similar to those for granulomatous enteritis. There is marked infiltration of the lamina propria with lymphocytes and plasma cells. Effective treatment has not been described. Control measures are not available.

OVINE MOUTH AND GUM OBSCURE DISEASE (OMAGOD)

During the outbreak of foot-and-mouth disease (FMD) in the UK in 2001, field investigations reported the appearance of oral lesions, initially in sheep and then in cattle which complicated the diagnostic process. While the lesions appeared to have a common, though obscure, etiology, prior to that they had not been identified as a differential diagnosis for FMD. The lesions were usually singular, located predominantly (but not exclusively) in the ginglyval mucosa ventral to the incisors, often in the midline; circular or nearly circular in shape and usually ranging in size...
diameter from 4 to 10 m; never vesicular but always erosive with a raised edge, giving the ulcer a crater-like appearance; and were more prevalent in adult sheep than in lambs.2

Experienced sheep veterinarians in the UK have reported ulceration of the gums of sheep as a regular occurrence in late winter and spring.1 It has been suggested that grazing sparse rough or short pasture, the provision of feed or salt blocks, and the use of feeding troughs with sharp edges, could be predisposing causes.

An abattoir survey of sheep in New Zealand examined the lesions of the anterior lips and gums of the animals after slaughter.3

Lesions of the midline of the lips and gums of traumatic or irritant etiology were common, and the prevalence was higher in adult sheep than in lambs. The lesions probably arose from the fright flight response behaviour of sheep, resulting in the mouth impacting against wire fences or yard railings while being handled. A smaller percentage of lesions may have been due to abrasive or irritant feed or soil. The presence of plant material and bacteria in lesions delayed healing and contributed to the formation of ulcers.

ULCERATION OF THE PARS ESOPHAGEA OF THE STOMACH OF SWINE (GASTRIC ULCER, HYPERKERATOSIS)

Naturally occurring ulcers of the stomach in swine occur in the pars esophagea (nonglandular part) of the stomach. They are single or multiple bleeding ulcers often associated with hyperkeratosis. Experimental lesions in the stomach are usually produced in the glandular part of the stomach as a model for the condition in humans. The condition was first reported in Illinois in 1897.

Lesions
Hyperkeratosis, erosions, ulcers of pars esophagea, gastric hemorrhage, anemia.

Diagnostic confirmation
Lesions at necropsy.

Differential diagnosis list
- Proliferative enteritis of swine
- Enteric salmonellosis
- Swine dysentery.

Treatment
None.

Control
Use of diets prepared through hammer mill screen of at least 6 mm. Incorporate S-methionine-sulphonium chloride in diet.

ETIOLOGY
The etiology is multifactorial. Finely ground and pelleted feed are important causes. Helicobacter heilmannii1 and Gastrospillum suis,2 have been found in gastric ulcers, but not ulcers of the pars esophagea of pigs and are unlikely to be the primary cause of the lesion.3 Certain environmental stressors may also be contributing factors.

EPIDEMIOLOGY
Occurrence
The disease is most common in pigs of 45–90 kg BW4 but the disease may also occur in pigs after weaning and in adult sows and boars. All breeds are susceptible. Prevalence in groups of pigs may vary anywhere in the world from 5 to 90%. In some countries the rate is 1% and in others 87%.5

Most gastric ulcers of pigs are localized in the pars esophagea and are referred to as esophagogastroduodenal ulceration. Examination of the stomachs of pigs at abattoirs in various countries has revealed a high proportion of pigs with varying degrees of hyperkeratosis, erosions, and ulcers of the pars esophagea. Extensive erosions of the pars esophagea may be present in up to 63% of sows and 36% of finishing pigs.6

The incidence is variable between countries which may reflect differences in feeding or husbandry methods. In the Netherlands 11% of the pigs may be affected.7 The incidence of ulceration may be increasing in pigs in the UK compared to earlier studies.8 An abattoir survey of the stomachs of pigs in the UK found ulceration of the pars esophagea in 23% with a range from 4 to 57%.8 The ulcers were mild in 9.5% and severe in 13.4%.

The disease has assumed increased economic importance with increased intensification of the swine industry.9 The feed manufacturing industry is faced with the dilemma of finely ground pelleted feed providing high digestibility and feed efficiency in growing and finishing pigs but with a high incidence of lesions of the pars esophagea which may affect performance. Pelleting swine feed is also advantageous because it flows more easily and effectively in automated distribution systems in swine farms compared to finely ground meal which may bridge and clog in distribution systems, decrease dustiness and segregation of ingredients and increase bulk density. Meal is less damaging than pellets.

The incidence of clinical disease is low but the case fatality rate is high when severe hemorrhage occurs. The effects of the lesions on performance may vary considerably. In one study, pigs with extensive lesions gained 50–75 g/day less than pigs with no lesions or while in another the presence of ulcers as determined at the abattoir did not influence growth rate.9 The disease has increased in significance with the occurrence of PMWS and PDNS associated with porcine circovirus 2. There is also an increased occurrence where there is a problem with porcine respiratory disease complex (PRDC) particularly during summer months.

Risk factors
Anything that causes an empty stomach which potentially increases the acidity in the pars esophagea region of the stomach is a risk factor.7 Back in the 1960s all that was needed to produce an esophageal ulcer in a pig was to keep the pig restricted in a feeding or farrowing crate and deprive it of water for 24 hours and it would have an ulcer. This would therefore include intermittent feeding and watering, respiratory disease and hot weather.

Dietary risk factors
The disease occurs primarily in penned pigs receiving a grain diet and growing rapidly. It has also occurred in pigs fed large quantities of cheese whey or skimmed milk. Too much copper and not enough zinc may also be a factor. The incidence is highest in pigs receiving diets containing a higher proportion of corn (maize) than other grains. The incidence is even greater if the corn is finely ground or is gelatinized or expanded. Ulceration in some pigs may be associated with Ascaris suis infection, but in other studies there is no significant association between the parasite and ulcers.

Finely ground feed
This is the most important risk factor.10 One of the explanations of this may be the rapid emptying of the stomach when fine particles are used.11 There is normally a gradation of ascending pH from the cardia to the esophagus but with rapid emptying there is the possibility of the low pH reaching the esophageal region.11,12

Feeding a diet based on finely ground barley to pigs beginning at 10–11 weeks results in lesions as early as 1 month later, and the incidence and severity of lesions increased progressively over the next
2 months. Diets high in wheat or corn starch may be worse than diets based on barley. The incidence and severity of hyperkeratosis may be greater in some breeds compared to others, but the effects of previous diets and environmental factors may have influenced the results.

The particle size and the physical form of the feed are important risk factors. Finely ground dierts and pelleting have detrimental effects on the gastric mucosa of finishing pigs.\textsuperscript{13} A pelleted diet uses grain that is finely ground before it is compressed into a pellet but on reaching the stomach it reverts to the fine particles. A diet finely ground through a 3 mm screen in a hammer mill and then pelleted will be associated with a 75\% incidence of pigs with hyperkeratosis of the \textit{pars esophagea} and 11\% of the pigs may have severe erosions and ulceration of the \textit{pars esophagea}.\textsuperscript{16} The incidence of lesions decreases when the diet is ground through a 6 mm screen.\textsuperscript{14} Finely ground barley or wheat is associated with a marked increase in gastric abnormalities compared to the use of coarsely ground grains. The size of particles in feed is significant whatever feed is used, even straw; coarsely ground barley straw at 5-10\% of the ration gives almost complete protection. In growing pigs, dietary fiber rich in structural polysaccharides has been shown to be important in preventing the development of parakeratotic lesions in the \textit{pars esophagea}.\textsuperscript{15} But an increase in the crude fiber content of a diet which is finely ground does not affect the occurrence of severe erosions and/or ulcers of the \textit{pars esophagea}.

Grinding barley through a 1.56 mm screen results in finely ground feed, which is associated with an increased incidence and severity of gastric ulcers in pigs. Grinding through a 4.68 mm screen approximates the screen size used most frequently for grinding barley for pigs in practice and is associated with a low incidence of ulcers.\textsuperscript{15}

Reducing particle size and pelleting improves growth performance of finishing pigs.\textsuperscript{16} For every 100 microns of decrease in size of the particle size there is an approximately 1.3\% increase in gain efficiency but each time the level of ulcers increases.\textsuperscript{17} The processes have additive effects on digestibilities of dry matter, nitrogen, and energy, with maximum nutrient digestibility in pelleted diets with corn milled to a particle diameter size of 400 \textmu m. Reducing the particle size to below 400 \textmu m causes practical problems with milling and an increased incidence of gastric lesions and it is suggested that a particle size of 600 \textmu m, or slightly less, is optimal for corn in either meal or pelleted diets for finishing pigs.

Using endoscopic examination of the stomachs of pigs fed a fine particle diet (geometric mean size of 578 \textmu m) it was found that as ulcer severity increases, the growth performance of individually fed pigs decreases. Feeding a coarse particle diet (geometric mean size of 937 \textmu m) for 3 weeks resulted in a decrease in the severity of the ulcers.\textsuperscript{18}

High levels of unsaturated dietary fat are not helpful especially if they are accompanied by low levels of vitamin E. Similarly pigs fed waste food had more severe gastric lesions.\textsuperscript{19}

Environmental and management risk factors

It has been suggested that confinement, crowding, transportation, changes in environment, and exposure to other pigs, were important in the etiopathogenesis of gastric ulcers of pigs. All of these stresses and many others including anxiety, fear, pain, fatigue, fasting, etc., will be associated with an increase of ulcers. There is an even greater occurrence in summer when water demands are higher. Males are always more affected in prevalence and severity but that may be that they are more easily stressed. One of the most important factors is time in the lairage. Pre-mortem handling is extremely important.\textsuperscript{20} Pigs kept overnight in the lairage have more ulcers than pigs killed on the day of arrival.\textsuperscript{21} Similarly there is no difference in the prevalence of lesions in small and medium farms but there is a considerable increase in the prevalence in these two groups compared to the larger producer.\textsuperscript{22} Larger herds always show more of the problem\textsuperscript{23} and it is probably a reflection of the different diets that they use (based on wheat and pelleted). The larger farms also have more infection pressure, more selection pressure, and more feed-related factors.

Pigs that receive porcine somatotrophin may have an increased level of ulcers possibly due to the elevated circulating gastrin.\textsuperscript{24} There are a variety of foreign bodies reported from the pigs' stomach including stones, which outside sows chew all the time, and also sand. The majority of stones is probably passed in the feces, but may accumulate in and stretch the stomach. The stomach capacity is normally about 3-6 L. This may lead to reduced appetite and gastritis but is not believed to be a contributor to esophageal ulceration. Similarly, hairballs are a common finding, reaching 10-15 cm in size in the stomach. The occurrence of rubbish indicates pica or a depraved appetite which is often an indicator of inadequate feeding. One of the other substances found in outdoor pigs stomachs is the flakes of bitumen that remain from clay pigeon shooting, which are toxic.

Increased frequencies of any of four combinations of behavioral indicators of stress, recorded 4 weeks after weaning, were weakly associated with increased risk of acute fonic ulcers in slaughter pigs from a conventional farrow-to-finish herd.\textsuperscript{25}

Pathogen risk factors

Gastric bacteria

The spiral-shaped \textit{Gastrospirillum suis} has been found in 84\% of the stomach of pigs with frank gastric ulcers of the \textit{pars esophagea}. The organisms were mainly in the mucus layer and in gastric foveolas of the antral and oxyntic mucosa and only occasionally in the cardiac- \textit{pars esophagea} region.\textsuperscript{26} The presence of the organism has been associated with lesions of the pyloric mucosa in pigs.\textsuperscript{27}

There is no known cause and effect relationship but the gastric environment associated with gastric ulcer may favor colonization of the organism. The oral inoculation of \textit{Gastrospirillum}-like bacteria into laboratory animals is capable of inducing gastric ulceration.\textsuperscript{27} \textit{Helicobacter heilmannii} type 1\textsuperscript{28} has been found more frequently in the stomachs of pigs with ulcers (100\%) and in those with pre-ulcer lesions (90\%) than in stomachs with macroscopically normal \textit{pars esophagea} (35\%).\textsuperscript{29} It has been suggested that \textit{Helicobacter heilmannii} may play a role in the pathogenesis of gastric ulcers in swine by causing increased acid secretion. \textit{H. pylori} can colonize the pig stomach. Experimental reproduction of \textit{Helicobacter suis} infection has recently been described.\textsuperscript{30} The pigs had no ulcers and infection was only accompanied by a mild superficial gastritis.

\textbf{PATHOGENESIS}

In pigs, nearly all naturally occurring gastroduodenal ulcers are localized in the \textit{pars esophagea} of the stomach. Excessive gastric acid production, depletion of the gastric buffering system resulting in prolonged activation of pepsinogens, and changes in mucus composition are suggested as important factors related to gastric ulceration in swine. The physical texture of the feed can influence pepsin and acid secretion, and the fluidity of the stomach contents induced by ulcerogenic diets may alter the normal pH gradient within the stomach. This allows greater pepsin and acid contact to the esophagogastric area.

The concentrations of short chain fatty acids are high in the proximal gastric contents of pigs and associated with intakes high in readily fermentable carbohydrates, like ground corn. These products of bacterial metabolism, principally acetate and lactate, reach high concentrations within 4 hours after feeding because of high pH
in the proximal gastric contents which may allow some types of bacteria to proliferate. These weak acids are lipid soluble in their undissociated form and could penetrate and acidify underlying tissue more readily than free hydrogen ions. In this way, rapid production of short chain fatty acids, followed by their absorption and tissue acidification, may be similar to ruminal acidosis and rumenitis in ruminants following the ingestion of large quantities of readily fermentable carbohydrates.\(^{30}\)

The rumen epithelium, also a stratified squamous mucosa, is easily injured by short chain fatty acids at pH ≤ 5.0. The breaking of the barrier by short chain fatty acids could result in underlying inflammation and widespread tissue destruction. Experimentally, exposing undissociated short chain fatty acids to swine gastric mucosa results in rapid penetration of the outer barrier and acidification of the underlying viable tissue.\(^{30}\) This results in cell swelling and vesicle formation, followed by sloughing of the outer barrier, erosion into deeper zones, and finally, ulceration.\(^{30}\)

Weak organic acids, at pH ≤ 2.5 induce a greater degree of functional and histological injury in 3 stomach zones (squamous, cardiac, and oxyntic) than does hydrochloric acid. The predilection for the squamous mucosa in naturally occurring ulcers may be attributed to the lack of defense or repair mechanisms that are present in the cardiac and oxyntic mucosa, which are capable of HCO\(_3\)\(^-\) and mucus secretion, which may raise the pH adjacent to these epithelial layers.\(^{30}\) Thus the increased digestibility associated with decreased particle size of the diet may promote rapid fermentation following eating resulting in the production of increased concentrations of short chain fatty acids. Any increase in fluid content will also contribute to the changes in pH gradient that exist in the stomach. Excessive gastrin is then stimulated and more acid secretion follows.

Normally, the \textit{pars esophagea} is white, smooth, and glistening and may be bile stained. The first stage in ulceration is hyperkeratosis. This is followed by erosions, ulcerations, and hemorrhage. The erosions may heal, resulting in a fibrous contraction. Chronic ulceration may occur with the development of several ulcers in combination with fibrous tissue involving all of the squamous mucosa. Advanced hyperkeratosis may cause partial stenosis of the terminal esophagus.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach.

The regurgitation of bile into the stomach and the intensity of bile staining of esophagogastric tissue have been linked to the pathogenesis of esophagogastric ulcers in pigs. Almost all stomachs of pigs contain bile and bile staining of the \textit{pars esophagea}; there is no evidence for the hypothesis that the regurgitation of bile into the stomach is associated with esophagogastric lesions in finishing pigs.\(^{32}\) There is no evidence of an association between gastritis and ulcer.\(^{32}\)

**CLINICAL FINDINGS**

Most cases are sub-clinical but sows will die from blood loss. Pigs frequently die from ulcers during concurrent disease such as respiratory disease\(^{34}\) and in this case anorexia may disturb the gastric contents and allow material of high acidity to reach the cardia. Similarly where there is a reduced consumption of water the integrity of the mucus may be broken by the dessication that results on mucosal surfaces.

Gastric ulceration is most common in pigs over 6 weeks of age and occurs in adult sows and boars; the clinical findings are dependent on the severity of the ulcers. The effects of ulceration on production may be highly variable. Most pigs with esophagogastric ulcers are clinically normal, and growth rate and feed intake appear unaffected. Some observations suggest that there is no effect of ulceration on growth rate, while others indicate that the presence of esophagogastric ulcers results in a marked decrease in growth rate and an increase in the length of time required for the pig to reach market weight. Some affected pigs also eat slowly and regurgitate frequently. Endoscopic monitoring of the stomachs of pigs fed ulcerogenic diets found that as the severity of the ulcer increased growth performance was decreased.\(^{10}\) The greatest economic losses were associated with sudden deaths due to hemorrhage and marked decreases in performance associated with fine particle size.

The erosion of a blood vessel within the ulcer will result in acute to subacute gastric hemorrhage. These cases are usually sporadic, causing deaths of individuals within a group, with cases occurring over a period of several weeks. Clinical signs are often not observed, affected pigs being found dead from acute hemorrhage into the stomach. When pigs are found dead from peracute hemorrhage, inspection of the in-contact pigs may reveal other animals with pallor and black tarry feces which represent those with subacute hemorrhage.

Cases with subacute gastric hemorrhage may survive for a few days and there is evidence of marked pallor, weakness, anorexia, and black pasty feces changing to mucus-covered pellets in small amounts. The weakness may be sufficient to cause recumbency. Vomiting frothy bile-stained fluid and grinding of the teeth may occur. Abdominal pain may be elicited by deep palpation over the xiphisternum and there may be a reluctance to walk with a rigid back indicative of pain.\(^{6}\) Animals that survive are often unthrifty, usually due to anemia from chronic blood loss with a few cases affected by chronic peritonitis. When the disease is occurring careful observation may detect early cases. Suggestive signs are a darkening of the feaces and the development of pallor.

**CLINICAL PATHOLOGY**

Laboratory testing is not indicated. Animals with gastric ulceration generally have lower hematocrit values, haemoglobin concentrations, and erythrocyte counts than normal. The black tarry feaces can be examined for the presence of blood.

**NECROPSY FINDINGS**

Ascarids have been found in the stomach but these are not a factor in the field.\(^{34}\)

At necropsy, the ulcers are confined to the esophageal region of the stomach. Affected stomachs consistently have more fluid contents than unaffected ones. If severe blood loss from the ulcer has been the cause of death then the carcass is pale and fresh blood is usually present in the stomach (there may be large blood clots) and intestines. The colonic contents may also appear melenic. Early lesions in clinically unaffected animals include hyperkeratinization of the mucosa (usually pale raised areas without bile staining initially) which progresses to epithelial erosion without actual ulceration. Ulcers usually initially occur along the junction of the \textit{pars esophagea} with the glandular stomach but may enlarge to efface the entire squamous portion of the stomach. These more diffuse ulcers are easily missed on cursory examination due to their uniform appearance. Chronic gastric ulcers develop thickened, raised edges due to ongoing fibrosis, occasionally resulting in a gastro-esophageal stricture. The histological appearance varies with the stage of lesion development but in fatalities there is typically complete loss of the epithelial layer, with exudation of neutrophils from a bed of mature granulation tissue. Recent studies have demonstrated \textit{Helicobacter}\(^{35}\) like bacteria in porcine stomachs but further research is required to determine if this infection plays a significant role in ulcer formation. Small clusters of \textit{H. helveticus} have been seen in the gastric crypts,\(^{35}\) but are not associated with histological changes.\(^{36}\) A recent survey suggested no correlation between infection
in the cardiac mucosa and the severity of the lesions shown by the esophagogastric region. The macroscopic findings are usually sufficient for the confirmation of an esophagogastric ulceration. The initial lesion of hyperkeratosis leads to parakeratosis with fissures and the lamina propria is then exposed. The epithelium sloughs off and then ulcers of the epithelium develop with hemorrhage from the vessels.

**Severity and extent of esophagogastric lesions can be graded according to the following scheme:**

0: intact epithelium
1: small degree of hyperkeratosis (< 50% of total surface)
2: distinct hyperkeratosis (= 50% of the total surface)
3: hyperkeratosis and less than 5 erosions smaller than 2.5 cm in size
4: hyperkeratosis and more than 5 erosions or erosions larger than 2.5 cm in size
5: hyperkeratosis and more than 10 erosions or erosions larger than 5 cm in size, and/or an ulcer (with or without bleeding) or stenos of the esophagus towards the stomach.

No difference in lesion score was found between Duroc, Landrace, and Iberian pigs.

**Differential Diagnosis**

The occurrence of sudden death with a carcase that shows extreme pallor and a marble-white skin suggests the possibility of peracute hemorrhagic enteropathy, swine dysentery, and salmonellosis. Black tarry feces in growing and finishing pigs are characteristically due to subacute hemorrhage associated with esophagogastric ulceration. It is possible to detect stomachs with Helicobacters by covering the stomach with urea gel containing an indicator sensitive to pH change. If there are large numbers of urease-positive bacteria then the pH changes.

Severe infestation with whipworms is a differential. The clinic diagnosis can be confirmed by endoscopy which requires an empty stomach (may cause ulceration in itself) and anesthesia.

**Treatment**

Vitamin K and hematinics have been tried with little success. Bovine serum concentrate given as a 1% solution is supposed to have reduced the extent and severity of signs associated with ulcers in growing pigs but in general medication does not help. If a diagnosis is made euthanasia is advised.

**Control**

Control of esophagogastric lesions of growing and finishing pigs is dependent on using diets with a particle size and physical form which will provide the most digestibility and feed efficiency and minimize the incidence of lesions.

The most desirable particle size or physical form of diet, meal, or pelleted form, has not been determined. The use of a diet ground through a 6 mm screen instead of 3 mm screen is recommended. However, screen size is not the only factor affecting particle size. Other factors include the condition of the screen and hammer, the type and variety of grain and its moisture content, the speed of the mill, the pelleting process and the flow rate in the distribution of the feed to the pigs. A particle size of 600 µm, or slightly less is suggested as optimal for corn in either meal or pelleted diets for finishing pigs.

The incorporation of S-methylmethionine-sulphonium chloride (MMSC), a nutritional component of many vegetables such as cabbage and carrots, has anti-gastric ulcer properties. Its addition to the diet, ground through a 3 mm screen, and fed to grower pigs from 45 to 107 kg liveweight, at 400 ppm decreased the incidence of severe erosions or ulcers by about 50%. The addition of lucerne meal to increase the crude fiber content of one of the experimental diets did not have an effect on the incidence or severity of the lesions.

The diet should contain adequate amounts of vitamin E and selenium. Where applicable a reduction of the amount of corn in the ration and the feeding of meal rather than pellets may also be of value. The reduction of environmental and managerial stressors with attention to stocking rates may be of value.

**Review Literature**

**Chronic Inflammatory Bowel Disease of Sheep**

This syndrome of unknown etiology is manifest with wasting, ill thrift and mortality, or culling for poor production, and is reported in England and Canada. It affects both housed and pastured sheep predominantly in their first year of life, but cases up to 3 years of age have been seen. Affected sheep are dull and anorectic with pale mucous membranes and have fecal staining of the perineum. The rumen fill is reduced and the feces are soft and malodorous. Blood examination shows hypoalbuminemia, an elevated blood urea nitrogen, and leukocytosis with neutrophilia. On post mortem there is lymphocytic enteritis with gross thickening of segments or the entire or distal part of the small intestine. There is no evidence for Johnne’s disease or parasitic gastroenteritis and the syndrome has similarities to the proliferative enteropathies of swine and horses.
The recognition that interstitial pneumonia can have an acute exudative phase was the reason for the designation of acute interstitial pneumonia in cattle as 'atypical' interstitial pneumonia. The use of the word 'atypical' may create some confusion in the interpretation and diagnosis of lesions and in the conveying of information. It may be more appropriate to use the term interstitial pneumonia and specify where possible, clinically, epidemiologically, and pathologically the various forms of interstitial pulmonary disease in cattle.

The diseases in which interstitial pneumonia is the essential lesion are listed in Table 36.1. Pulmonary congestion and edema, alveolar exudation, hyaline membrane formation, interstitial emphysema, and alveolar epithelial cell hyperplasia and fibrosis of the supporting stroma without lesions of the smaller airways are the characteristic lesions, with their presence and extent varying according to the stage of the disease process.

The term atypical interstitial pneumonia as originally proposed is still useful in describing some of the diseases clinically and sets them apart from the common acute infectious diseases, especially the viral diseases of the respiratory tract of cattle. Clinically, they are atypical with regard to most clinical signs, especially when compared to the bacterial pneumonias:

Some are acute, like fog fever, while others are chronic as in 'bovine farmer's lung'.

### Synopsis

**Etiology**
- Inhalation of certain gases
- Hypersensitivity to molds: Mycotoxins
- Organophosphate insecticide poisoning
- Nitrate poisoning
- Other interstitial pneumonias
- Bovine farmer's lung or extrinsic allergic alveolitis
- Lungworm pneumonia
- Verminous pneumonia caused by aberrant migration of Ascaris suis larvae
- Feedlot interstitial pneumonia
- Enzootic pneumonia of calves

**Clinical pathology**
- None clinically applicable

**Lesions**
- Enlarged firm lungs which do not collapse, diffuse congestion and edema, interstitial and bullous emphysema, cranoventral consolidation, hyaline membrane formation, alveolar epithelial hyperplasia, fibrosis

**Diagnostic confirmation**
- Lesions at necropsy

**Differential diagnosis list**
- Pneumonic pasteurellosis
- Organophosphatic insecticide poisoning
- Nitrate poisoning
- Other interstitial pneumonias
- Bovine farmer's lung or extrinsic allergic alveolitis
- Lungworm pneumonia
- Verminous pneumonia caused by aberrant migration of Ascaris suis larvae
- Feedlot interstitial pneumonia
- Enzootic pneumonia of calves

**Treatment**
- None

**Control**
- Grazing management. Use of antimicrobials to control conversion of tryptophan to 3-methylindole. Adequate housing and ventilation to control hypersensitivity pneumonias.
ETIOLOGY

There are several different possible causes.

Acute bovine pulmonary emphysema and edema (ABPEE) or fog fever

This is an acute atypical interstitial pneumonia also known as acute respiratory distress syndrome of cattle. The cause in adult cattle which have been moved from a dry to a lush pasture in the autumn season is related to the ingestion of a toxic level of D,L-tryptophan in the forage. The experimental oral administration of toxic amounts of D,L-tryptophan to cattle causes clinical and pathological findings similar, if not identical, to those of the naturally occurring disease. D,L-tryptophan is converted in the rumen to 3-methylindole which, when given orally or intravenously, also produces the characteristic lesions in cattle and goats. The 3-methylindole exerts a direct effect upon cells and cell membranes of bronchioles and alveolar walls, perhaps as a result of strong lipophilic properties. Specific forages have not been implicated, but affected cattle have often been consuming alfalfa, kale, rape, turnip tops, rapidly growing pasture grass, and several other feeds. However, pasture levels of tryptophan are not necessarily higher in those associated with the disease compared to normal pastures. In some naturally occurring cases of fog fever in beef cows changed from a dry summer range to a lush green pasture, there is a marked increase in the ruminal levels of 3-methylindole while in other cases the levels are not abnormal. Failure to detect abnormally high levels in the rumen and plasma of naturally occurring cases may be related to the rapid metabolism and elimination of 3-methylindole.

The levels of tryptophan in lush pasture are sufficient to yield toxic doses of 3-methylindole. A 450 kg cow eating grass at an equivalent DM intake of 3.5% of BW/day with a tryptophan concentration of 0.3% of DM would ingest 0.11 g tryptophan/kg BW/day. The total amount ingested over a 3-day period would approximate the single oral dose of 0.35 g/kg BW needed to reproduce the disease experimentally.

Diffuse fibrosing alveolitis

This is a chronic interstitial pneumonia of cattle which occurs sporadically and is suspected of being caused by repeated subclinical incidents of ABPEE or from recovered cases of the disease. Experimentally, repeated oral doses of 3-methylindole can result in diffuse pulmonary fibrosis and alveolitis in cattle.

Parasitic infestation

For many years it was thought that massive infestation of the lungs by large numbers of lungworm larvae in a lungworm-sensitized animal could cause an allergic reaction resulting in the development of acute bovine pulmonary emphysema. The possibility of such hypersensitivity as being associated cannot be totally ignored but at the present time there is no evidence to support such a theory. Such hypersensitivity may occur when the level of larval infection of pasture is extremely high but it is not involved in the great majority of cases. In most cases of naturally occurring fog fever there is no laboratory evidence of lungworms in the lungs or feces of affected and in-contact animals. Reinfestation of cattle with lungworm will occur 2–3 weeks following introduction to an infected pasture and cause acute respiratory distress which is indistinguishable clinically from fog fever. The migration of abnormal parasites, particularly Ascaris suum, has been observed to cause an acute interstitial pneumonia in cattle which were allowed access to areas previously occupied by swine.

Inhalation of irritant gases

The experimental inhalation of nitrogen dioxide gas is capable of causing acute interstitial pneumonia in cattle and severe alveolar edema and emphysema in pigs but it seems unlikely that animals of either species would be exposed naturally to a significant concentration of the gas for a sufficiently long period to produce such lesions.

Pigs which survived experimental exposure to silo gas did not have the lesions seen in silo-fillers' disease in man, and experimental exposure of cattle to nitrogen dioxide gas produces lesions which do not occur in naturally occurring fog fever. Acute pulmonary emphysema and deaths have occurred in cattle exposed to zinc oxide fumes produced by the welding of galvanized metal in an enclosed barn housing cattle.

Hypersensitivity to molds

The ingestion or inhalation of molds may be a cause of the disease in cattle. The disease has been associated with hypersensitivity to moldy hay based on the presence of serum precipitins of the thermophilic antigens of Thermopolyspora polyspora, Micropolyspora faeni, and Thermoactinomyces vulgaris in cattle affected with extrinsic allergic alveolitis or bovine farmer's lung.

In Switzerland, a high incidence of serum precipitins against Micropolyspora faeni (60%) and moldy hay antigen (80%) was demonstrated in exposed but apparently healthy cattle from an area where 'allergic pneumonia' is common. The precipitins decreased during the pasture season and increased during winter housing.

Outbreaks of acute respiratory disease in adult cattle due to acute allergic pneumo-monitis can occur 15 hours after the introduction of severely moldy hay. Serological investigation and provocative challenge may reveal a hypersensitivity pneumonitis due to allergens of Micropolyspora faeni. A hypersensitivity pneumonitis has been produced experimentally in calves by exposure to aerosols of Micropolyspora faeni with or without prior sensitization by subcutaneous injection of the antigen.

In some Canadian cattle barns the disease occurred in cattle located near the hay chute from which hay and bedding are thrown down from the hay storage above the floor where the animals are kept. It has been suggested that the degree of exposure to dusty hay was greater in these cattle but that has not been substantiated. Similarly, it has been proposed that feeding finely ground feed may be associated with interstitial pneumonia in feedlot cattle but there is little evidence to support the observation.

The high incidence of ABPEE in the autumn when many legumes and other pasture plants are flowering, and the common occurrence at this time of allergic rhinitis in cattle, suggest that the inhalation of pollen may cause an allergic response of the alveolar epithelium. However, many outbreaks of the disease have occurred in cattle solely on grass pasture with no flowers; intradermal tests of sensitivity to many pasture plants and to the ruminal contents of affected animals have been negative, and blood histamine levels are within the normal range.

Cryptococcosis and plant poisonings

In North America, the ingestion of sweet potatoes infested with the mold Fusarium solani has been incriminated as a cause of acute interstitial pneumonia in cattle. Growth of the mold on the potatoes produces the toxins ipomeamarone and ipomeamaronal, and a lung edema factor. The latter is a collective term for a group of substances capable of causing death associated with severe edema and a proliferative alveolitis of the lungs of laboratory animals. It produces a respiratory syndrome which is clinically and pathologically indistinguishable from ABPEE.

The fungus Fusarium semitectum growing on moldy garden beans, Phaseolus vulgaris, which were discarded on pasture, was associated with acute pulmonary emphysema in cattle that consumed the beans and their vines. The fungus produces a pulmonary toxin. The pulmonary toxin, 4-ipomeanol (ipomeanol), accumulates in mold-damaged sweet potatoes and induces pulmonary edema, bronchiolar necrosis and interstitial pneumonia in many mammalian species. Outbreaks have occurred in lactating cows following ingestion of sweet potatoes damaged by M. tarsisca. Other Fusarium spp. have been found in...
peanut-vine hay, which has been associated with acute respiratory distress and atypical interstitial pneumonia in adult beef cattle. The population mortality rate due to respiratory disease was about 12% and the case fatality rate 77%. Clinical signs occurred within a few days to 2 months after the animals were fed the peanut-vine hay.

A weed, *Perilla frutescens*, is considered to be a cause of the disease in cattle in the US and wherever the plant is found. High morbidity and high case fatality rates are characteristic, and the plant contains a perilla ketone which can be used to produce the disease experimentally.

Turf-quality perennial ryegrass straw (*Lolium perenne*) infected with the endophyte (*Acremonium lolii*) which yields toxic substances, including lolitrem-B has been associated with atypical pneumonia in weaned beef calves. However, feeding the suspect hay resulted in typical ryegrass stickers but not atypical interstitial pneumonia.

**Bacterial and Mycoplasma spp. infections**

There is no evidence that any of the common bacterial pathogens of cattle such as *Mannheimia haemolytica*, *Pasteurella multocida*, *Histophilus (Haemophilus) somni*, or *Mycoplasma* spp. are primarily associated with acute interstitial pneumonia. In a series of feedlot cattle with clinical findings consistent with acute interstitial pneumonia, the pathogens were present in the lung tissues of some animals at necropsy but their presence was not considered as a primary cause of the pneumonia but rather secondary to the initial injury of the lung which was undetermined.

**Viral infections**

Certain viral infections of the lung may result in interstitial pneumonia. In the interstitial pneumonias caused by the bovine respiratory syncytial virus (BRSV) there is a bronchiolitis and alveolitis and these should be termed bronchointerstitial pneumonias. The BRSV is an important cause of outbreaks of acute interstitial pneumonia in beef calves 2–4 weeks after weaning. Pathologic evaluation of the lung tissues of feedlot cattle which had acute interstitial pneumonia found that BRSV was not a causative agent. In a series of cases of interstitial pneumonia in feedlot cattle in Saskatchewan the presence of the BRSV antigen was demonstrated in only 7% of cases and there was more severe bronchiolar epithelial necrosis than in the other cases which were negative for the virus.

**Epidemiology**

Acute pulmonary emphysema and edema (ABPEE) or fog fever occurs almost exclusively in adult cows and bulls, usually 4–10 days after they are moved abruptly from a dry or overgrazed summer pasture to a lush autumn pasture. The new pasture may or may not have been grazed during that summer and the species of grass or plants does not seem to make a difference, but usually there is some lush regrowth of grass, legume or other palatable plants. Merely changing pasture fields in the autumn has precipitated the disease. In the mountainous areas of North America the disease occurs commonly in cattle brought down from high altitude grasslands to the cultivated and perhaps irrigated lush pastures.

ABPEE usually occurs in outbreaks, the morbidity ranging from 10% in some herds up to 50% and higher in others, with a case fatality ranging from 25 to 50%. It is not unusual to observe a mild form of the disease in about one-third of the adults at risk but only 10% of those at risk may be severely affected. Often, a number of cows are found dead without premonitory signs; many others are severely ill and die within 24 hours and the owner believes that the entire herd will die because of the sudden onset and the large number of animals which are affected at once. Calves and young growing cattle up to 1 year of age grazing the same pasture are usually unaffected.

A retrospective analysis and random sample survey of cattle ranches in northern California found that the type of forage management has a significant effect on the occurrence of the disease. The greatest occurrence of the disease was in herds where the cattle were moved from summer ranges to second-growth hay fields or to irrigated pastures, or from one irrigated field to another. The adult morbidity rate was 2.6% and the case fatality rate about 55%. The disease did not occur on ranches with limited or no movement of cattle from summer ranges to lush autumn pastures.

Placing cattle on rape or kale forage fields or in fields where turnips have been pulled and the cattle allowed access to the tops may have the same effect. The disease has also occurred commonly in western Canada when cattle have been placed in a stubble field following harvesting of any of the cereal crops. Veterinarians have noted that the timespan over which the disease occurs during the autumn months is only 2–4 weeks and that, following the first frost in the fall, the incidence of the disease declines rapidly. The disease has also occurred in the same herd on the same pasture in successive years.

**ABPEE in adult cattle in autumn** has been recorded in Canada and the US, Great Britain, Holland, and New Zealand. The disease is rare in Australia. The chronic form of the disease in housed cattle appears to be the predominant form of the disease in Switzerland, but the acute form in cattle which have been changed from a dry to lush pasture is now reported. The disease has been recognized in France for many years as aftermath disease or aftermath emphysema, especially in the Normandy region. Some reports have suggested a breed incidence, Herefords being more commonly affected than the Jersey, Holstein, Shorthorn, and Angus breeds, but there are few exact epidemiological data to support the observation. One report suggested that the chronic type in housed cattle was more common in the Channel Island breeds.

**Acute interstitial pneumonia in feedlot cattle.** Interstitial pneumonia is recognized as an important cause of economic loss in feedlot cattle in western Canada and the United States. The disease occurs sporadically and the incidence is about 3.1% of all cattle placed in feedlots. Cases occur most commonly during the summer and fall months and new cases occur in an even distribution across all stages of the finishing period. In southern Alberta, the disease is most common during hot, dry, dusty, spring and summer days, and typically affects animals expected to be ready for slaughter within 15 to 45 days. Some feedlot operators have observed that the disease is more common in cattle exposed to excessive dust from bedding.

In southern Alberta feedlots the disease occurred late in the finishing period, when animals had been on feed an average of 114 days and weighed 475 kg. All confirmed cases were in heifers and plasma concentrations of 3-methylindole metabolites (adducts) were higher in heifers with interstitial pneumonia than in controls. Most of the heifers were receiving melengestrol (MGA) to suppress estrus. The BRSV antigen was not found in lung tissue of confirmed cases. The odds of an animal with acute interstitial pneumonia being a heifer were 3.1 times greater than the odds that an animal with the disease was a steer. In some large feedlots the estimated relative risk was 4.9. The role of 3-methylindole (3MI) has been examined as a possible cause of interstitial pneumonia in feedlot cattle. Anaerobic ruminal fermentation of large amounts of tryptophan leads to a surge in 3-methylindole concentrations, which is readily absorbed across the ruminal and intestinal wall and disseminated throughout the body. Bioactivation of 3MI by Clara cells leads to profound cellular injury in Clara and type-1 alveolar epithelial cells and, ultimately, acute interstitial pneumonia. It is postulated that the compound
responsible for causing the injury is the electrophilic metabolite of 3MI, 3-methylenedolene (3MEIN) which forms stable adducts with cellular macromolecules. (Adducts are compounds formed by an addition reaction.)

Concentrations of 3-methylenedolene (3MEIN) in lung tissue and blood were higher in feedlot cattle that had died of acute interstitial pneumonia than in healthy feedlot cattle. However, lung tissue concentrations of 3MEIN were similar in samples from cattle with interstitial pneumonia and bronchopneumonia. Time-dependent patterns and magnitudes of plasma concentrations of 3MI and blood concentrations of 3MEIN-adduct in feedlot cattle during the first 8 weeks after arrival have been followed. Mean concentration of 3MEIN-adduct increased to a maximum value on day 33 and then decreased to a minimum on day 54. Plasma 3MI concentrations initially decreased and remained low until after day 54. Neither 3MEIN-adduct concentrations nor plasma 3MI concentrations were associated with deleterious effects on weight gains. A single dose of acetylsalicylic acid (aspirin) to feedlot cattle on arrival did not affect serum or rumen concentrations of 3MI. The combination of aspirin and vitamin E fed daily to feedlot cattle did not decrease the risk of developing respiratory tract disease.

Sheep. Acute interstitial pneumonia has been recorded in sheep and there was extensive alveolar epithelialization. In Norway, an acute respiratory distress syndrome has occurred in lambs moved from mountain pastures onto lush aftermath pasture. The lesions were those of acute interstitial pneumonia and alveolar epithelial hypersensitivity to molds in the grass is being explored. The experimental oral administration of 3-methylindole to lambs will result in acute dyspnea and lesions similar to those which occur in cattle and adult sheep following dosing with 3-methylindole. However, the lesions in experimental lambs are different from those which occur in lambs affected with the naturally occurring disease.

The other types of interstitial pneumonia occur sporadically and may affect only a single animal or several over a period of time. There is not necessarily a seasonal incidence except in areas where cattle are housed and fed dusty and moldy hay during the winter months. The disease has occurred in feedlot cattle in open feedlots and in young cattle fed on fattening rations indoors. Acute interstitial pneumonia occurs in weaned beef calves about 4 weeks after weaning. The interstitial pneumonia which may be the result of anaphylaxis also occurs sporadically and therefore not in outbreaks.

**PATHOGENESIS**

Because of the number and variety of circumstances in which acute or chronic interstitial pneumonia occurs, it is difficult to suggest a basic underlying cause, or to explain the mechanisms for the development of the lesions and the variations which occur from one circumstance to another. The reaction which occurs is a non-specific but fundamental reaction of the pulmonary parenchyma to a wide variety of insults which may be ingested, inhaled or produced endogenously. The reaction to sublethal injury is a combination of congestion, edema, an outpouring of protein-rich fluid into the alveoli, hyaline membrane formation, alveolar and interstitial emphysema which is secondary, and proliferation of alveolar septal cells and fibrosis of the interstitial spaces. Unlike the bacterial pneumonias, the emphasis is on edema and proliferation rather than on necrosis. Because mild cases of ABPEE may recover completely, it is suggested that the lesion can be reversible.

**Experimental ABPEE**

There has been considerable effort to experimentally induce ABPEE similar to the naturally occurring disease, by the oral administration of L-tryptophan or one of its metabolites, 3-methylindole, to cattle, sheep, and goats. The L-isomer of tryptophan is metabolized by ruminal microorganisms to indolacetic acid which is then converted to 3-methylindole. The conversion of L-tryptophan to 3-methylindole is maximal at a ruminal pH near neutrality. When cattle are moved from a relatively dry pasture to a lush green pasture, there is an increase in ruminal ammonia, a decrease in ruminal pH, and a decrease in ruminal buffering capacity. The 3-methylindole is absorbed from the rumen and metabolized by a mixed-function oxidase system to an active intermediate which has pneumotoxic properties.

Pulmonary edema is the first morphological change occurring in ruminants given 3-methylindole, and the severity and extent of the lesion is probably the single most important factor which determines the severity of the clinical response and the likelihood of survival. The edema is preceded by degeneration, necrosis, and exfoliation of type I alveolar septal cells. During the acute phase, there is flooding of the alveoli with serofibrinous exudate, congestion, and edema of alveolar walls, and hyaline membrane formation. Varying degrees of severity of interstitial emphysema also occur. The interstitial emphysema may spread within the lymphatics to the mediastinum and into the subcutaneous tissues over the withers, over the entire dorsum of the back and, occasionally, over the entire body including the legs. If the acute phase is severe enough there is marked respiratory distress and rapid death from hypoxemia.

In the experimental disease, the typical clinical signs of respiratory disease appear within 24–36 hours after the oral administration of L-tryptophan to adult cattle and within 4 days 50% of the dosed cows will die. The predominant pulmonary lesions include edema, interstitial emphysema, hyaline membranes, and hyperplasia of alveolar lining cells. The L-tryptophan is converted to indolacetic acid, which is decarboxylated to 3-methylindole, which is absorbed and metabolized by a mixed function oxidase system in the lung to produce pneumotoxicity.

The lesions have also been produced in cattle, sheep, and goats following oral or IV administration of 3-methylindole. Calves may be more resistant to experimental toxicity with 3-methylindole than adults, which supports the observation that the naturally occurring disease is uncommon in calves grazing the same pasture in which adults are affected. Young calves, 30–45 days of age, are susceptible to pulmonary injury induced by 3-methylindole characterized by pulmonary edema and damage to type-1 alveolar epithelial cells and non-ciliated bronchiolar epithelial cells. The 3-methylindole injury does not make the bovine lung more susceptible to the bovine respiratory syncytial virus as is the case for the parainfluenza-3 virus.

**Proliferative stage.** If the animal survives the acute phase, proliferation of alveolar type II cells marks the beginning of the shift from the exudative to the proliferative stages of pneumonia. There is alveolar epithelialization and interstitial fibrosis, the latter being progressive and irreversible. The central features of chronic interstitial pneumonia are intra-alveolar accumulation of mononuclear cells, proliferation and persistence of alveolar type 2 cells, and interstitial thickening by accumulation of lymphoid cells and fibrous tissue. Diffuse fibrosing alveolitis is a form of chronic interstitial pneumonia of uncertain etiology, but possibly the chronic form of ABPEE. Repeated oral administration of 3-methylindole in cattle provides a good experimental model for diffuse pulmonary fibrosis.

**Effects of 3-methylindole on pulmonary function**

The effects of 3-methylindole on pulmonary function and gas exchange have been examined in cattle, goats, and horses. In cattle there is impairment of sympathetic pulmonary vasconstriction, and changes in intra-acinar pulmonary arteries which may be related to a sudden elevation in arterial
and venous pressures in the pulmonary system. There are large increases in respi- 

gatory rate, minute viscous work, PCO₂ 

and large decreases in tidal volume 
dynamic lung compliance, and PO₂. All 

of these are compatible with the severe pul- 

monary edema and alveolar injury.

In goats there is a pronounced decrease 
in lung compliance, a moderate increase in 

airway resistance, a concomitant hypox- 

emia, a progressive decrease in tidal volume 

and alveolar ventilation and an increase in 

the dead-space-to-tidal volume ratio. These 

changes are characteristic of a restrictive 

type of respiratory tract disease in goats in 

which pulmonary edema and the pulmo- 

ary function changes are similar to those of 

adult respiratory distress syndrome in man.

**CLINICAL FINDINGS**

Acute bovine pulmonary edema and edema

This disease, also known as 'fog fever', is 

usually obvious, because of its charac- 

teristic clinical presentation. The onset is 

sudden. Within 4-10 days after adult cattle 

have been moved onto a new pasture, they 

may be found dead without any premoni- 

tory signs. Many cattle exhibit labored 

breathing, often with an expiratory grunt, 

open-mouthed breathing, frothing at the 

mouth, and anxiety. Severely affected cattle 

do not graze, stand apart from the herd, 

and are reluctant to walk. If forced to walk 

they may fall and die within a few minutes. 

Often, removal of the affected herd from 

the pasture will result in an increased 

number of deaths. Moderately affected 

cattle continue to graze but their respira- 

tions are increased above normal. Coughing 

is infrequent regardless of the severity. The 

temperature is normal to slightly elevated 

(38.5-39.5°C, 102–103°F) but may be up to 

41-42°C (106–108°F) during very warm 

weather. There is a similar variation in the 

heart rate (80-120/min) and those with a 

rate of more than 120/min are usually in 

the terminal stages of the disease. Bloat 

and ruminal atony are common in severe 

cases. Subcutaneous edema is common 

over the withers and may extend to the 

axillae and ventral aspects of the thorax. 

The nostrils are flared and the nasal dis- 

charge is normal. Diarrhea may occur but 

is mild and transient.

Loud, clear breath sounds audible over 

the ventral aspects of the lung, indicating 

consolidation without bronchial involve- 

ment, are the characteristic findings on 

auscultation in the early stages of the 

acute disease. The intensity of the breath 

sounds may be less than normal over the 

dorsal parts of the lung if involvement is 

severe, but in animals which survive for 

several days the loud crackles characteristic of interstitial emphysema are of diagnostic 

significance. Most severely affected cases 

will die within 2 days of onset but less 

severe cases will live for several days and 

then die from diffuse pulmonary involve- 

ment. Those which survive longer than 

1 week will often have chronic emphysema 

and remain unthrifty. Of those moderately 

affected cattle which recover in a few days, 

some will develop congestive heart failure 

a few months later, due to chronic inter- 

stitial pneumonia (cor pulmonale). Calves 

running with their adult dams will usually 

not be affected.

Other interstitial pneumonias

These diseases usually occur sporadically, 

but several animals may be affected over a 

period of time. There may or may not be 

a history of a change of feed or the feeding 

of moldy or dusty feed. In many cases, a 

few days elapse after the appearance of 

signs before the owner is aware of the 

affected animals. The animal may have been 

treated with an antimicrobial for a bacterial 

pneumonia with little or no response. 

Dyspnea, increased respiratory effort 

sometimes with a grunt, deep coughing, a 

fall in milk production, an absence of 

toxemia, a variable temperature (38.5–40°C, 

102–104°F) and a variable appetite are all 

common. On auscultation there are loud 

breath sounds over the ventral aspects of 

the lungs and crackles over both dorsal 

and ventral aspects. The presence of moist 

crackles suggests secondary bacterial 

bronchopneumonia. Subcutaneous emphy- 

sema is uncommon in these and most will 

become progressively worse.

Yearling cattle with acute interstitial 

pneumonia which may be viral in origin 

may become much worse and die in a few 

days in spite of therapy. Mature cattle 

affected with bovine farmers' lung will sur- 

vive in an unthrifty state with the chronic 

disease for several weeks and even months.

The major clinical features of all these 

other interstitial pneumonias are obvious 

respiratory disease, lack of toxemia, poor 

response to treatment, progressive worsen- 

ing, and abnormal lung sounds distrib- 

uted over the entire lung fields.

**CLINICAL PATHOLOGY**

There are no abnormalities of the hemogram or serum biochemistry which 

have any diagnostic significance. Examination of feces and forage for lungworm 

larvae will aid in differentiation from ver- 

minous pneumonia if past the prepatent 

period. The observed high levels of 'farmer's lung hay' antibodies in serum are not of 

much value diagnostically because of the 

similar levels found in many clinically 

normal cows; many cases of classic fog fever 

have negative serum precipitin levels.

**NECROPSY FINDINGS**

In ABPEE, the lungs are enlarged and firm 

and do not collapse on cutting. In the early 

stages of acute cases they contain much 

fluid which is more viscid than usual edema 

fluid. The pleura is pale and opaque and 
appears to be thickened. In peracute cases, 

the entire lungs are homogeneously affected in this way. Such cases usually 

have edema of the larynx.

In the more common acute case, the 
lung has a marbled appearance. Adjacent 

lobes may be affected with any one of four abnormalities. Areas of normal, pink 

lung are restricted to the dorsal part of the 

caudal lobes. There are areas of pale tissue 

indicative of alveolar emphysema, areas of 
a dark pink color affected by early alveolar 

exudation, yellow areas in which the alveoli 

are filled with coagulated protein-rich fluid, 

and dark red areas where epithelialization 
has occurred. The latter two lesions are 

firm on palpation and resemble thymus or 

pancreas. They are more common in the 

ventral parts of the cranial lobes.

In chronic cases, as a sequel to the acute 

form described above, the obvious differ- 
ces in the age of the lesions suggest that 

the disease progresses in steps by the per- 

iodic involvement of fresh areas of tissue. 

In all cases there is usually a frothy exudate, 
sometimes containing flecks of pus, in the 

bronchi and trachea, and the mucosa of 

these passages is markedly hyperemic.

Histologically, the characteristic findings 

are an absence of inflammation, except in 

the case of secondary bacterial invasion, and 

the presence of an eosinophilic, protein- 

rich fluid which coagulates in the alveoli, 
or may subsequently be compressed into a 
hyaline membrane. This is more apparent 
in acute cases and, if animals live for a few 
days, there is evidence of epithelialization 
of the alveolar walls. In longstanding 
cases, there is extensive epithelialization 
and fibrosis.

The pathology of bovine farmer's lung 

diffuse fibrosing alveolitis has been 

described and consists of variations of the 

lesions of chronic interstitial pneumonia.

Bacteriological examination of the lungs 
is often negative, although in long-standing 
cases in which secondary bacterial pneu- 

monia has developed Pasteurella multocida, 
*Mann. haemolytica*, *Streptococcus spp.*, and 
*Arcanobacterium pyogenes* may be found. 
A careful search should be made for 

nematode larvae.

**TREATMENT**

The treatment of fog fever in cattle is 

empirical and symptomatic. The lesion is 

irreversible in severe cases and treatment 
is unlikely to be effective. When outbreaks 
of the disease occur on pasture the first 

reaction is to remove the entire herd from 

the pasture to avoid the development of 

new cases. However, almost all new cases 

will usually occur by the 4th day after the 

onset of the outbreak and removal from
Acute bovine pulmonary emphysema and edema

Acute bovine pulmonary emphysema and edema is usually obvious when presented with an outbreak of acute respiratory disease in adult cattle which have recently been moved onto a new pasture. The onset is sudden, many cattle are found dead and many are dyspneic. ABPEE must be differentiated from:

- **Pneumonic pasteurellosis**
  - Characterized by fever, toxemia, mucopurulent nasal discharge and less dyspnea; young cattle are more commonly affected and there is a beneficial response to therapy within 24 hours.

- **Organophosphatic insecticide poisoning**
  - May resemble the pasture form of pulmonary emphysema because of the dyspnea but additionally there is purulent rhinitis, mucoid diarrhea, muscular tremor and stiffness of the limbs, and no abnormal lung sounds.

- **Nitrate poisoning**
  - May occur in cows moved into a new pasture with high levels of nitrate. Many cows are affected quickly, they are weak, stagger, gasp, fall down, and die rapidly. The chocolate brown coloration of the mucous membranes, the lack of abnormal lung sounds, and the response to treatment are more common in nitrate poisoning.

- **Other interstitial pneumonias**
  - All of the other types of acute interstitial pneumonia in cattle not associated with a change of pasture in the autumn are difficult to diagnose clinically and pathologically, especially when they occur in a single animal. Their epidemiological characteristics summarized on p. 513 will often offer some clues.

- **Bovine farmer’s lung**

  - Allergic alveolitis occurs in housed cattle exposed to dusty or moldy feeds for a prolonged period and is characterized by a history of chronic coughing, weight loss, poor milk production, occasionally green-colored nasal discharge, and dry crackles over most aspects of the lungs. Not infrequently, acute cases occur and die within a week after the onset of signs.

**Lungworm pneumonia**

Lungworm pneumonia occurs in young cattle on pasture in the autumn months and causes subacute or acute disease which may resemble bovine farmer’s lung clinically but not epidemiologically. Necropsy is necessary for the diagnosis.

**Verminous pneumonia**

Verminous pneumonia caused by aberrant migration of Ascaris suis larvae may be indistinguishable from acute interstitial pneumonia, but a history of previous occupation of the area by pigs may provide the clue to the diagnosis which can only be confirmed on pathological examination of tissues. It is impossible to differentiate clinically between verminous pneumonia and some of the acute interstitial pneumonias seen in yearling cattle except by identification of the larvae in the feces or tissues of affected animals.

**Feedlot interstitial pneumonia**

Feedlot interstitial pneumonia occurring in recently weaned beef calves or feedlot cattle is characterized by the sudden onset of respiratory distress, absence of toxemia, lack of abnormal nasal discharge, and a poor response to treatment with antibiotics. It is difficult to differentiate clinically from acute viral interstitial pneumonia or pneumonic pasteurellosis. However, in acute interstitial pneumonia there is marked dyspnea and the abnormal lung sounds are usually distributed over the entire lung fields.

**Enzootic pneumonia of calves**

Enzootic pneumonia of calves may resemble acute or chronic interstitial pneumonia but is almost entirely restricted to housed calves less than 6 months of age. They respond to treatment gradually over a few days.

Inhibition of 3-methylindole production in rumen

Controlling the conversion of DL-tryptophan in forage to 3-methylindole is a plausible control strategy. Experimental tryptophan-induced ABPEE can be prevented by simultaneous oral administration of chlortetracycline or polyether antibiotics such as monensin. The daily oral administration of 2.5 g/head of chlortetracycline beginning 1 day before and for 4 days following administration of a toxin of L-tryptophan will prevent clinical signs.

The daily oral administration of monensin at the rate of 200 mg/head/day beginning 1 day before and for 7 days after an abrupt change from a poor quality hay diet to a lush pasture reduced the formation of 3-methylindole during the 7 days of treatment, but the effect of the drug was diminished on day 10, 3 days after withdrawal. Because the effects of monensin on ruminal 3-methylindole are diminished within 48 hours after withdrawal of the drug, effective prevention of acute pulmonary edema and emphysema may require continuous administration of monensin for the critical period of approximately 10 days after the mature animals are exposed to the lush pasture. The daily feeding of monensin in either an energy or protein supplement will effectively reduce ruminal 3-methylindole formation in pasture-fed cattle.

Successful prevention of the disease requires monensin supplementation with organized grazing management to reduce the intake of lush pasture by hungry cows. This may be accomplished in several ways: feed dry, mature hay ad libitum to adult cattle just before and during the transition period of a pasture change, then continue to feed hay for at least 4 days into this grazing period; cut all lush forage and allow to wilt before allowing adult cattle access to the pasture.
pasture. Alternatively, over a 7-day period, gradually increase the amount of time cattle spend grazing lush pasture. If possible, this may be accomplished by rotating cattle back and forth, either between the summer and fall pastures, or between the fall pasture and a drylot where ample supply of dry, mature hay is available. Any combination of these management practices while providing monensin at 200 mg/head per day in an energy or protein supplement may reduce 3-methylindole production to a greater extent than just providing monensin or implementing grazing management techniques.

To maximize the effectiveness of monensin in reducing 3-methylindole formation, dry hay plus wilted forage should be fed to pastured cattle for at least 4 days after they are allowed access to lush pasture. Lasalocid at a dose of 200 mg per head daily in ground grain for 12 days reduced the conversion of tryptophan to 3-methylindole and prevented pulmonary edema.

The daily administration of inhibitors during the critical period immediately before and after the cattle are turned onto the lush pasture may be a practical method.

Other interstitial pneumonias

The control of non-pasture cases of interstitial pneumonia depends on the suspected cause and removal of it from the environment of the animals. Every attempt must be made to control the concentration of dust and moldy foods to which cattle are exposed. Feed supplies must be harvested, handled, and stored with attention to minimizing dust and molds. In the preparation of mixed ground feed for cattle, the fineness of grind must be controlled to avoid dusty feed particles which may be inhaled. Because of the creation of dust, the grinding and mixing of dry feeds like hay, straw, and grains should not be done in the same enclosed area in which cattle are housed. If dusty feeds must be used they should be wetted to assist in dust control.

Lungworm control is essential in endemic areas where the disease occurs. This may necessitate careful monitoring and regular treatment to reduce the level of infestation on pasture.

Viral interstitial pneumonias. In countries where cattle are housed, especially during the winter months, the provision of adequate ventilation is necessary to minimize aerosol viral interstitial pneumonias. Vaccination is a consideration.

REFERENCES

TRAQUEAL STENOSIS OF FEEDLOT CATTLE

Tracheal stenosis, also known as 'honker cattle', occurs in feedlot cattle. The etiology is unknown. It is characterized by extensive edema and hemorrhage of the dorsal wall of the trachea, resulting in coughing (honking), dyspnea, and respiratory stertor. Complete occlusion of the trachea may occur. Affected animals may be found dead without any premonitory signs.

In tracheal stenosis of feedlot cattle, there is marked submucosal hemorrhage dorsal and ventral to the tracheal muscle resulting in ventral displacement of the mucosa and partial to complete occlusion of the tracheal lumen. Diffuse hemorrhage in the peritracheal connective tissue and surrounding muscles of the neck is common in animals dying of asphyxia. Histologically there is hyperemia and hyperplastic tracheal mucosa with focal erosions, squamous metaplasia, and loss of cilia. In acute cases the mucosa is markedly thickened because of hemorrhage and edema. Culture reveals a mixed bacterial flora.

REFERENCE

INTERSTITIAL PNEUMONIA OF ADULT HORSES

In its most severe form, this is a disease characterized by insidious progression of pulmonary inflammation and fibrosis. Less severe forms, associated with transient viral or bacterial infections of the lungs, resolve when the infection is cleared from the lungs.

ETIOLOGY

There are many potential agents but few have been conclusively implicated as being associated with the disease. In most instances of the disease no causal association is identified.

Interstitial pneumonia is a common finding in horses associated with various infectious agents (Hendra virus infection, Rhodococcus equi in foals, Aspergillus sp., Cryptococcus sp., and Histoplasma sp., Pneumocystis carinii, Paracoccidioides brasiliensis, and Dictyocaulus arnfieldi). Inhalation of perilla ketone, derived from Perilla frutescens, causes acute restrictive lung disease of horses.2,3 Similarly, ingestion of Espartrum sp. in Australia and Hawaii causes interstitial pneumonia in horses. Inhalation of silica causes a similar disease in horses in California. Inhalation or ingestion of agricultural chemical or environmental toxins (e.g. paraquat) has the potential to cause interstitial pneumonia in other species, but this has not been demonstrated in horses.

Hypersensitivity reactions may cause severe respiratory disease in horses. Incriminating allergens include fungi (unspecified) and chicken dust.6,7 Interstitial pneumonia has also been reported subsequent to administration of an immunostimulant containing mycobacterial cell wall extract.8

EPIDEMIOLOGY

The disease occurs in adult horses without apparent breed, sex, or age predisposition. In cases in which the cause is infectious, the epidemiology of the disease is characteristic of that of the causal organism.

PATHOGENESIS

The initial insult causes injury to parenchymal cells and an acute alveolitis.9 Alveolitis results from damage to epithelial and endothelial cells by toxic, metabolic (free radicals), or infectious agents. This is followed by a phase of cellular proliferation of type 2 pneumocytes and fibroblasts with connective tissue deposition. At this time there is an influx of inflammatory cells, the exact type depending to some extent on the cause of the disease. Infiltration of neutrophils, lymphocytes, and macrophages is common. Continued injury to the lung results in development of severe interstitial fibrosis and destruction of gas exchange units.

Interstitial pneumonia results in altered pulmonary function including reduced compliance, impaired pulmonary gas exchange, and a reduction in total and vital lung capacity. The work of breathing is increased.10

CLINICAL SIGNS

Horses with idiopathic interstitial pneumonias have various combinations of: weight loss, recurrent cough, depression,
anorexia, fever, or respiratory distress. Signs of respiratory disease are not readily apparent at initial examination in all affected horses. As the disease progresses respiratory distress develops in most, but not all, cases. The usual history of is a gradual onset of increased respiratory effort, although some horses have a sudden onset of respiratory distress. Heart and respiratory rates may be elevated. Pyrexia is not a constant finding. There may be a nasal discharge. Thoracic auscultation may reveal only increased intensity of normal breath sounds or the presence of occasional crackles and wheezes. Typically, there is tachypnea with an increased respiratory effort.

Thoracic radiography reveals pulmonary disease, usually apparent as severe, diffuse interstitial disease. The interstitial opacity may be diffuse or nodular with multiple well defined opacities against an overall background of increased interstitial density. Ultrasonographic examination may reveal the presence of multiple nodules in the lung parenchyma confluent with the pleural surface. There is no excess pleural fluid.

Intradermal skin testing may be useful to identify the inciting allergen in cases of allergic interstitial pneumonia.7

The prognosis is poor in most cases of the idiopathic disease. Should recovery occur, it does so within approximately 2 weeks of diagnosis.

CLINICAL PATHOLOGY

Hematologic examination usually reveals a neutrophilic leukocytosis.13,12 Mild anemia and hyperfibrinogenemia are common. Examination of a tracheal aspirate reveals neutrophil inflammation. In cases of verminous pneumonia, there may be an increased proportion of eosinophils in tracheal aspirate. Bronchoalveolar lavage fluid can reveal a similar neutrophilic leukocytosis or may be normal.13 Serologic testing for antibodies to fungi or other inciting agents may be useful.9

Definitive diagnosis is provided by examination of tissue obtained by lung biopsy.

NECROPSY FINDINGS

The lungs do not deflate as anticipated and there may be indentations from the ribs on the surface of the lungs. Multiple pale, yellowish-white nodules 3–4 cm in diameter may be apparent on the surface of the lung and throughout the lung parenchyma. There is histologic evidence of severe, fibrosing alveolitis with minimal airway involvement. The acute phase of the disease is evident as extensive alveolar edema and hemorrhage.14

TREATMENT

Treatment should be directed toward any cause of the disease that is identified such as administration of anthelmintics. In cases of idiopathic disease, treatment is frequently unrewarding as by the time the animal is examined the disease is often advanced. Treatment includes anti-inflammatory drugs including dexamethasone or prednisolone, antimicrobials, and supportive care. Immunosuppressive drugs, such as vincristine, are not effective. Bronchodilating drugs, such as clenbuterol, may be considered, but bronchoconstriction is not a prominent component of the disease.

CONTROL

Prevention of exposure to potential infectious, toxic or environmental causes is prudent.

REFERENCES

NECROPSY FINDINGS

Necropsy examination reveals the presence of diffusely reddened, wet and firm lungs that fail to collapse.3,4 The predominant histologic lesion is necrosis of the epithelium of terminal bronchioles and alveoli.

TREATMENT

Principles of treatment are correction of hypoxemia, reduction of inflammation and removal of inciting causes. Severely affected foals may require nasal insufflation of oxygen to ameliorate or correct hypoxemia. Administration of corticosteroids has been associated with improved survival.5 Broad spectrum antibiotics are administered to treat concurrent bacterial infections and prevent secondary infection.

CONTROL

There are no specific control measures, but reduction of exposure of foals to infectious respiratory disease would be prudent.

REFERENCES

CHRONIC INTERSTITIAL PNEUMONIA OF FOALS

A sporadic disease of foals less than 10 months of age characterized by respiratory distress of several weeks duration is caused by chronic interstitial pneumonia. The etiology is unknown, but the disease likely represents a common final response to injury caused by any one of a number of infectious or toxic agents (see 'interstitial pneumonia of horses' and 'acute bronchointerstitial pneumonia of foals').
Affected foals are bright and alert and have markedly increased respiratory effort. The respiratory rate is elevated and there is a prominent abdominal component to respiratory effort. Fever is low grade and intermittent. Thoracic auscultation reveals increased intensity of normal breath sounds and the presence of wheezes and crackles in most affected foals. Ultrasonographic examination of the thorax reveals extensive 'comet tail'signs in most cases. Radiography demonstrates the presence of moderate to severe interstitial pneumonia which in some cases can include focal opacities suggestive of alveolar disease. The prognosis with appropriate treatment is excellent.

Affected foals have neutrophilic leukocytosis and hyperfibrinogamenemia. Serological examination for antibodies to common respiratory viruses is unrewarding. Culture of tracheal aspirates does not consistently yield growth of known pathogens. Lung biopsy is not warranted because the characteristic changes on radiographic examination, combined with the clinical signs, are diagnostic for the disease. The risk of adverse events associated with lung biopsy outweighs any diagnostic utility given the good prognosis for complete recovery from the disease.

Treatment consists of administration of corticosteroids such as dexamethasone phosphate at an initial dosage of 0.1–0.25 mg/kg intravenously for 3–5 days followed by a declining dose administered orally over 2–3 weeks. Prednisolone can be substituted for dexamethasone. Broad spectrum antibiotics (combination of penicillin and aminoglycoside, trimethoprim-sulfonamide, or doxycycline) should be administered for 1–2 weeks.

There are no recognized control measures, although control of infectious respiratory disease in the herd is prudent.

<table>
<thead>
<tr>
<th>Synopsis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Etiology Several different causes including thiamin inadequacy, sulfate toxicity.</td>
</tr>
<tr>
<td>Epidemiology Sporadic disease in young well-nourished ruminants on high level grain diets and not synthesizing sufficient thiamin. Ingestion of preformed thiaminase in certain plants or production by ruminal microbes may also cause destruction of thiamin. May also occur in cattle and sheep of all ages ingesting excess amount of sulfates in feed and water.</td>
</tr>
</tbody>
</table>

**Signs**
- Sudden blindness, ataxia, staggering, head-pressing, tremors of head and neck, ear twitching, champing fits, clonic-tonic convulsions, recumbency, opisthotonus, rumen contractions normal initially, pupils usually normal and responsive, nystagmus, death may occur in 24–48 hours. Hydrogen sulfide odor of ruminal gas in sulfate toxicity.

**Clinical pathology**
- Erythrocyte transketolase activity decreased and thiamin pyrophosphate effect increased but both measurements difficult to interpret: blood thiamin levels decreased but not reliable.
- Lesions
  - Diffuse cerebral edema, flattened dorsal gyri, coning of cerebellum, multifocal to linear areas of fluorescence in gray and white matter borders of cortical gyri and sulci.

**Diagnostic confirmation**
- Fluorescence of gray and white matter of cortical gyri and sulci of brain.

**Differentiation diagnosis list**

**Cattle:**
- Lead poisoning
- Hypovitaminosis-A
- Histophilus meningocerephalitis

**Sheep:**
- Pregnancy toxemia
- Clostridium perfringens Type D Enterotoxemia
- Focal symmetrical encephalomalacia
- Lead poisoning.

**Goats:**
- Caprine leukoen cephalomyelitis
- Listeria meningocerephalitis
- Clostridium perfringens Type D Enterotoxemia
- Lead poisoning.

**Treatment**
- Thiamin hydrochloride parenterally.
- Control Thiamin supplementation of diet. Avoid excess feeding or access to sulfate in feed and water supplies.

**ETIOLOGY**
Historically, PEM was considered to be caused by a thiamin inadequacy. It is now known that there are several different causes of the disease.

**Thiamin inadequacy**
The evidence that a thiamin inadequacy can be associated with the disease includes the following:
- Affected animals respond to the parenteral administration of thiamin if given within a few hours after the onset of clinical signs.
- Affected animals have biochemical findings consistent with thiamin diphosphate (TDP) inadequacy.
- The clinical signs and pathological lesions can be reproduced in sheep and cattle by the administration of large daily doses of pyrimidine containing structural analogs of thiamin, principally amprolium, given orally or intraperitoneally.

**Excess dietary sulfur**
The ingestion of excessive quantities of sulfur from the diet and water supply can cause the disease in cattle and sheep. The ingestion of thiamin at toxic levels may also cause the disease in lambs, goats, and other ruminants. In North America, UK, Australia, and New Zealand, the disease has been most common in cattle and sheep which are being fed concentrate rations under intensified conditions such as in feedlots. An inadequate amount of roughage can result in a net decrease in the synthesis of thiamin. The disease occurs most commonly in well-nourished heavy cattle 6–18 months of age (peak incidence 9–12 months of age) which have been in the feedlot for several weeks. Feedlot lambs may also be affected only after being on feed for several weeks. The disease also occurs in goats and in antelope and white-tailed deer. The disease may affect goats from 2 months to 3 years of age and is commonly associated with milk-replacer diets in kids or concentrate feeding in older goats. The disease occurs only rarely in adult cattle which may be a reflection of the greater quantities of roughage they usually consume. However, there are recent reports of the disease occurring in adult cows on pasture with access to drinking water containing excessive concentrations of sulfates.

**EPIDEMIOLOGY**

**Occurrence**
PEM occurs sporadically in young cattle, sheep, and goats, and other ruminants. In North America, UK, Australia, and New Zealand, the disease has been most common in cattle and sheep which are being fed concentrate rations under intensified conditions such as in feedlots. An inadequate amount of roughage can result in a net decrease in the synthesis of thiamin. The disease occurs most commonly in well-nourished heavy cattle 6–18 months of age (peak incidence 9–12 months of age) which have been in the feedlot for several weeks. Feedlot lambs may also be affected only after being on feed for several weeks. The disease also occurs in goats and in antelope and white-tailed deer. The disease may affect goats from 2 months to 3 years of age and is commonly associated with milk-replacer diets in kids or concentrate feeding in older goats. The disease occurs only rarely in adult cattle which may be a reflection of the greater quantities of roughage they usually consume. However, there are recent reports of the disease occurring in adult cows on pasture with access to drinking water containing excessive concentrations of sulfates.

**Morbidity and case fatality**
Accurate morbidity and case fatality data are not available, but outbreaks can occur suddenly in which up to 25% of groups of feeder cattle may be affected, with case fatality rates from 25 to 50%. Case fatality rates are higher in young cattle (6–9 months) than in the older age group (12–18 months) and mortality increases if treatment with thiamin is delayed for more than a few hours after the onset of signs. In feedlot lambs, it has been suggested that approximately 19% of all deaths are due to polioencephalomalacia.

**Risk factors**
When PEM was first described in 1956, and for about 30 years, it was considered.
to be a thiamin deficiency conditioned by dietary factors such as high-level grain feeding and inadequate roughage. PEM occurred most commonly in well-nourished young cattle from 6 to 12 months of age which were being fed high-level grain rations. The scientific investigations centered on the effects of dietary factors such as grain diets, and the presence of thiaminases in certain diets on thiamin metabolism in the rumen. The occurrence of the disease, and in some instances the thiamin status of the affected animals is within the normal range. Notable examples are the recent observations linking dietary sulfate with the occurrence of the disease.

Dietary risk factors
While there has been general agreement that thiamin inadequacy is associated with the cause of PEM, the possible mechanisms by which this occurs are uncertain. Thiamin inadequacy in ruminants could, theoretically, occur in any of the following situations where inadequate net microbial synthesis of thiamin in the rumen may occur:

- Concentrate-fed animals receiving inadequate roughage
- Impaired absorption and/or phosphorylation of thiamin
- The presence of a thiamin inhibitor in the tissues of the host
- Lack of sufficient or appropriate apo-enzyme or coenzyme-apoenzyme binding for thiamin dependent systems
- Increased metabolic demands for thiamin in the absence of increased supply
- Increased rate of excretion of thiamin resulting in its net loss from the body.

Thiamin can be destroyed by thiaminases of which significant amounts can be found in the rumen contents and feces of cattle and sheep affected with naturally occurring polioencephalomalacia.

Thiamin inadequacy
In cattle under farm conditions, using transketolase activity as a measurement of thiamin status, up to 23% of cattle under 2 years of age and 5% over 2 years may be in a thiamin-low state. Newly weaned beef calves on a hay diet are not subject to a thiamin deficiency but a low and variable proportion of young cattle on barley-based feedlot diets (17%) may have some evidence of thiamin deficiency based on a thiamin pyrophosphate activity effect in excess of 15%. The supplementation of the diet of feedlot steers on an all-concentrate barley-based diet with thiamin at 1.9 mg/kg DM resulted in an increase in average daily gain and final carcass weights. Thus some animals may be marginally deficient in thiamin which may be associated with decreased performance in cattle fed all-concentrate diets. However, thiamin supplementation of cattle on all-concentrate diets does not consistently result in improved animal performance. The experimental disease can be produced in young lambs fed a thiamin-free milk diet and it may be unnecessary to postulate that thiamin analogs produced in the rumen are essential components of the etiology.

Thiaminases
A major factor contributing to PEM in cattle and sheep is a progressive state of thiamin deficiency caused by the destruction of thiamin by bacterial thiaminases in the rumen and intestines. Certain species of thiaminase-producing bacteria have been found in the rumen and intestines of animals with PEM. Bacillus thiaminolyticus and Clostridium sporogenes produce thiaminase type I and Bacillus aneurinolyticus produces thiaminase type II. While there is good circumstantial evidence that the thiaminases from these bacteria are the real source of thiaminases associated with the disease, it is not entirely certain. The experimental oral inoculation of large numbers of thiaminase type I producing Clostridium sporogenes into lambs did not result in the disease.

Certain species of fungi from moldy feed are also thiaminase producers but the evidence that they destroy thiamin and are associated with PEM is contradictory and uncertain.

The factors which promote the colonization and growth of thiaminase-producing bacteria in the rumen are unknown. Attempts to establish the organism in the rumen of healthy calves or lambs have been unsuccessful. Thiaminases have also been found in the rumen contents and feces of normal animals which may suggest the existence of a subclinical state of thiamin deficiency. Poor growth of unweaned and weaned lambs can be associated with a thiaminase-induced subclinical thiamin deficiency. Weekly testing of young lambs over a period of 10 weeks revealed that 90% of unthrifty lambs were excreting high levels of thiamin in their feces; low levels of thiaminase activity were present in 20% of clinically normal animals, and there were significant differences in the mean erythrocyte transketolase activity of the unthrifty animals excreting thiaminase compared to the thiaminase-free normal animals.

Field and laboratory investigations have supported an association between inferior growth rate of weaner sheep in Australia and a thiaminase-induced thiamin deficiency. Thiaminase activity has been detected in the feces of lambs at 2–5 days of age, with the levels increasing for 10 days and then declining over the next 3–4 weeks. Decreased erythrocyte transketolase activity indicated a thiamin insufficiency in lambs with high thiaminase activity and mean growth rates were 17% less than lambs with low thiaminase activity. The oral supplementation with thiamin at 2–3 weeks of age was the most appropriate prevention and treatment for subclinical thiamin deficiency.

The parenteral or oral administration of thiamin to normal calves raised under farm conditions resulted in a marked reduction in the percentage thiamin pyrophosphate effect which is an indirect measurement of thiamin inadequacy. Goats with PEM were found to have elevated ruminal and fecal thiaminase activities, low erythrocyte transketolase activity, elevated thiamin pyrophosphate effect, low liver and brain thiamin levels, and elevated plasma glucose levels compared with goats not affected with the disease. With the increased interest in goat farming, some breeders attempt to improve body condition of breeding stock for sale or show by feeding grain or concentrate, which creates a situation similar to feedlot rearing of sheep and cattle which is conducive to the establishment of thiaminases in the rumen and the occurrence of polioencephalomalacia.

High levels of thiaminase type I are present in the rhizomes of bracken fern (Pteridium aquilinum) and horsetail (Equisetum arvense). The feeding of the bracken fern rhizomes (Pteridium esculentum) to sheep will cause acute thiamin deficiency and lesions similar to those of polioencephalomalacia but neither of these plants is normally involved in the natural disease. The disease has occurred in sheep grazing the Nardoo fern, Marsilea drummondii, in flood-prone or low-lying wet areas in Australia. The fern contains a high level of thiaminase type I activity. Anaranthus blitoides (prostrate pigweed) may contain high levels of thiaminase and be associated with polioencephalomalacia in sheep.

Sulfates
Polioencephalomalacia has been associated with diets high in sulfur, particularly in the form of sulfate. A high concentrate of sulfates in the diet of cattle has been associated with episodes of the disease in 6–18-month-old cattle. Inorganic sulfate salts in the form of gypsum (calcium sulfate) added to feedlot rations to control the total daily intake of the diet may cause PEM. Seasonal outbreaks have occurred in feedlot beef cattle between 15 and 30 days after introduction to a high-sulfur diet.
diet and the risk may increase when water is an important source of dietary sulfur, and during hot weather, when the ambient temperatures exceeded 32°C.8

Initial outbreaks may follow the use of a new well of water containing more sulfate than water used previously from another well, increasing from a monthly incidence of 0.07% to 0.88%. Growing cattle consume 2.4 times more water when the temperature is 32°C than at 4°C and consequently total ingestion of sulfur by consumption of high sulfate water increases during hot weather. The feed contained 2.4 g of SO4/kg DM with a total sulfur content of 0.20%. Samples of drinking water contained between 2.2 and 2.8 g of SO4/L. During hot weather daily sulfate ingestion from feed and water combined was estimated to be 64 g/animal corresponding to total dietary sulfur of approximately 0.67% of DM. Daily SO4 ingestion was approximately 160 g/animal.9 The ruminal sulfide levels were much higher 3 weeks after entering the feedlot, when the incidence of the disease was greatest, than 2 months after entering the feedlot when the risk of the disease was low.

In western Canada, there is an association between PEM and high levels of sodium sulfate in water, and range cattle are usually affected when certain waters become concentrated with this salt during the summer months.2 Water containing high levels of magnesium sulfate, often called 'gyp water', is common in the western plains and intermountain areas of the United States and Canada.9 Ideally, water for livestock consumption should contain less than 500 ppm sulfate, and 1000 ppm is considered the maximum safe level in water for cattle exposed to moderate dietary sulfur levels or high environmental temperatures. A level of 2000 ppm of sulfate in drinking water is the taste discrimination threshold for cattle. Performance of feedlot cattle is reduced when offered water with sulfate levels of 2000 ppm or higher. The National Research Council states that the requirement of sulfur in feed to be 1500 to 2000 ppm for both growing and adult beef cattle, 4000 ppm is considered the maximum tolerated dose.8 Ruminant diets normally contain between 1500 to 2000 ppm (0.15–0.20% sulfur).

Based on National Research Council guidelines, 30 g of sulfur is the calculated maximum tolerated dose of sulfur for a 650 lb (294 kg) steer consuming 16.25 (7.39 kg; 2.5% BW) of feed daily. If the ambient temperature reaches 32°C, a 650 lb steer can drink 14.5 gallons (53.9 L) of water daily. Consumption of 14.5 gallons of water containing 3000 ppm sulfate results in a daily intake of 55 g sulfur. A feed intake of 2.5% BW would also consume 22.2 g of sulfur from feed containing 3000 ppm sulfur for a total daily intake of 77.2 g of sulfur from both feed and water which is 2.5 times the maximum tolerated dose.

In some surveys, water supplies in western Canada contained 8447 ppm of total dissolved solids and 5203 ppm of sulfate. A survey of the sulfate concentrations in water on farms, found that high levels of sulfate can have a detrimental effect on the thiamin status of the cattle on those farms.10 Cattle exposed to sulfate concentrations >1000 ppm had blood thiamin levels lower than those drinking water with low levels <200 ppm. This raises the possibility that a sub-population of cattle under such circumstances could be marginally deficient in thiamin.

The total dietary intake of sulfur by cattle must be considered when investigating sulfur as a cause of PEM. In a study of one farm, water from a 6.1 m well containing 3875 mg/L of total dissolved solids with 3285 mg/L of sodium sulfate was associated with PEM in heifers 6 months of age.11 However, the water contributed about 20% of the total sulfur content in the diet of the heifers, and 60% of the dietary sulfur intake was supplied by the hay and 20% by the grain supplement. The hay contained 0.4% total sulfur which is at the maximum tolerable level for cattle and at the upper limit for hay.11 The hay consisted of variable amounts of kochia (Kochia scoparia) and Canada thistle (Cirsium arvense). Kochia scoparia (summer cypress or Mexican fireweed), is high in sulfur content and has been associated with the disease in range cattle.

PEM has occurred in pastured cattle usually 5–10 days after change from a poor to a good pasture, and may occur in range cattle grazing on dry, short, grama grass pasture.12

The levels of sulfate in water which have affected feed intake in cattle have varied from 2800 to 3340 mg sulfate per/L while other studies found no reduction in feed intake with levels up to 7000 mg/L.11 It appears that the different effects of sulfur toxicity for similar sulfur contents in saline water are attributed to the total sulfur intake. Outbreaks of the disease may occur in adult cattle on pasture drinking water containing 7200 ppm of sodium sulfate. Thus established guidelines for saline drinking water are not applicable when cattle are fed feeds grown in saline areas.

A combination of excessive intake of sulfur and a low dietary intake of trace minerals, especially copper, may affect the thiamin status of a cattle herd and contribute to PEM.13 Sulfur adversely affects both thiamin and copper status in sheep.14 A nutritionally related PEM has also been reproduced in calves fed a semipurified, low-roughage diet of variable copper and molybdenum concentrations and it was not related to copper deficiency.15 The disease has occurred in cattle in New Zealand fed chou moellier (Brassica oleracea) which contained sulfur concentrations of 8500 mg/kg DM.16 The morbidity was 25% and mortality 46% despite rapid conventional therapy.

Ammonium sulfate used as a urinary acidifier in the rations of cattle and sheep has been associated with outbreaks of PEM.3 Morbidity rates ranged from 16 to 48% and mortality rates from 0 to 8%. Affected animals did not respond to treatment with thiamin.

Outbreaks have occurred in sheep exposed to an alfalfa field previously sprayed with 35% suspension of elemental sulfur.17 The disease can be induced experimentally in lambs by the administration of sodium hydrosulfide into the esophagus18 and has occurred in lambs 3–4 weeks after being fed a concentrate ration containing 0.43% sulfur.19 Feeding experimental diets containing inorganic sulfur to young lambs was associated with PEM and supplementation of those diets with thiamin decreased the severity of the lesions.20 Rumen microbes are able to reduce sulfate to sulfides which may be directly toxic to the nervous system. Feeding calves (115–180 kg) a semipurified diet high in readily fermentable carbohydrate, without long fiber, and with added sodium sulfate for a total sulfur content of 0.36% resulted in PEM within 21 days of the introduction of the experimental diet.21 An odor of hydrogen sulfide was frequently detected upon passage of a stomach tube into the rumen of all calves during the experiment. The total thiamin concentrations in affected and control calves remained within normal limits.

The dietary content of copper, zinc, iron, and molybdenum may also have important modifying influences on sulfur toxicity. Molybdenum and copper can combine with sulfur to form insoluble copper-thiomolybdate. Copper, zinc, and iron form insoluble salts with sulfide, and their expected effect would be to decrease the bioavailability of sulfide in the rumen. Conversely, low, but not necessarily deficient, dietary contents of these divalent metals could be prerequisites for excess absorption of sulfide to occur. PEM is not associated with copper deficiency but copper and sulfur metabolism are interdependent. An excess of dietary sulfur may result in depression of serum copper, or alternatively, low serum copper may potentiate the actions of toxic levels of sulfur. Chronic copper poisoning in a lamb has been associated with PEM.22 It is suggested that the copper toxicity may have caused decreased hepatic function resulting in
increased plasma concentration of sulfur containing amino acids which may have predisposed to sulfur toxicity encephalomalacia.

**Molescence toxicity occurs in Cuba in cattle** fed on a liquid molasses-urea feeding system with limited forage. The clinical and necropsy findings are identical to polioencephalomalacia. However, molasses toxicity is not thiamin responsive and can be reversed by feeding forage. Molasses has high inorganic sulfur content and the thiamin concentrations in the brain and liver with PEM were low while molasses and urea did not differ from those in normal cattle.

Other dietary circumstances

**Deprivation of feed and water.** In some outbreaks there is a history of deprivation of feed and water for 24–28 hours, because of either a managerial error or frozen water supplies. In other cases, a rapid change in diet appears to precipitate an outbreak. Some outbreaks are associated with a temporary deprivation of water for 24–36 hours, followed by sudden access to water and an excessive supply of salt, a situation analogous to salt poisoning in pigs, but these require more documentation to insure that they indeed are not salt poisoning.

In sheep flocks, a drastic change in management, such as occurs at shearing time, will precipitate outbreaks in which only the yearlings are affected. Changing the diet of sheep from hay to corn silage resulted in a decrease in thiamin concentrations in ruminal fluid to about 25% of control values on hay. The cause of the drop in thiamin concentrations is unknown.

**Phalaris aquatic** 'polioencephalomalacia-like' sudden death in sheep and cattle. The Mediterranean perennial grass, Phalaris aquatic (formerly *Phalaris tuberosa*) can cause sudden death in sheep and cattle throughout southern Australia. The nervous form of disease is similar clinically to polioencephalomalacia but atypical because of the very rapid onset and the absence of either neuronal necrosis or malacia in cerebral cortical sections from affected animals. The available evidence suggests that this form of phalaris sudden death is more likely to involve a paracetic form of ammonia toxicity than a paracetic form of polioencephalomalacia.

**PATHOGENESIS**

**Thiamin inadequacy**

High levels of thiaminases are formed in the rumen, which destroy thiamin that is naturally synthesized. The circumstances in the diet or in the rumen which allow for the development of high levels of thiaminases are unknown but may be related to the nature of the ruminal microflora in young cattle and sheep fed concentrate rations which results in the development of ruminal acidosis. These rations may also allow for the development and growth of thiaminase-producing bacteria which, combined with a smaller net synthesis of thiamin in the rumens of concentrate-fed ruminants, could explain the higher incidence in feedlot animals. Experimentally PEM has been produced in lambs by continuous intraruminal infusion of a highly fermentable diet. Animals changed very rapidly to high concentrate rations develop increased ruminal thiaminase levels.

The possibility that intraruminal thiaminases may also create thiamin analogs capable of acting as thiamin antimetabolites and accentuating the disease has been studied but the results are inconclusive. The presence of naturally occurring second substrates (cosubstrates) in the rumen could produce, by the thiaminase type I reaction, a potent thiamin antimetabolite capable of accentuating the condition. In vitro studies have shown that thiaminase only caused rapid destruction of thiamin when a second substrate was added, and a large number of drugs commonly used as anthelmintics or tranquilizers may be active second substrates. Many compounds found in the rumen of cattle are potential cosubstrates.

Amprolium has been used extensively to produce the lesions in the brains of cattle and sheep that are indistinguishable from the naturally occurring disease. However, since amprolium has been found in the brain tissue, the experimental disease should perhaps be known as 'amprolium poisoning encephalopathy'. The administration of other antagonists such as oxothiamin and pyruvithiamin does not produce the disease. This suggests that polioencephalomalacia is a particular form of thiamin deficiency in which the supply of thiamin is reduced by the action of intraruminal thiaminases. Thus, the thiamin status of the animal will be dependent on dietary thiamin intake, thiamin synthesis, the presence of thiaminase in the rumen and the effects of possible antimetabolites. Subclinical states of thiamin deficiency probably exist in apparently normal cattle and sheep being fed diets which are conducive to the disease. This suggests that in outbreaks of the disease the unaffected animals of the group should be considered as potential new cases and perhaps treated prophylactically.

Thiamin is an essential component of several enzymes involved in intermediary metabolism and a state of deficiency results in increased blood concentration of pyruvate, a reduction in the lactate to pyruvate ratio and depression of erythrocyte transketolase. These abnormalities affect carbohydrate metabolism in general, but in view of the specific requirements of the cerebral cortex for oxidative metabolism of glucose, it is possible that a thiamin inadequacy could have a direct metabolic effect on neurons. The brain of the calf has a greater dependence on the pentose pathway for glucose metabolism, in which pathway the transketolase enzyme is a rate-limiting enzyme. Ultrastructural examination of the brain of sheep with the natural disease reveals that the first change which occurs is an edema of the intracellular compartment, principally involving the astrocytes and satellite cells. This is followed by neuronal degeneration which is considered secondary. It has been suggested that the edema may be due to a reduction in ATP production following a defect of carbohydrate metabolism in the astrocyte. There are three basic lesions which are not uniform: compact necrosis, edema necrosis, and edema alone. This may suggest that a uniform etiology such as thiamin deficiency cannot be fully supported.

In the cerebral cortex of affected animals, autofluorescent spots are observed under ultraviolet 365 nm illumination and are a useful diagnostic aid. The distribution of autofluorescence corresponds to that of mitochondria in cerebrocortical neurons in affected calves, suggesting that metabolic impairment occurs and the autofluorescent substance is produced in the mitochondria. Mitochondrial swelling and disorganization of cristae are also observable in brain tissue, but are not specific to polioencephalomalacia.

**Sulfate-induced polioencephalomalacia**

Diets high in sulfur result in hydrogen sulfide production in the rumen and anaerobic bacteria from rumen samples of cattle fed high-carbohydrate, short fiber diets with added sulfate will generate hydrogen sulfide in rumen fluid broth medium. Rumens microflora adapt to higher dietary sulfate content over a period of 10–12 days before they are capable of generating potentially toxic concentrations of sulfide. In experimental sulfate diets which induce PEM, the rumen pH decreases during the transition to the experimental diet and acidic conditions in the rumen favor increased rumen gas cap concentrations of hydrogen sulfide. With a change of pH from 6.8 to 5.2, the percent hydrogen sulfide in the rumen gas cap increased from 47 to 97%.

If ruminants inhale 60% of eructated gases, inhalation of hydrogen sulfide could be a route of systemic sulfide absorption,
in addition to gastrointestinal absorption. Sulfide inhibits cellular respiration leading to hypoxia which may be sufficient to create neuronal necrosis in polioencephalomalacia. The nervous system lesions of sulfur toxicosis are indistinguishable from lesions in the naturally occurring disease.

**Acute cerebral edema and laminar necrosis**

Acute cerebral edema and laminar necrosis occur and the clinical signs are usually referable to increased intracranial pressure from the edema, and the widespread focal necrosis. Recovery can occur with early treatment which suggests that the lesions are reversible up to a certain point. ECGs of buffalo calves with ammonium-induced PEM found decreased frequency patterns, occasional spindles and decreased voltage patterns during the onset of clinical signs. In the comatose stage, there was little evidence of electrical activity. EEGs of animals treated with thiamin hydrochloride found normal awake patterns.

**CLINICAL FINDINGS**

**Cattle**

Animals may be found dead without premonitory signs especially in beef cattle on pasture. The clinical findings are variable but characteristically, there is a sudden onset of blindness, walking aimlessly, ataxia, muscle tremors, particularly of the head with ear twitching, champing of the jaws and frothy salivation, head-pressing, and the animal is difficult to handle or move. Dysphagia may be present when one attempts to force feed hay by hand. Grinding of the teeth is common. Initially, the involuntary movements may occur in episodes, and convulsions may occur, but within several hours they become continuous. The animal usually then becomes recumbent, and there is marked opisthotonos, nystagmus, clonic-tonic convulsions, particularly when the animal is handled or moved, and tetany of the forelimbs is common. The temperature is usually normal but elevated if there has been excessive muscular activity. The heart rate may be normal, subnormal, or increased and is probably not a reliable diagnostic aid.

Rumen movements remain normal for a few days, which is an important distinguishing feature from lead poisoning in which the rumen is static.

The menace reflex is always absent in the acute stage and its slow return to normal following treatment is a good prognostic sign. The palpebral eye-preservation reflex is usually normal. The pupils are usually of normal size and responsive to light. In severe cases the pupils may be constricted. Dorsal strabismus due to stretching of the trochlear nerve is common. Nystagmus is common and may be vertical or horizontal. Optic disc edema is present in some cases but is not a constant finding.

Calves 6–9 months of age may die in 24–48 hours, while older cattle up to 18 months of age may survive for several days. Recovery is more common in the older age group.

In less severe cases, affected animals are blind, head-press into walls and fences, and remain standing for several hours or a few days. In outbreaks, some cattle will be sterrally recumbent; others remain standing with obvious blindness, while others are anorexic, mildly depressed, and have only partial impairment of eyesight. Those with some eyesight will commonly return to almost normal. Some survivors are permanently blind to varying degrees but may begin to eat and drink if provided with assistance. Some cases will recover following treatment and may grow and develop normally.

Evidence of recovery within a few hours following treatment with thiamin indicates that the disease is associated with thiamin inadequacy. A failure of response indicates the possibility of sulfur toxicity polioencephalomalacia.

**Sheep**

Sheep usually begin to wander aimlessly, sometimes in circles, or stand motionless and are blind, but within a few hours they become recumbent with opisthotonos, extension of the limbs, hyperesthesia, nystagmus, and periodic tonic-clonic convulsions. Hoggets affected at shearing time may show blindness and head-pressing but, if fed and watered, usually recover within a few days. Occasional animals show unilateral localizing signs, including circling and spasmodic deviation of the head. In goats, early signs may include excitability and elevation of the head. Blindness, extreme opisthotonos, and severe extensor rigidity and nystagmus are common.

In sulfur-induced PEM in sheep introduced to a diet containing 0.43% sulfur, clinical signs occurred 15–32 days later and consisted of depression, central blindness, and head-pressing, but no hyperesthesia or hypothermia, or opisthotonos were observed. In sulfur toxicity in lambs with PEM, the rumen contents may have a strong odor of hydrogen sulfide (rotten egg smell).

There are some reports from Australia of unthriftness in unweaned and weaned lambs being associated with thiamin deficiency due to the presence of thiaminases in the alimentary tract. In affected flocks the incidence of illthrift in lambs is much higher than the usual incidence and other causes of unthriftness were ruled out. Affected lambs lose weight, may have chronic diarrhea, and become emaciated and die from starvation. In some flocks, clinical signs of PEM may occur in a small percentage of animals. The disease occurs most commonly in early July which is the coldest part of the year in Australia for lambs which are born in May and June. In affected lambs the fecal thiaminase levels are high and the blood transketolase level activity is increased above normal. Treatment of affected lambs with thiamin resulted in an increase in growth rate.

**CLINICAL PATHOLOGY**

**Thiamin status and metabolism**

The biochemical changes occurring in cattle and sheep with the thiamin-deficiency PEM have not been well-defined diagnostically based on thoroughly investigated naturally occurring clinical cases. However, some estimates are available including the changes which occur in the experimental disease. Interpretation of the values may also be unreliable if the animals have been treated prior to death.

The erythrocyte transketolase activity is decreased and the thiamin pyrophosphate (TPP) effect is increased. The erythrocyte transketolase activities in normal sheep will range from 40 to 60 μmol/L red blood cells. A TPP effect of 30–50% is commonly found in normal healthy cattle and sheep and an increase to above 70–80% occurs in animals with polioencephalomalacia.

The thiamin concentrations of blood of animals with polioencephalomalacia have varied widely and may be difficult to interpret because of the possibility of thiamin analogs inducing deficiency even when blood thiamin levels are normal. However, this would not apply when blood thiamin levels are below normal. A normal reference range of 75–185 nmol/L is suggested for both cattle and sheep, and levels below 50 nmol/L are considered indicative of deficiency. In normal goats, the mean thiamin content of blood was 108 nmol/L, with a range of 72–178 nmol/L. In goats with polioencephalomalacia, blood thiamin levels were less than 66 nmol/L with a mean of 29 nmol/L. Levels as low as 1.8–3.6 μg/dL (6–12 nmol/L) have been found in suspected cases of polioencephalomalacia. The thiamin concentrations of liver, heart, and brain of cattle and sheep with polioencephalomalacia are decreased. The levels of blood pyruvate and lactate are also increased and thiamin pyrophosphate-dependent enzymes such as pyruvate kinase are decreased. The thiaminase activity of the feces is increased. The hemogram is usually normal; the total and differential leukocyte counts may indicate a mild stress reaction, a finding which may be useful in differentiation.
from encephalopathies due to bacterial infections.

Cerebrospinal fluid pressure taken at the cisterna magna is increased from a normal range of 120–160 mm saline to levels of 200–350 mm. The level of protein in the CSF may be normal to slightly or extremely elevated. A range from 15 to 540 mg/dL with a mean value of 90 mg/dL in affected cattle is recorded. There may also be a slight to severe pleocytosis in the CSF in which monocytes or phagocytes predominate.

Ruminal sulfide measurement. Changes in rumen gas cap H2S concentrations are larger than changes in rumen fluid H2S concentrations and estimation of rumen gas H2S concentration may be a simple, rapid, minimally invasive method for detecting pathological increases in ruminal hydrogen sulfide gas.26,27 A simple, rapid, minimally invasive method may be useful for estimating the H2S concentration of ruminal gas under field conditions. A sterile 8.9 cm 18 g needle with stilette is introduced into the gas cap of the rumen by way of the left paralumbar fossa. The needle is then connected to calibrated H2S detector tube. In cattle, with sulfate-induced polioencephalomalacia, increases in ruminal gas H2S may be as high as 100 times more than control animals.28

Brain function. The effects of high dietary sulfur on brain function have been examined using evoked potentials techniques.31 Altered nerve conduction pathways occur in sheep fed high sulfur diets without supplemental thiamin compared to animals which have received thiamin.32 The visual evoked potentials are abnormal in ruminants with thiamin-responsive polioencephalomalacia.32

NECROPSY FINDINGS

Diffuse cerebral edema with compression and yellow discoloration of the dorsal cortical gyri is evident and the cerebellum is pushed back into the foramen magnum with distortion of its posterior aspect.

In recovered animals, there is macroscopic decortication about the motor area and over the occipital lobes. The lesion can be identified grossly using ultraviolet illumination which results in a fluorescence that indicates necrosis of brain and engulfment of necrotic tissue by lipophages. In general, there is a good correlation between the presence of characteristic fluorescence and the biochemical changes in cases of polioencephalomalacia. A small percentage of false negatives may occur.

Histologically the lesions are widespread but most common in the cerebral cortex. There is bilateral laminar necrosis and necrosis of deeper cerebral areas. The necrosis is most prominent in the dorsal occipital and parietal cortex, but bilateral areas of necrosis are also seen less frequently in the thalamus, lateral geniculate bodies, basal ganglia, and mesencephalic nuclei. Lesions of the cerebellum are also present. The severity and distribution of the lesions probably depend on the inter-relationships between clinical severity, age of affected animal, and length of illness before death.

Subnormal levels of thiamin are detectable in the liver and brain of calves with the natural disease and low levels are also found in the experimental disease.21 In the molasses-induced disease in Cuba, the tissue thiamin levels were within the normal range.

In some cases of sulfur- associated polioencephalomalacia, the rumen contents have a strong odor of hydrogen sulfide – the rotten egg smell.

DIFFERENTIAL DIAGNOSIS

None of the biochemical tests described under clinical pathology is practical. The diagnosis must be made on the basis of clinical findings and the readily available simple tests which rule out other diseases that resemble polioencephalomalacia. A careful consideration of the epidemiological history often assists in the diagnosis.

Cattle

The differential clinical diagnosis for cattle is summarized in Table 32.3. Polioencephalomalacia in cattle occurs primarily in young growing animals 6–9 months of age on concentrate rations and is characterized clinically by a sudden onset of blindness, muscular tremors of the head and neck, head-pressing, nystagmus, and opisthotonos. The disease also occurs in mature beef cattle on pasture containing a high level of sulfate in their water and feed. In cattle the disease must be differentiated from:

- Acute lead poisoning which is most common in calves after spring turnout but occurs in adult cattle too and is characterized by central blindness, tremors, convulsions, uncontrollable activity with bellowing, champing fits, hyperexcitability, rumen stasis, and death in several hours. Early treatment may be successful.
- Subacute lead poisoning characterized by blindness, stupor, head pressing, rumen stasis, weak palpebral reflexes, and no response to therapy.
- Hypovitaminosis-A characterized by a history of a vitamin A deficient diet and nyctalopia, peripheral blindness, dilated and fixed pupils, optic disk edema, and transient convulsions followed by recovery.
- Histophilus meningoenocéphalitis characterized by sudden onset of ataxia, recumbency, fever, depression with eyes closed, lesions of the fundus, marked changes in hemogram, enlarged joints, and death in several hours if not treated early.

Sheep

In sheep polioencephalomalacia must be differentiated from:

- Enterotoxemia (pulp kidney disease) due to Cl. perfringens type D in unvaccinated sheep, especially feedlot lambs, in which the clinical findings are almost identical; it occurs under the same management conditions as polioencephalomalacia. Enterotoxemia in lambs usually develops within several days after being placed on a grain ration, whereas polioencephalomalacia occurs after several weeks of grain feeding.
- Gloscosia in pulse kidney disease may assist the diagnosis but a necropsy is usually more informative.
- Focal symmetrical encephalomalacia also resembles polioencephalomalacia but is sporadic, usually involves only a few animals and will not respond to treatment.

Goats

In goats the disease must be differentiated from caprine leukoencephalomyelitis, listeriosis, enterotoxemia, pregnancy toxemia, lead poisoning, and meningoencephalitis.

TREATMENT

Thiamin hydrochloride

The treatment of choice for thiamin deficiency PEM is thiamin hydrochloride at 10 mg/kg BW IV initially and followed by similar doses every 3 hours for a total of 5 treatments. When treatment is given within a few hours of the onset of signs, a beneficial response within 1–6 hours is common and complete clinical recovery can occur in 24 hours. Goats and sheep will commonly respond within 1–2 hours. For those which take longer to recover, the eyesight and mental awareness will gradually improve in a few days and the animal will usually begin to eat and drink by the third day after treatment. Rumen transplants of rumen juice from roughage-fed cattle may improve appetite and rumen function in those responding slowly. In sheep, following treatment with thiamin the blood transketolase activity begins to return to normal in 2–4 hours and is considered normal 24 hours after treatment.

Some cattle improve to a subnormal level within a few days and fail to continue to improve. These are usually affected with diffuse cortical and subcortical necrosis and will usually not improve further in spite of continued treatment. Those which return to a clinically normal state will usually do so by 48 hours or sooner after initial treatment. Those which are still clinically sub-normal and anorectic by the end of the third day will usually remain at that level and should be slaughtered for salvage.

Treatment is ineffective in advanced cases, but unless an accurate history is...
available on the length of the illness, it is usually difficult to predict the outcome until 6–12 hours following treatment. Thus, it is usual practice to treat most cases with thiamin at least twice and monitor the response. If there is no beneficial response in 6–8 hours, emergency slaughter for salvage should be considered.

The oral administration of thiamin or thiamin derivatives is indicated when thiaminases are thought to be in the alimentary tract. Thiamin hydrochloride at a rate of 1 g for goats and lambs and 5 g for calves, in a drench, is recommended. However, because the action of thiaminase type I on thiamin may result in the production of thiamin analogs which may act as inhibitors of thiamin metabolism, the use of thiamin derivatives which are resistant to thiaminases, lipid soluble and absorbed from the intestine are being explored as therapeutic and prophylactic agents. Thiamin propyldisulfide can depress the thiaminase activities in the ruminal fluid of sheep with polioencephalomalacia within 2 hours after oral administration. The blood pyruvate levels and transketolase activities are also restored to normal and treated animals recovered clinically.

Outbreak management
In outbreaks, the in-contact unaffected animals on the same diet as the affected animals may be on the brink of clinical disease. The diet should be changed to one containing at least 50% roughage or 1.5 kg of roughage per 100 kg BW. Thiamin may be added to the ration at the rate of 50 mg/kg of feed for 2–3 weeks as a preventive against clinical disease, followed by a level of 20–30 mg/kg of feed (cattle and sheep) if the animals remain on a diet that may predispose them to the disease.

Sulfur toxicity polioencephalomalacia
There is no specific treatment for PEM caused by sulfate toxicity. The use of thiamin hydrochloride in doses given above is recommended.7

CONTROL
Thiamin supplementation
A rational approach to the control of PEM associated with thiamin inadequacy is to supplement the rations of concentrate-fed cattle and sheep with thiamin on a continuous basis. The daily requirements for protection have not been determined using controlled feeding trials but a rate of 3 mg/kg DM of feed for cattle and sheep has been recommended. This level may not be protective in all situations and response trials may be necessary to determine protective levels for different situations. Levels up to 20–30 mg/kg of feed may be necessary for protection. Most natural feedstuffs for ruminants contain thiamin at about 2 mg/kg DM which when combined with the thiamin synthesized in the rumen will meet the requirements. However, the presence of thiaminases in the rumen will necessitate dietary supplementation with thiamin, but the optimal amount that will provide protection under practical conditions is uncertain.

The IM injection of 500 mg thiamin 3 times weekly into 6-month-old calves raised under practical farm conditions will steadily reduce the percentage pyrophosphate effect to zero in about 6 weeks. The daily oral administration of 100 mg thiamin to young calves fed initially on milk substitutes and then on concentrates and hay results in a decrease in percentage pyrophosphate effect.

For animals which are fed diets associated with thiamin inadequacy, it is recommended that thiamin be added to the diet at the rate of 5–10 mg/kg DM.12 Cattle and sheep on concentrate-fed rations must also receive supplements containing all necessary vitamins and minerals, especially cobalt, a deficiency of which may be associated with some outbreaks of the disease.

Feeding roughage
The minimum amount of roughage which should be fed to feedlot cattle and sheep in order to prevent the disease and still maintain them on high levels of concentrates is unknown. A level of 1.5 kg of roughage per 100 kg BW has been recommended but this may not be economical for the feedlot whose profits are dependent on rapid growth in grain-fed cattle. Supplementation of the diet with thiamin appears to be the only alternative.

The prevention of the disease in sheep which are being moved long distances or gathered together for shearing and other management practices will depend on insuring an ample supply of roughage and water and avoiding drastic changes in management.

Sulfate toxicity PEM
The prevention of the disease associated with a high sulfate intake in the feed and water supplies will depend on analysis of the feed and water for sulfate and making appropriate adjustments in the sources of feed and water in order to decrease the intake of sulfur to safe levels.

REFERENCES

EQUINE NEONATAL ENCEPHALOPATHY (NEONATAL MALADJUSTMENT SYNDROME OF FOALS, DUMMY FOAL, BARKERS, AND WANDERERS)
This is a syndrome of foals less than 36 hours of age characterized by a spectrum of changes in mentation ranging from failure to suckle, abnormal behavior, seizures, through coma in otherwise apparently healthy foals.

ETIOLOGY
A number of diseases cause the clinical signs consistent: with this syndrome. These include antenatal, natal or postnatal hypoxia, congenital and metabolic anomalies, placental abnormalities, intracranial hemorrhage, prematurity, and thoracic trauma.1 Of these causes, hypoxia before, during or soon after birth is considered the most common cause of neonatal encephalopathy, although hypoxia is rarely documented. It is important to realize the neonatal encephalopathy is one of many manifestations of hypoxia of the fetus or neonate, the other manifestations including gastrointestinal and renal damage.23

EPIEDEMOLOGY
The disease is sporadic and occurs worldwide with an annual incidence in foals of approximately 1%.4 Foals of either sex and of any breed born to mares of any age
It is speculated that hypoxia resulting from intracranial vascular accidents, asphyxia at birth or placental insufficiency before birth damages the central nervous system. Neurological abnormalities and a failure to nurse, result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia.

**CLINICAL SIGNS**

Foals that are abnormal at birth can display a range of behavioral abnormalities, from lack of suckle reflex to convulsions with extensor rigidity. The placenta of affected foals is often abnormal or there is a history of prolonged parturition. Affected foals either do not develop or lose the suck reflex, and have no affinity for the mare and are unable to locate the udder or teat. Aimless wandering and vocalization are sometimes present. Recumbent foals struggle wildly and in an uncoordinated fashion to stand. Convulsing foals usually display opisthotonos with extensor rigidity. Other signs of convulsive activity include facial twitching and grimacing, nystagmus, rapid blinking, sucking, chewing, and drooling. Between episodes foals are usually depressed or somnolent. Affected foals display little or no interest in the mare. Convulsing foals are tachypneic, tachycardic (>180 bpm), and hyperthermic (>39°C, 102°F) during and immediately after convulsions. It is important to recognize that the severity of clinical signs varies from very mild (foals are often described by owners as being a bit slow or dimwitted) to grand mal seizures.

**Foals that are normal at birth may** develop signs by 24 hours of age. The case fatality rate is very low for appropriately treated foals without other systemic illness.

**PATHOGENESIS**

It is speculated that hypoxia resulting from intracranial vascular accidents, asphyxia at birth or placental insufficiency before birth damages the central nervous system. Neurological abnormalities and a failure to nurse, result in a failure of the transfer of maternal immunoglobulins, which predisposes the foal to septicemia and hypoglycemia.

</table>
Affected foals can take days to weeks to recover completely. Blind foals that do not have ocular lesions can take as long as 4–6 weeks to regain vision.

Ancillary testing is not usually indicated unless the foal fails to respond after approximately 7 days. At that time, CT or MRI examination of the brain might be indicated to detect congenital anomalies such as hydrocephalus. Examination of cerebrospinal fluid should be performed in any foal with signs of CNS dysfunction in the presence of fever or other signs of sepsis.

CLINICAL PATHOLOGY

There are no hematological or serum biochemical abnormalities characteristic of the disease:

- Affected foals usually have failure of transfer of maternal immunoglobulins (serum IgG <400 mg/dL)
- They may be hypoglycemic (<80 mg/dL, 4 mmol/L)
- Cerebrospinal fluid is often normal, although it may contain red blood cells or upper xanthochromia as a result of bleeding.

DIAGNOSTIC CONFIRMATION

Definitive diagnosis of the disease is difficult and is based on exclusion of other diseases that can cause similar signs and, at necropsy, demonstration of intracranial lesions consistent with the disease.

NECROPSY FINDINGS

Gross changes are typically limited to diffuse pulmonary congestion with a variable degree of atelectasis. In cases in which dystocia has been a contributing factor, fractured ribs, and foci of subcutaneous edema and hemorrhage are sometimes noted. Occasionally, macroscopic cerebral hemorrhages are visible. Histologically, the key findings are hemorrhagic foci within the brain and areas of ischemic necrosis in the cerebral cortex. Meconium and other components of aspirated amniotic fluid accompanied by atelectasis and a mild inflammatory response may be present within the lung. In less affected foals the brain lesions are restricted to hemorrhage, cerebral swelling, and edema. Many affected foals have evidence of intracranial vascular accidents. Affected foals that are euthanased often have no detectable lesions in the brain.

Samples for post-mortem diagnostic confirmation

Formalin-fixed brain, including cerebral cortex, cerebellum and brain stem, and lung for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other diseases that cause neurological or behavioral abnormalities in foals including: sepsis; renal, hepatic, or gastrointestinal disease, which can occur secondary to fetal hypoxia; hydrocephalus; hypoglycemia; meningitis; neonatal isoimmune hemolytic anemia; and prematurity, dysmaturation, or immaturity.

TREATMENT

The principles of treatment are:

- Control of convulsions
- Treatment of cerebral edema and hemorrhage
- Correction of failure of transfer of passive immunity
- Nutritional support and general nursing care. The management of affected foals is mainly supportive and is time consuming and labor intensive.

Provision of nutritional support, treatment of failure of passive transfer of maternal immunoglobulins, and nursing care is dealt with in detail in the section ‘Principles of care of the critically ill neonate’.

For other than emergency treatment of seizures, in which diazepam (0.1–0.4 mg/kg, intravenously, as required) or midazolam (0.05–0.1 mg/kg IV, as required) are useful, phenobarbital (phenobarbitone), phenytoin and primidone are the drugs of choice for long-term control of seizure activity. Phenobarbital is administered initially at a dose of 1–3 mg/kg intravenously in 30 mL of isotonic saline infused over 15–30 minutes. Maintenance therapy is a similar dose intravenously or orally, every 8 hours, and the dose adjusted to provide control of seizures while minimizing the degree of sedation. Because of the long elimination half life of phenobarbitol in foals (~200 hours) and the transient nature of the disease, once seizure control is achieved administration of phenobarbitol can be discontinued. Drug concentrations will be at or above the target concentration (5–30 μg/mL) for several days after the final dose. Phenytoin (5–10 mg/kg intravenously or orally initially, then 1–5 mg/kg every 4 hours) or primidone (20–40 mg/kg orally every 12–24 hours, to effect) are also used to control convulsions.

Definitive demonstration of the presence of cerebral edema or intracranial hemorrhage is impossible without sophisticated imaging devices, such as magnetic resonance imaging or computed tomography (CT). However, treatment is often initiated on the basis of clinical signs. None of the treatments have demonstrated efficacy, and some are controversial. Dimethyl sulfoxide (DMSO) is given intravenously at 0.5–1 mg/kg once or twice daily for 3 days as a 10% solution. Mannitol (0.25 g/kg, intravenously as a 20% solution) may be effective in treating cerebral edema but is contraindicated if intracranial hemorrhage is present. Glucocorticoids (dexamethasone, 0.2–1 mg/kg or prednisone, 1–2 mg/kg) might reduce intracranial inflammation and swelling. They might be contraindicated in foals with sepsis.

Magnesium sulfate (0.05 mg/kg per hour for one hour, then 0.025 mg/kg/h IV for up to 48 hours) is often administered to foals with suspected hypoxic encephalopathy in an attempt to minimize neuronal damage. There is no objective evidence of its efficacy in foals.

Foals with respiratory depression can be administered caffeine (10 mg/kg orally once and then 3.0 mg/kg orally q 24 hours). Adverse effects include agitation, hyperesthesia, tachycardia, and convulsions.

Good nursing care is critical in affected foals, and a concerted and persistent effort should be made to encourage the foal to nurse the mare. Encouraging the foal to nurse can be frustrating for the handler and mare, but should be done regularly, about every 4 hours, and preferably when the foal is hungry. Affected foals often begin to nurse quite suddenly.

Affected foals can require up to 4–6 weeks to recover completely, although most do so within 1 week of birth, and hasty decisions regarding euthanasia should not be made without recognition of the sometimes long time required for complete recovery.

CONTROL

Prevention of hypoxia in neonates by close monitoring of the health of the mare and of parturition may reduce the incidence of the disease.

**CONGENITAL TREMOR SYNDROMES OF PIGLETS**

Tremors in pigs are not a common clinical sign. Recently, generalised tremors have been described in grower pigs\(^1\) but until this report the condition has only been described as a neonatal condition. The condition has been known for a long time in Britain.

This group of at least four etiologically distinct congenital diseases of the nervous system has a similar clinical and pathological identity. In particular they all have congenital tremor (myoclonia congenita) and these rhythmic tremors are most evident while the piglet is standing, are reduced when it lies down, and disappear when it is asleep. It is therefore not encephalitis or an increased sensitivity of the spinal cord reflexes.

Although the tremor is present at birth it may not be observed until the piglets are 2 or 3 days old and beginning to move about actively. The tremor varies from a very rapid twitch affecting only the head to a slow tremor causing the pig to 'dance'; there may be such a severe tremor that the body and head tremble violently and rock from side to side. There is no muscular weakness and the piglets get up and scamper about, but there may be ataxia and dysmetria so that the gait may be badly affected. Mildly affected piglets are not greatly incapacitated and can survive and eventually recover in 2–8 weeks; the tremor fades gradually, and near the end of the course it may be evident only during exercise. Badly affected piglets may be unable to get to the teat to suck and may die of starvation. Many are fatally crushed or trampled by the sow.

For convenience, entities within the syndrome have been classified into two types.

**Type A** has morphological lesions and there are 5 types AI, AII, AIII, and AIV for which the causes are known.

Type AI (*myoclonia congenita*) results from transplacental infection of the fetus by particular strains of swine fever virus.\(^2\) In litters affected by swine fever virus usually about 40% of the litter is affected. The characteristic lesions are cerebellar hypoplasia and cerebrospinal dysmyelogenesis. When the disease caused by the unidentified viral infection of the fetus first appears in a piggy all litters are affected. Most pigs in each litter have the disease, but after a period of several months the disease disappears, apparently because of herd immunity. The principal sign as in the swine fever induced disease is myoclonia, and most piglets recover. Spinal dysmyelogenesis is the characteristic lesion.

Type AII (*myoclonia congenital*) is caused by transplacental infection with an agent presumed to be a virus and it is believed to be the most common type of congenital tremor.

Type AIII (congenital cerebrospinal hypomyelogenesis) is a hereditary form so far found only in Landrace and known as Landrace trembles.\(^5\) The inherited sex-linked disease occurs in the progeny of Landrace or Landrace-cross sows. Up to 11% of Landrace piglets may be affected compared to only 0.3–0.8% in the Yorkshire, Hampshire, and Duroc breeds. The mode of transmission is via a monogenic sex-linked recessive character, and half of all male pigs born are affected. Histologically, there is cerebrospinal myelogenesis. Most affected pigs die. It is essentially a deficiency of oligodendrocytes.

Type AIV is also a genetically determined condition due to an autosomal recessive condition found in Saddlebacks. It is seen in about 25% of the progeny, and is fatal in most of them. Cerebrospinal dysmyelogenesis is the characteristic lesion. It is characterised by a deficiency of myelin throughout the CNS.\(^6\) A type distinct from this has also been reported in Saddleback × Large White sows.\(^7\)

Type AV occurs naturally in Scandinavia\(^8\) and is characterized by cerebellar hypoplasia and has been experimentally produced following dosing of pregnant sows between 45 and 75 days of gestation with trichlorfon.\(^9\)

**Type B** is a form of congenital tremor not yet adequately characterized and without morphological lesions and is of unknown etiology. The differentiation of these diseases is now possible on the basis of histopathological and neurochemical findings and relating these to the epidemiological data. In piglets born from sows inoculated with the Weybridge congenital tremor strain of the swine fever virus in early pregnancy, the severity of the clinical signs was related to the degree of spinal myelin deficiency. Semiautomated planimetry can be used to determine the cross-sectional areas of spinal gray and white matter of affected piglets. The spinal cord cross-sectional area is significantly reduced in piglets affected with Type AI congenital tremor. The reduction is similar to Type AII. The neurochemical findings relate to the presence of particular fatty acid profiles in the cholesterol esters in the lipids of the spinal cord.

Control of the disease depends on its cause. If it is inherited the recommended procedure is to keep none of the affected recovered pigs for breeding. If the cause is one of the maternal infections of early pregnancy it is recommended practice to deliberately expose empty females to affected piglets so that they become immunized before pregnancy. Failure to identify the cause may necessitate adopting both procedures.

The disease appears to occur sporadically but when it does occur it may remain great importance. As many as 15% of litters born in a piggery may be affected, and of these 72% of the piglets may be affected and the case fatality rate amongst these may be as high as 50%. There is a feeling amongst veterinarians that the condition has increased recently but this may just be an increased awareness. If there is an increase, the specific cause of the increased prevalence has not been identified but it is possibly the unidentified virus referred to above: the virus of congenital tremor Type AII. There is also the possibility that the observed concurrent increase in prevalence of both splay leg and congenital tremor may indicate that they are possibly caused by the same virus. In this context, there is conjecture, that the PCV2 virus which is extremely small and similar in size to the particles that were described in the early electron micrographs of the spinal cord of affected piglets may be responsible. As yet there is no confirmation that splay leg and congenital tremor are PCV2 associated disorders.\(^10\)

**REFERENCES**

**OVINE HUMPBACK**

This is a disease of sheep, mainly Merino wethers, in western Queensland, characterized by stiffness and shortness of steps when forced to walk for about a kilometer. The sheep stops walking and adopts an arched back posture. At this time the body temperature is significantly elevated and the level of lymphocytes in the blood is lowered. The greatest incidence is in summer after rain and when the sheep are in full wool, and the hyperthermia and ataxia disappear when the sheep are shorn. Environmental temperatures at the time of the greatest prevalence of the disease are high,
commonly $40^\circ$C. This occurs in spite of the presence of a characteristic degeneration of spinal cord tracts. The obvious explanation of the phenomenon is that it is a form of heat stroke and that the nervous system lesions are incidental.

REFERENCE

EQUINE CERVICAL VERTEBRAL STENOTIC MYELOPATHY, (WOBBLER, 'WOBBLES', EQUINE SENSORY ATAXIA, CERVICAL VERTEBRAL INSTABILITY)

Synopsis

Etiology Unknown.
Epidemiology Sporadic or endemic disease of young horses. Young, rapidly growing male horses are most commonly affected. Separate presentation in middle-aged horses in which it is sporadic.
Clinical signs Spinal ataxia evident as truncal sway, ataxia and paraisy usually more severe in the hind limbs. Radiographic evidence of narrow spinal canal.
Clinical pathology None.
Lesions Malacia and Wallerian degeneration in the cervical spinal cord.
Differential diagnosis Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis, West Nile encephalomyelitis, equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, congenital vertebral malformation, diskospondylitis, and rye-grass staggers.
Treatment Anti-inflammatory drugs. Surgical fusion of vertebrae.
Control None.

ETIOLOGY
The cause of neurologic disease is compression of the cervical spinal cord, hence the term compressive myelopathy. The compression may be static, that is the compression is present constantly with the neck in a neutral position, or dynamic and only present intermittently when the neck is either flexed or extended. The second situation is often referred to as cervical vertebral instability. The etiology of equine cervical stenotic myelopathy (CSM) in most cases is not known. Several basic syndromes of compressive myelopathy, based on age of occurrence, are recognized:

- Equine stenotic myelopathy (ESM) in immature horses (less than 3 years of age, depending on breed) that is often associated with developmental joint disease in the axial and appendicular skeleton. The fundamental underlying defect appears to be a narrow diameter of the cervical vertebral canal.
- Cervical vertebral instability (CVI), a disease of horses less than 1 year of age, is often associated with malformations of one or more of the cervical vertebrae.
- Compressive myelopathy in mature horses, 4-6 years (usually >7 years) of age, associated with osteoarthritis of the articular facets of the caudal cervical vertebrae, with subsequent impingement of the vertebral canal by bony and soft tissue proliferative lesions.
- Miscellaneous causes of cervical cord compression by neoplasia (melanoma, sarcoma, lymphoma), trauma (cervical vertebral fractures), arachnoid or synovial cysts or, rarely, diskospondylitis.

An alternative categorization is based on the nature of the bony lesion and not on the cause of compression of the spinal cord.
- Type 1 cervical vertebral malformation occur in horses <2 years of age that have vertebral changes that likely began in the first few months of life, and include malformations causing stenosis of the vertebral canal, malformations at the articulations of the vertebrae including osteochondrosis, and enlarged physes of growth areas.
- Type II cervical vertebral malformations tend to occur in older horses with severe osteoarthritic lesions of the vertebral articulations.

EPIDEMIOLOGY
Occurrence
The disease in mature horses occurs sporadically throughout the world.
- The disease in young horses is sometimes endemic on farms or studs, and in particular lines of horses. There is a suggestion of a familial tendency for the disease, although this has not been well documented.

The morbidity rate may be as high as 25% of each foal crop on individual Thoroughbred farms, although the overall frequency of the disease in the general horse population is much lower.

Risk factors
Animal risk factors
The disease in young horses is commonly recognized in Thoroughbred, Standardbred, Warmblood, and Quarter horses, but other breeds can be affected. Ponies are rarely, if ever, affected. The disease occurs in horses less than 4 years of age, with most cases occurring in 1-3-year-old horses. Males are more commonly affected than females. Horses with cervical stenotic myelopathy have a narrower spinal canal than do unaffected animals and this condition, with degenerative joint disease of the articular facets and thickening of the ligamentum flavum, contributes to the greater likelihood that the horse will have spinal cord compression.

It is suspected that predisposition to the disease is heritable, but this has not been demonstrated by appropriate studies. The stenotic myelopathy is believed to be the result of a combination of fast growth rate and over nutrition, and dietary restriction may reduce the incidence of the disease. A relationship of ESM to developmental bone disease (osteochondrosis) and dietary copper has been suggested, but is unproven.

The disease in mature horses tends to be in horses used for athletic endeavours, and is uncommon in brood mares or retired animals.

PATHOGENESIS
The disease is attributable to injury to the spinal cord as a result of compression by either soft tissue (joint capsule, intervertebral ligaments, or, rarely, intervertebral disk material) or cartilage and bone. Constant or intermittent pressure on the spinal cord causes necrosis of white matter and neurons at the site of compression, and degeneration of fibers of ascending tracts cranial to the site of compression, and of descending tracts caudal to the compression. The ascending tracts are those associated with general proprioception whereas the descending tracts are upper motor neurons. These tracts are located superficially in the dorsolateral aspect of the cervical spinal cord and damage to them results in signs of ataxia and weakness. Tracts from the caudal limbs are more superficial, and therefore more easily injured, than ar tracts associated with the cranial limbs. Consequently, clinical signs are usually more severe in the hind limbs. The spinal cord lesions are usually, but not always, bilaterally symmetrical, as are the clinical signs. Propriconeptive pathways are disrupted, causing the signs of ataxia (incoordination) typical of the disease. Clinical signs vary depending on the site of the lesion (see below).

CLINICAL FINDINGS
The onset of clinical signs is sometimes acute in both ESM and CVI in young horses and there may be a history of trauma, such as falling. However, the onset of clinical signs in ESM in both young and mature horses is usually gradual and insidious and in mildly affected horses the nervous disease may be mistaken for lameness of musculoskeletal origin. Affected horses are bright and alert and have a normal appetite. There may be evidence of pain on manipulation of the neck, especially in mature horses, or on firm pressure over the lateral facets.
The severity of clinical signs varies from barely detectable to recumbency. There are no defects of cranial nerves, with the exception of the cervicofacial reflex.

Mildly affected horses may have deficits that are difficult to detect and only apparent under saddle or at high speed. The owner may complain of poor performance of a race horse or dressage animal, of an animal that frequently changes leads or that is poorly gaited. Careful examination may reveal excessive circumduction of the hind feet, stumbling, and pacing when the head is elevated.

Moderately affected animals have truncal sway, the body of the horse and hind quarters swaying laterally when the horse is walked in a straight line, and excessive circumduction of the hind feet. Having the horse move in a very tight circle about the examiner often causes the circumduction to become worse in the outside hind leg and the horse to place one foot on top of the other. Affected horses will sometimes pace when walked in a straight line with the head elevated. Blindfolding the horse does not exacerbate the signs. Affected horses will stumble when walked over low objects, such as a curb, and will knuckle at the fetlocks and stumble when walked down a steep hill.

Severely affected horses often fall easily when moved or are unable to stand. The horses are bright and alert, but anxious, and display marked truncal sway and ataxia. When standing they will often have their legs in markedly abnormal positions.

Mature horses with disease secondary to arthritis of the articular facets can have hypalgesia of the skin overlying those regions and atrophy of the cervical musculature.

Horses with lesions in the cervical spinal cord cranial to C6–C7 have signs in both fore and hind limbs. The hindlimbs are more severely affected and the signs are usually, but not always, bilaterally symmetrical. Lesions of the cervical intumescence (C6 to T2) may cause signs that are more severe in the forelimbs than in the hindlimbs. Lesions at this site may also cause signs typical of brachial plexus injury. Pseudosclerosis is not characteristic of ESM or CVI and there are never signs of cranial nerve, cerebral, or cerebellar disease.

After initial progression the clinical signs usually stabilize or partially resolve. However, complete spontaneous recovery is very unusual. Death is unusual unless it is by misadventure, although many affected animals are killed for humane reasons.

Ancillary diagnostic tests

The ‘slap test’, in which the response of the arytenoid cartilages to a slap on the thorax is examined through an endoscope, has poorer sensitivity and specificity for detecting spinal cord disease than does a routine neurological examination. Acupuncture has no proven value in the diagnosis of ESM or CVI and should not be used for this purpose.

Radiographic examination

Radiographic examination of cervical vertebrae of affected horses reveals narrowing of the spinal canal. This has diagnostic utility, e.g. a ratio of spinal canal to vertebral body diameter of less than 30% for C4 is associated with a 28-fold increase in the probability of ESM. Other measures of spinal canal diameter are useful in the detection of stenosis and compressive myelopathy. Other radiographic signs consistent with ESM or CVI include:

- Encroachment of the caudal vertebral physis dorsally into the spinal canal (‘ski jump lesion’)
- Extension of the arch of the vertebrae over the cranial physis of the next vertebra
- Sclerosis of the spinal canal
- Kyphosis between adjacent vertebrae
- Degenerative joint disease of the articular facets

However, these signs are also common in normal horses and have poor predictive value. Myelography has been considered to provide the definitive ante mortem confirmation of spinal cord compression. However, the sensitivity of this technique, using a 50% reduction in the width of the dorsoventral dye column as a cut-off for diagnosis of the disease is 53% (95% confidence interval 34–72%, n = 22) and the specificity is 89% (95% confidence interval of 84–93%, n = 228). Others have found similar values for sensitivity and specificity. These results indicate that a positive finding on myelography is highly suggestive of the disease, but that a negative finding does not eliminate the possibility of the disease. The false-positive rate is increased to 12–27% for compression at mid–cervical sites during neck flexion. Myelography is superior in diagnosing compressive lesions at C6–C7 than at more proximal sites. Occasionally the compression is lateral rather than dorso-ventral and is not readily apparent on routine myelography.

CLINICAL PATHOLOGY

Hematological and serum biochemical values are usually within reference ranges in affected horses. Cerebrospinal fluid from affected horses may have increased protein concentration, but this finding is neither characteristic nor specific for ESM or CVI. However, other causes of spinal ataxia may cause characteristic changes in the cerebrospinal fluid. Measurement of creatine kinase activity in CSF has no diagnostic value in horses.

DIFFERENTIAL DIAGNOSIS

Equine degenerative myelopathy, equine protozoal myeloencephalitis, trauma, equine infectious anemia, cerebrospinal nematodiasis (Hypoderma spp., Setaria sp., Halicephalobus megalenuis), equine herpesvirus-1 myelopathy, aorto-iliac thrombosis, West Nile encephalomyelitis, congenital vertebral malformation (especially in Arabian foals), discospondylitis, tumors involving the spinal canal (melanoma, lymphoreticular neoplasia), and rye-grass staggers. See Table 36.3.

TREATMENT

Medical treatment of the acute disease consists of rest and administration of anti-inflammatory drugs (dexamethasone 0.05–0.25 mg/kg, IV or IM every 24 hours; flunixin meglumine 1 mg/kg, IV every 8–12 hours; phenylbutazone 2.2–4.4 mg/kg, orally every 12–24 hours; and/or dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline, IV every 24 hours for 3 treatments).

Treatment of arthritis of the facets of mature horses can be achieved by injection of the articular facets joints with corticosteroids (40 mg methylprednisolone acetate). Injection of the joint is facilitated by ultrasonographic guidance. Injection of the joints with anti-inflammatory drugs is assumed to result in reduction in inflammation and soft tissue swelling with consequent reduced compression of the cervical spinal cord.
A ‘paced growth’ program of slowed growth achieved by nutritional restriction of young horses (foals and weanlings) has been suggested as conservative treatment for immature horses with compressive myelopathy or at high risk of developing the disease.19

**Surgical fusion** of cervical vertebrae is useful in the treatment of mildly to moderately affected horses, although because of issues of safety of future riders there are concerns by some authorities about the advisability of this treatment.

**CONTROL**

Control measures are not usually employed, although insuring an appropriate diet and growth rate of at-risk animals would be prudent. Because of the possible inherited nature of the disease, a corrective breeding program may be advisable.

**REVIEWS**

---

**STRINGHALT**

Stringhalt is an involuntary, exaggerated flexion of the hock during walking. It can affect one or both hindlimbs. Classic...
stringhalt occurs sporadically, is usually unilateral, and is usually irreversible without surgical intervention. Stringhalt can also occur secondarily to injury to the dorsal metatarsus.1

A clinically identical disease, Australian stringhalt, occurs in outbreaks in Australia, New Zealand, California, Japan, and Chile.2,3 The outbreaks tend to occur in late summer or autumn and are related to drought conditions or overgrazing of pasture with consequent ingestion of plants that would otherwise not be eaten.4 Outbreaks in Australia, California, and Virginia are related to the ingestion of Hypochoeris radicata (flatweed, cats ear).4,8 Other plants suspected to play a role in the etiology include Taraxacum officinale (dandelion), Arctotheca calendula (capeweed) or Malva parviflora (mallow) but good evidence of the role of any of these plants is lacking.

The abnormal movement is only elicited when the horse begins to move forward. The characteristic movement occurs in mildly affected horses when they are backed or turned. Most cases are manifested by a flexion of the hock that can be violent enough for the horse to kick itself in the abdomen. The hoof is held in this position for a moment and then stamped hard on the ground. If both hind legs are affected progress is very slow and difficult and the horses often use a ‘bunny hopping’ gait. In the most severe cases the horse is unable to rise without assistance. The horse’s general health is unaffected although it may be difficult for it to graze. Some cases have other signs of neurologic disease such as stiffness of the forelimbs or respiratory distress due to laryngeal paralysis. Many affected horses have unilateral (usually left) laryngeal hemiplegia evident on endoscopic examination of the larynx. Electromyographic examination reveals markedly abnormal activity including prolonged insertion activity, fibrillation potentials, and positive waves at rest and enhanced EMG activity in the right lateral digital extensor muscle on muscle contraction consistent with denervation. The changes are most severe in the long digital extensor muscle.5 Most horses recover without treatment, although complete recovery might not occur for over 1 year.2,5

There are no characteristic abnormalities in a complete blood count or serum biochemical profile. Pathological findings are restricted to a peripheral neuropathy in the tibial, superficial peroneal and medial plantar nerves and in the left and right recurrent laryngeal nerves.9,10 Lesions in affected muscles are consistent with denervation atrophy and fiber type grouping.

The signs of the disease are characteristic. Differential diagnosis of the disease involving one leg is ossifying myopathy of the semimembranosus and semitendinosus muscles. Lead toxicosis can induce similar signs in horses.

Treatment with phenytoin (15 mg/kg orally daily for 14 days) effected some improvement but the signs recurred within 1 or 2 days after treatment was discontinued.11 Myotectomy of the lateral digital extensor muscle and tendon is reported to provide immediate relief in affected horses, even in those horses with severe bilateral disease.12 However, recovery is spontaneous in most cases and there might only be a need for surgery in the most severely affected horses. Control involves the prevention of overgrazing of pastures, particularly during droughts.

REFERENCES

OVINE ‘KANGAROO GAIT’

Etiology Not known

Epidemiology Seasonal occurrence involving only adult female sheep that are lactating, or in some cases, pregnant. Spontaneous recovery following cessation of lactation.

Clinical findings Bilateral forelimb locomotor disorder

Lesions Axonal degeneration of the radial nerve followed by regeneration.

Treatment Supportive

Control None recognized

ETIOLOGY
A neuropathy of unknown cause.

EPIDEMIOLOGY
Occurrence
This condition is recorded in New Zealand and the United Kingdom and is manifest with acute onset of bilateral radial nerve paralysis followed by spontaneous recovery.

Risk factors
It occurs only in adult ewes with an onset in late pregnancy or early lactation.1-5 Spontaneous recovery occurs following cessation of lactation1-3 but also occasionally while ewes are still nursing lambs.4 Average annual cumulative incidence varies between flocks but is less than 1%.5

In the areas of northern England and southern Scotland the condition is significantly more common in upland and lowland flocks than in those hill grazing. Stocking density is higher in affected flocks than that in non-affected flocks. Onset occurs while on pasture between March and June with a separate smaller peak in October. This seasonal occurrence could be a reflection the parturition status of flocks or an effect of seasonal influences.5

PATHOGENESIS
Clinical signs can be attributed to the generalized polyneuropathy affecting principally the radial nerves. Subsequent to the axonal degeneration a remyelination of the radial nerve occurs, explaining the clinical recovery. Bilateral compression of the radial nerves appears to be the cause but there is no indication of how such an injury can occur.3

CLINICAL FINDINGS
The name comes from the gait exhibited by affected ewes which are unable to move their forefeet except in a synchronized bounding action. There is bilateral forelimb paresis, a palpable loss of muscle bulk in the forelimbs, and some cases also have proprioceptive deficits. The hind limbs are normal. Affected ewes lie down more frequently and may graze on their knees but continue to eat and effectively suckle their lambs.

CLINICAL PATHOLOGY
There are no consistent abnormalities in haematology, blood biochemistry, or trace element analysis of affected sheep.4

NECROPSY FINDINGS
There is axonal degeneration of the myelinated fibers of the radial nerve fibers and regeneration in recovering cases.2,3 Ventral root gangliopathy and neuronal degeneration within the spinal cord is reported1-3 but may not be evident in all cases.1

DIFFERENTIAL DIAGNOSIS

Foot rot or foot abscess involving the front feet can have the same grazing behaviour but there is no problem in differentiation when the limbs and feet are examined. Hypocalcemia in sheep occurs in late pregnancy or during lactation and in the developing stages there is incoordination and muscle weakness. However there is rapid progression to complete muscular paresis and a dramatic response to treatment. Spinal abscess or fracture.

TREATMENT
Without the knowledge of etiology there is no specific treatment. Easy access to food and water should be provided.
EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease is a recently recognized neurodegenerative disease of horses in the US and Canada, with a small number of cases being recorded in Europe and South America. The disease affects horses of all breeds, with Quarter horses most commonly affected, and the incidence of the disease increases with age. Horses older than 2 years of age are affected. The disease is associated with stabling and lack of access to pasture, and the risk of the disease increases with decreasing serum vitamin E concentration. The etiology of the disease is unknown but is suspected to be due to oxidative injury to neurons subsequent to vitamin E deficiency. The clinical signs are attributable to degeneration of motor neurons in the ventral horns of the spinal cord, with subsequent peripheral nerve degeneration and widespread neurogenic muscle atrophy.

The onset of clinical signs is usually gradual but in a small proportion of affected horses the first sign is an acute onset of profound muscle weakness. Chronically affected horses have weight loss in spite of a normal or increased appetite, pronounced trembling and fasciculation of antigravity muscles, increased recumbency, and a short-strided gait; they often assume a posture with all feet under the body and a low head carriage, and frequently shift weight – all signs attributable to muscle weakness. The tail head is elevated in a large proportion of severely affected horses, likely a result of atrophy of the sacrocaudalis dorsalis medialis muscle or the spinal accessory nerve. The sacrocaudalis dorsalis medialis muscle is preferred because that muscle is predominantly composed of type 1 fibers and is severely affected by the disease.

Necropsy examination reveals moderate to severe diffuse muscle atrophy. Predominant histologic findings at necropsy examination include degeneration of neurons in ventral horns at all levels of the spinal cord. Muscle atrophy is evident as angular fibers, with predominantly type 1 fibers, or a combination of type 1 and type 2 fibers, affected. There is accumulation of lipofuscin in the fundus and in capillary endothelium of the nervous tissue.

Treatment consists of administration of vitamin E, although the efficacy of this treatment has not been determined. Administration of lyophilized, water soluble D-α-tocopherol is apparently superior to administration of the DL-α-tocopherol acetate in increasing concentrations of vitamin E in blood of horses. The usual dose is 4 IU of D-α-tocopherol per kg body weight orally once daily. Control measures should insure that horses have adequate access to pasture or are supplemented with good quality forage and/or vitamin E.

CRUSHED TAIL HEAD SYNDROME IN CATTLE

The crushed tail head syndrome is a recently recognized neuromusculoskeletal disease of dairy cattle which has occurred in the US and UK. It occurs most commonly in housed lactating dairy cattle in mid-lactation and that have calved 60 days or more previously. The onset is sudden and characterized clinically by hindlimb weakness, prolonged recumbency in alleyways, but still able to stand. The hindlimbs are drawn forward under the abdomen. Walking is awkward because of hindlimb weakness or pain and affected animals walk with a still rolling gait. Knuckling of the fetlocks and hock joints are characteristic. There is flaccid paralysis of the tail and defecation and urination are not usually affected. During urination and defecation the tail is not lifted and becomes covered with feces and wet with urine. The anal reflex is commonly diminished. There may be some evidence of traumatic injury to the sacral area of the vertebral column with either visible abnormal alignment of the sacral area on movement by the animal or if the animal is rocked from side to side. In other cases, there is no external evidence of trauma or misalignment of the sacrum. No other clinical abnormalities have been observed; appetite is normal, vital signs are normal, and rumen function and the feces are normal in amount and character.

The cause is unknown. In some cases, estrus activity was observed a few days before the onset of signs which suggests that affected animals were mounted by others in the herd causing injury to the tail head and sacrum. It is suggested that traumatic injury to the sacral nerves is the cause of the paresis.

Most cases respond spontaneously and recover within a few weeks. Some reports describe the successful use of long-acting corticosteroids but there insufficient clinical information available to make any useful recommendation.
POLYNEURITIS EQUI (EQUINE CAUDA EQUINA SYNDROME)

Polyneuritis equi (formerly cauda equina neuritis) is a demyelinating, inflammatory disease of peripheral nerves of adult horses. The etiology of the disease is unknown although infectious (adenovirus, equine herpesvirus type 1), immune (autoimmune disease), and toxic etiologies have been suggested, without conclusive substantiation. Adenovirus was isolate from 2 of 3 horses with the disease, but this observation has not been repeated and it appears unlikely at this time that adenovirus is the cause of polyneuritis equi.1 Equine herpesvirus-1 is not consistently isolated from affected horses.2

The disease occurs in adult horses in Europe and North America but has not been reported from the Southern Hemisphere. The disease is usually sporadic with single animals on a farm or in a stable affected. However, outbreaks of the disease can affect multiple horses from the same farm over a number of years.

The pathogenesis of the disease involves nonsuppurative inflammation of the extradural nerves and demyelination of peripheral nerves. Initial inflammation of the nerves causes hyperesthesia which is followed by loss of sensation as nerves are demyelinated. Both motor and sensory nerves are affected, with subsequent weakness, paresis, muscle atrophy, urinary and fecal retention and incontinence, and gait abnormalities.

The acute disease is evident as abrupt onset of hyperesthesia of the perineum and tail head, and perhaps the face, evident as avoidance of touching, and chewing or rubbing of the tail. The hyperesthesia progresses to hypesthesia or anesthesia of the affected regions.

The disease usually has a more insidious onset with loss of sensation and function occurring over days to weeks. The most common presentation is that of cauda equina syndrome with bilaterally symmetrical signs of posterior weakness, tail paralysis, fecal and urinary incontinence and retention, and atrophy of the gluteal muscles. Tail tone is decreased or absent and the tail is easily raised by the examiner. The anus is usually atonic and dilated.

There are signs of urinary incontinence with urinary scleritis of the escutcheon and hind legs. Rectal examination reveals fecal retention and a distended bladder that is readily expressed. Male horses can have prolapose of the penis with maintained sensation in the prepuce—a finding consistent with the separate innervation of these anatomic regions. Affected horses can also have ataxia of the hind limbs, but this is always combined with signs of cauda equina disease.

Signs of cranial nerve dysfunction occur as part of the disease, but not in all cases. Cranial nerve dysfunction can be symmetrical, but is usually asymmetric. Nerves prominently involved in the genesis of clinical signs are the trigeminal (cranial nerve V), facial (CN VII), and hypoglossal nerve (CN XII), although all cranial nerves can be affected to some extent. Involvement of the cranial nerves is evident as cranial paralysis (CN VII), weakness of the tongue (CN XII), and loss of sensation in the skin of the face (CN V). There can be loss of movement of the pinnae (CN VII) and head tilt (CN VIII).

Electromyography is consistent with denervation with prolonged insertion potentials, positive sharp waves, and fibrillation.

Not all clinical signs occur in all horses and, depending on the stage and severity of the disease, some animals can have loss of sensation as the only abnormality, especially during the early stages of the disease.

The disease is inexorably progressive, the prognosis for life is hopeless, and the course of the disease is usually less than 3 months.3

Clinical pathologic abnormalities are not diagnostic. There is sometimes a mild neutrophilic leukocytosis and hypergammaglobulinemia. Serum vitamin E concentrations are usually normal. Analysis of cerebrospinal fluid demonstrates mild mononuclear pleocytosis and increased protein concentrations, but these changes are not diagnostic of the disease. Horses with polyneuritis equi have antibodies to P2 myelin protein in serum, but the diagnostic value of this test has not been determined.4

 Necropsy findings are definitive for the disease. Gross findings include thickening of the epidural nerve roots that is most severe in the cauda equina. The bladder and rectum can be distended. There can be evidence of fecal and urine scalding and self-trauma of the perineum. There can be thickening of the facial nerves. Microscopic changes are characterized by a granulomatous inflammation of the extradural nerves although radioculangionaleuritis and myelitis can also occur. There is loss of axons with demyelination and signs of remyelination. The inflammatory cells are initially lymphocytes, plasma cells, and macrophages. As the inflammation becomes more severe or chronic there is extensive proliferation of fibroblasts and fibrocytes in addition to infiltration of lymphocytes and macrophages.2 There is axonal degeneration with proliferation of the perineurium. The chronic inflammatory changes result in loss of peripheral neural architecture. Lesions are present in many regions of the spinal cord, but are most severe in the sacral division and cauda equina.2 Lysosomal accumulations are present in the semilunar, geniculate, and sympathetic chains and granulomatous lesions in the celiaco-mesenteric ganglion.5 Lesions of the cranial nerves similarly involve infiltration with lymphocytes and histiocytes, and the inflammation can extend to the terminal branches of the nerves.3

The diagnosis of polyneuritis equi is based on the presence of clinical signs of the disease, rule out of other diseases causing similar clinical signs, and necropsy examination. Diseases with manifestations similar to polyneuritis equi include:

- Equine herpesvirus-1
- Myeloencephalopathy
- Migrating parasites (Table 36.3)
- Sorgum–Sudan grass neuropathy
- Equine protozoal myeloencephalitis
- Rye grass staggers (Acremonium lolii)
- Dourine
- Trauma to the sacral vertebral column
- Abscess or neoplasia involving the sacral or caudal lumbar vertebral column
- Meningitis
- Intentional alcohol sclerosis of tail head nerves in Quarter horses.

There is no definitive treatment for polyneuritis equi. Administration of anti-inflammatory agents, including corticosteroids, appears to be without sustained benefit. Supportive care includes evacuation of the rectum and bladder and maintenance of hydration and provision of adequate nutrition. Feeding a diet that softens feces, or administration of fecal softeners or lubricants can be beneficial. Bethanecol (0.05 to 0.1 mg/kg q8-12 hours, orally) might increase bladder tone. Topical administration of petroleum jelly or similar products can protect the skin of the perineum and escutcheon from fecal and urine scalding.

HEAD SHAKING IN HORSES

Head shaking by horses is a perplexing and troubling syndrome for which there is often no readily identifiable cause or treatment. The disorder is characterized by repeated, sudden shaking or tossing of the head.

ETIOLOGY

The etiology is complex and often unclear and conditions associated with head shaking include:1,2

- Ear mites
- Otitis interna/externa
- Ophthalmic disease (uveitis)
- Trichinella spiralis (chiggers)
- Infestation of the muzzle
- Guttural pouch disease (mycosis)
- Stylohyoid arthropathy
- Osteitis of the petrous temporal bone
- Dental disease (wolf teeth, ulceration, periodontal disease, periapical abscesses)
- Behavioral abnormalities
- Trigeminal neuralgia
- Optic neuritis
- Photic head shaking (optic-trigeminal summation)
- Neck pain
- Rhinitis or sinusitis
- Ethmoidal disease including hematoma
- Infraorbital neuritis
- Excessive neck flexion by rider
- Equine protozoal myeloencephalitis
- Ill-fitting tack including bit and bridle
- Obstructive airway disease (heaves, laryngeal hemiplegia, epiglottic cysts, etc.).

Most cases of the disease are idiopathic despite intensive investigation of affected horses,1 Photic head shaking is a common cause of the disease.3 Most cases have some seasonal distribution, though the reason for this is undetermined. Trigeminal neuralgia is considered an important cause of the disease.3

EPIDEMIOLOGY

The epidemiology of the disease is not well defined. The syndrome occurs in horses throughout the world.4 The syndrome is sporadic, usually affects only one horse on a farm, and does not occur as outbreaks. The syndrome has a seasonal occurrence in approximately 60% of horses with the majority first demonstrating head shaking, or being most affected, during spring and summer.4,5 Head shaking is worst on sunny days and less severe on cloudy days, in approximately 60% of horses.5 Seventy five percent and 80% of affected horses have less severe signs at night or when ridden indoors, respectively.5

Affected horses are usually mature adults with onset of head shaking at 7–9 years of age in over one-half of cases,6,5 although signs can occur in horses as young as 1 year. The disease is reported twice as often in geldings as in mares.6,5 There is an apparent predisposition to the disease in Thoroughbred horses6 but this is not consistently reported.5 Most affected horses are used for general riding, although this might represent an age effect because the syndrome tends to occur in older horses which are not used for racing.5 There is no apparent association of temperament and risk of head shaking.

PATHOGENESIS

The pathogenesis of head shaking depends on the cause, but is assumed to involve the trigeminal nerve in most cases because of its role in sensory function of the nose and nasal mucosa.2 Head shaking is related to exposure to bright light in some animals, a condition referred to as photic or optic-trigeminal summation because of its similarity to a syndrome in people. Trigeminal neuralgia is believed to cause acute, sharp, and intense pain in the face. Although this cannot be definitively diagnosed in horses, its presence is inferred from the horse's behavior and response to analgesia of the infraorbital or posterior ethmoidal nerves.

CLINICAL FINDINGS

The clinical signs of head shaking are unmistakable. Movements of the head are sudden and apparently spontaneous and involve lateral, dorsal, ventral, or rotatory movement of the nose usually during exercise. Horses rarely have the behavior only at rest, with most being affected both at rest and during exercise and about 10% exhibiting signs only during exercise.4,5 The action often resembles that of a horse trying to dislodge something from its nose. Approximately 90% of horses have vertical movement of the head (as if flipping the nose).5 The headshaking can be so severe as to cause lateral, dorsal, or ventral flexion of the neck to the level of the caudal cervical vertebrae, although more commonly on the rostral one-third of the neck is involved, if it is involved at all. Some horses rub their nose on objects, the ground, or their front limbs, sometimes during exercise. Affected horses often snort or sneeze. There can be twitching of the facial muscles and flipping of the upper lip. The movements are sudden and at times appear to catch the horse by surprise. The frequency and/or severity of movements are usually increased during exercise. Severely affected horses can stumble and fall if headshaking occurs during exercise, rendering the horse unsafe to ride.

A grading system to classify the severity of signs is:1
0. No signs of head shaking
1. Intermittent and mild clinical signs.
   Facial muscle twitching. Rideable.
2. Moderate clinical signs. Definable conditions under which head shaking occurs. Rideable with some difficulty.
3. Rideable to unpleasant to do so.
4. Unrideable and uncontrolable.
5. Dangerous with bizarre behavior patterns.

This system might be useful for assessing response to therapy and concisely describing the severity of the signs.

Ancillary testing involves radiography of the skull; endoscopie examination of both nostrils and ethmoidal regions; nasopharynx, larynx, and guttural pouches; otoscopic examination of the external auditory canal and tympanic membrane (difficult to achieve in a conscious horse, a small endoscope is necessary); desensitization of the infraorbital and posterior ethmoidal nerves; biopsy of the nasal mucosa (in horses with suspected rhinitis); radiographic examination of the neck; and therapeutic trials including application of contact lenses or masks, or administration of medications (see Treatment).

CLINICAL PATHOLOGY

There are no characteristic hematologic or serum biochemical abnormalities.

NECROPSY FINDINGS

There are no characteristic findings on necropsy, apart from those of any underlying disease. Evidence of lesions in the trigeminal nerve is lacking.

DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from the stereotypic weaving that occurs during stabling and not during exercise.6

TREATMENT

The principles of treatment include relief of specific underlying diseases, removal of management or environmental conditions that cause head shaking, and administration of medications.

If underlying conditions are detected, such as ear mites, dental disease, and others listed under 'Etiology', then these conditions should be treated effectively. Effective treatment of these conditions will alleviate head shaking, if in fact the condition was the cause of the disease. However, most horses with head shaking have seasonal or photic disease and treatment is more difficult. A survey of owners of 254 horses with head shaking revealed that
only 129 horses had been treated by a veterinarian and, of those, only 6% had complete resolution of head shaking, whereas 72% had no response to treatment.6 Other treatments used were on the advice of lay 'back specialists', homeopathy, alternative therapies or face or head masks. Success rates for these interventions varied between 6 and 27%, with the most success obtained by use of a nose net (27%).7 Nose nets provided better control of signs than did face or eye masks. These figures on the success of treatment illustrate the refractory, and therefore frustrating, nature of the disease.

Fitting of nose masks alleviates or lessens head shaking in some horses.7,8 The design of the nose mask does not appear to be important at least in regard to whether it covers the entire rostral face or just the nostrils.9 The nose masks were most effective for treatment of up-and-down head shaking, but not for side-to-side or rubbing behavior.8 Blue tinted contact lenses have been suggested for use in horses with photic head shaking.9 Others have not found this intervention useful.4

Sclerosis of the infraorbital or posterior ethmoidal nerves is performed in those horses that have reduced or eliminated head shaking after injection of local anesthetic into the infraorbital foramen or around the posterior ethmoidal nerve.1 Sclerosis is achieved by injection of 5 mL of 10% phenol in oil.1 Care must be taken to ensure that the phenol is deposited only around the nerve. The procedure should be done under general anesthesia.

Cyproheptadine (0.3 mg/kg, orally q12 hourly) improved head shaking in 43 of 61 horses, based on owner reported efficacy.4 Responses were usually observed within 1 week of the start of therapy. Others have not replicated this success3 but found that the combination of carbamazepine (4 mg/kg orally q6–8 hours) and cyproheptadine improved clinical signs in 7 horses within 3 to 4 days of starting treatment.1

Acupuncture and chiropractic manipulation appear to be minimally effective.4,7 Prevention of exposure to bright light is an obvious recommendation, but not practical for most horse owners.

CONTROL
There are no recognized measures for preventing development of the disease.

CONGENITAL NECROTIZING ENCEPHALOPATHY IN LAMBS

This condition is reported as the most common diagnosis of neurological disease in lambs under 7 days of age by VLA diagnostic laboratories in the north of England and is defined by its pathology.4 Affected flocks have single or multiple cases with up to 10% morbidity in lambs of a flock. Cases have all come from ewes carrying multiple fetuses. There is variation in the clinical manifestations between sibling lambs. The most severely affected may be stillborn. Less severely affected lambs are born weak, are small, maybe unable to rise or show ataxia and head tremor. Some lambs survive but may have residual signs of cerebellar dysfunction. The common lesion is superficial cerebrocortical neuronal necrosis. A significant proportion also has necrosis of the Purkinje cells in the cerebellum and leucomencephalopathy of the thalamus and brainstem. It is possible that this syndrome reflects hypoglycemia consequent to negative energy balance in late pregnancy.

Diseases characterized by involvement of the musculoskeletal system

HYENA DISEASE OF CATTLE

Hyena disease of cattle occurs worldwide and is characterized clinically by a lateral body appearance similar to the hyena.1,2 The cause is unknown but excessive intake of vitamins A and D may be contributing factors.

In some naturally occurring cases in yearlings from one large dairy herd approximately 1% of calves were affected annually. Affected calves had received vitamins A and D3 immediately after birth, and from birth to weaning received the same vitamins from fresh milk, whole corn, a customized feed mix, and a milk supplement.2 The mean daily intake of vitamin A from birth to 6 weeks of age was approximately 80 000 IU and 6300 IU of vitamin D3 and progressively less vitamin A and D3 was fed from 6 weeks until weaning at 3 months. The National Research Council recommendations for daily vitamin intake are 2100 IU of vitamin A at birth, increasing to 6360 IU at 2 months and 330 IU of D3 increasing to 990 IU over the same period.2 Experimentally, the IM injection of vitamins A and D (2 000 000 IU and 300 000 IU, respectively) on the first day after birth followed by 30 000 IU/kg BW added to the milk replacer daily resulted in gross lesions in the proximal tibial growth plates in 3 weeks.3 Excessive vitamin A and vitamin D3 administration to young calves can cause hyena disease by suppression of the activity of differentiation and proliferation in chondrocytes and osteoblasts.4,5 The administration of excessive amounts of vitamins A, D3 and E to Holstein sucking calves can cause hyena disease characterized by severe emaciation, generalized alopecia, dome-like cranial deformation, and high mortality.5

There is premature closure of the growth plates of the long bones resulting in a marked dissimilarity in growth and development between the forequarters and the hindquarters, the latter being comparatively underdeveloped. This gives the animal the classic contours of the hyena and this resemblance is heightened by a crest of thick, stiff bristles along the back in the midline. An aggressive attitude also develops. Affected calves are normal at birth and only develop the abnormality at 5–6 months of age. There is no apparent abnormality of sex hormones. The femur and tibia are shorter in affected than in normal animals. There are accompanying difficulties of locomotion with a tendency to fall sideways, and to frequently adopt a position of lateral recumbency. The gait is described as ‘bunny-hopping’. German Simmental, Charolais, Black Pied, German Holstein-Friesian, and German Red Pied cattle have been involved. Genetic analysis appears to indicate that the disease is inherited as a simple recessive with incomplete penetrance but this is obviously not so in some herds.

The lesion is a chondrodystrophy affecting particularly the long bones and the lumbar vertebrae. Gross examination and radiography of the longitudinal slabs of the humeri, tibias, and femurs reveal focal to almost complete closure of the physes and physes subjected to compression are affected more than those subjected to tension.2

ASYMMETRIC HINDQUARTER SYNDROME OF PIGS

This condition was first reported in Germany and Belgium and was recognized in the UK in 1968 and reported later. In these cases perineurial fibrosis was a feature and it was thought that the condition resulted from either a neurogenic atrophy or a periaricular fibrosis extending to the peripheral nerves. There is variable asymmetry of the hindquarters which is generally evident during the early grower period and obvious by 80 kg liveweight stage. An asymmetrical distribution of subcutaneous fat is also noted and possibly skin dimpling.

The muscle most frequently affected was the M. semimembranosus, followed by the M. semitendinosus, M. biceps femoris, M. adductor femoris, and M. gracilis. The muscles show changes that can be described as myofibre degeneration, interstitial fibrosis, and dystrophic changes. Several breeds, including Landrace, Large White, and Hampshire have been found affected but the problem is generally restricted to certain herds and to certain families within these herds, suggesting that a genetic liability exists for this condition. The mechanism of inheritance studied from test matings is not simple. Whatever the cause, there is a marked reduction in the number of muscle fibres. Both sexes may be involved and the condition may involve either hindlimb. Despite a marked reduction in muscle mass there is no detectable abnormality in gait. The cause is unknown, although it appears to result from suboptimal muscle growth rather than degenerative loss. In the only cases recorded from outside Europe a group of 7 Australian pigs were examined in detail and in one of these the affected M. semitendinosus weighed only 41% of the normal unaffected one. Perineurial fibrosis and myopathy have been observed in some cases but have not been found consistently.

SPRAYLEGG SYNDROME IN NEWBORN PIGS

This syndrome is also called spraddle leg, but more usually myofibrillar hypoplasia. This may be an erroneous term as this hypoplasia occurs in many normal pigs and may be a normal feature of post-natal muscle growth. This clinical condition of splayleg occurs in newborn piglets in most countries and is characterized by a temporary inability to stand with the hindlimbs.

ETIOLOGY

The etiology is unknown, but based on epidemiological evidence it is multifactorial. The current hypothesis is that the disease is caused by an interaction of genetic and non-genetic factors, a polygenic mode or expression of many genes without dominance.

The studies of Czech workers have suggested that the pathomorphology of the condition resembles that of glucocorticoid induced myopathy in man and animals. Dexamethasone given to minisows from the first to the last days of pregnancy produced in newborn piglets a disorder characterized by the splayleg syndrome with retardation of both muscle growth and myofibrillogenesis. It has also been experimentally produced following the administration of pyrimethamine.

EPIDEMIOLOGY

The prevalence of the disease in the UK is 0–4% and the morbidity in affected herds varies from 2 to 27%. The case fatality rate is approximately 50% and is due to crushing, chilling, and starvation because affected piglets are not able to move around normally. The disease is more common in the Pietrain, Welsh, Landrace, and Large White breeds of swine; Landrace pigs may be especially susceptible. This suggests a genetic basis, but test-matings, with the exception of a few, have not been successful in reproducing the disease. On most farms the disease affects both male and female piglets. In a recent retrospective analysis of the incidence of the disease in a swine herd over a period of 5 years, the overall frequency was 1.74 times more in males than females and the birth weight of splayleg piglets tended to be subnormal. The environmental factors which have been associated with some outbreaks include slippery floors, a dietary choline deficiency and the ingestion of Fusarium toxin by pregnant sows. Choline deficiency is unlikely to be a factor and none of the other factors have been substantiated as etiological factors or epidemiological determinants.

PATHOGENESIS

The pathogenesis of the disease is unclear. In affected pigs there is myofibrillar hypoplasia, but this is also a feature of many muscles in normal pigs. There are simply too few maturing type I fibris in the muscles, particularly of the foreleg, lumbar epaxial group and the hind limb to carry weight. The M. semitendinosus appears to be the worst affected muscle. However, because myofibrillar hypoplasia may also be present in normal unaffected litters it has been difficult to explain the pathogenesis of the muscular weakness. The use of morphometrics has enabled the detailed determination of the myofibrillar hypoplasia. In addition to myofibrillar hypoplasia, in splayleg pigs there is a higher content of sarcoplasmic RNA, reflected ultrastructurally by the presence of numerous ribosomes. The extra-myofibrillar space was also filled with glycogen in splayleg pigs. In myofibrillar hypoplasia induced with glucocorticoids given to the pregnant sow, none of the pigs had splaylegs but the extra-myofibrillar space contained little glycogen. There were also many glycogen-filled phagosomes and residual bodies which indicate a difference in the metabolism of glycogen in the first 2 or 3 days after birth. In a study of natural cases there was hypoplasia but there was an increased accumulation of glycogen especially within the large extra-myofibrillar spaces in comparison with the normal pigs. These authors also found an anomalous distribution of glucose-6-phosphatase in splaylegged muscles in that the activity was concentrated at the periphery of the extremely dilated cisternae of the sarcoplasmic reticulum. In the normal muscles this enzyme activity was normal. This distribution could account for the slower utilization of glycogen in affected muscles and therefore would account for the build up. Quantitative image analysis of skeletal muscle revealed that the arrangement of the myofibrils within the fascicles of affected and unaffected pigs was different.

Some studies have found both quantitative (hypoplastic-type) and qualitative (dystrophic-type) insufficiencies in affected pigs which represent a temporary perinatal developmental disturbance. This could explain the muscular weakness and the recovery which occurs.

CLINICAL FINDINGS

Larger litters may be more affected possibly because these tend to be born earlier. The clinical signs are usually obvious in 2–3 hours after birth when the litter should be standing and walking around the creep area. Affected piglets are unable to stand, and their hindlimbs are splayed sideways or forwards and the animals are resting in sternal recumbency. Sometimes the fore limbs are also splayed. Most severely affected piglets are unable to move; less severely affected animals are able to move slightly. Many pigs have soiled hindlimbs and perineum as a result of being unable to stand. As a result, the piglets are likely to be crushed or have difficulty gaining access to their source of
nourishment. Affected piglets are normal in other respects and have a normal appetite and will suck the sow if placed near a teat. In the experimental induction there was hypoplasia but there were no clinical signs, which is further evidence for suggestions that the condition has a threshold for clinical signs and has strong maternal influences.

TREATMENT

Treatment can be successful. If the pigs are able to suck or if they are fed artificially for 2–4 days, recovery will occur within 1 week in about 50% of cases. The ambulatory capacity of affected pigs can be improved, and mortality reduced, by tapping or loosely tying together the hindlimbs for a period of up to 1 week. The method of tying of the hindlimbs consists of a figure-of-eight bandage (2.5 cm wide adhesive tape) being fixed around the metatarsal bones, leaving a space between the legs of up to 7 cm depending on the size of the piglet. The legs should be tied together within a few hours after the syndrome is obvious; a delay of several hours will decrease the prognosis. The provision of a non-slip floor surface such as a carpet or sack may also be helpful. Many farmers will tell you that repeated massaging of the limbs will also improve the survival rate.

CONTROL

Whether or not to cul the boar depends on the pedigree value of the animal, the incidence of the disease, and the probability that the boar is responsible. There is no evidence that the disease is monogenic. However, the incidence is highest in the Landrace breed, which suggests a hereditary predisposition. In deciding whether to use a suspected carrier animal, there is a need to distinguish between different situations. The consequences of disease are felt differently at the different levels of organization of the pig industry. A boar of high merit for performance traits may be more economical to retain as breeding stock even though some progeny are affected with the disease than a superior boar whose progeny are unaffected. If stress of the pregnant sow is a factor, control of the disease may be dependent upon the selection of stress-resistant boars and sows.

Concurrent disease should be controlled as producers will tell you that after a period of PRRS infection they had a higher percentage of splayleg piglets. There are also suggestions that induced early farrowing and zearalenone poisoning may also be complicating factors to prevent.

DEGENERATIVE JOINT DISEASE (OSTEOCHONDROSIS, OSTEOARTHRITIS, EPIDEMIOLOGY AND APOPHYSIOLOGY, LEG WEAKNESS IN PIGS)

Leg weakness in pigs is a very loose term which includes a wide variety of conditions and is best discarded. In Finland 15% of gilts are culled due to leg weakness. Degenerative joint disease would be a much better general term to describe the lameness of young rapidly growing pigs affected with a non-infectious joint disease which includes osteochondrosis (OC), epiphyseolysis, and degenerative osteoarthritis (OA). The disease is characterized by varying degrees of intermittent but progressive lameness in rapidly growing pigs from 4 to 8 months of age, and pathologically by the presence of OA and OC. The disease is of major economic importance because of the high culling rate of breeding age swine.

ETIOLOGY

The cause of the articular abnormalities is unknown. The etiology and factors underlying these syndromes are poorly defined, partly because of the difficulty of definitive clinical examination of affected pigs and the frequent lack of apparent significant pathological changes in necropsy examination of mild cases. There are no specific associations between degenerative joint disease and infectious diseases.

EPIDEMIOLOGY

Occurrence

Recently, a study of 9411 newborn piglets showed that 9.8% were treated for lameness. For parity 3 sows, the level had risen to 11.4%, but by parities 4–7 only 8% were treated. The treatments were in pigs of less than 3 weeks of age in 73% of the cases. Litters with 12 or more pigs had the highest incidences of lameness. Osteoarthritic changes are strongly associated with osteochondrotic changes in the humeral and femoral condyles. Osteochondrosis has been recorded as early as 1 day of age so the lesions may be congenital. There may be some degree of change in up to 85% of pigs.

The intensification of the swine industry has required that pigs grow rapidly and with high feed efficiency. Under such intensified conditions, rapidly growing pigs develop lesions of the bones and joints, especially the femur. Most pigs near market weight have varying degrees of osteochondrosis (OC). Except for severe lesions, which usually occur in a relatively small proportion of the total population examined, the lesions seen at slaughter often have no detrimental effect on growth rate of pigs up to market weight. An advanced degree of OC however, can result in severe degenerative joint disease and lameness in breeding stock. It is not associated with adventitious bursitis.

The disease occurs in both male and female pigs and the incidence of lame pigs can be as high as 20–30%. It is a particular problem in gilt and boar testing stations where it may necessitate slaughter of affected animals before the testing period is complete. The lesions develop...
most commonly in growing pigs, particularly boars from 20 to 30 weeks of age, raised in confinement. The onset occurs when pigs are between 4 and 8 months of age which coincides with a period of maximal growth rate. The peak period of clinical manifestation is from the late grower stage until 18 months of age, although the effect of OA may carry through to the adult period. Extensive multicentric degenerative joint disease in adult sows and boars can cause severe lameness which often warrants euthanasia. However, sows ranging in age from 1.5 to 3.0 years and culled for impaired reproductive performance, with no history of lameness may have lesions of the femoral condylar surface.

Risk factors
Numerous risk factors contribute to the disease. They include nutrition and rate of growth, genetic, and breed predisposition, sex, type and quality of floor, and exercise and confinement. The pig carries 53-51% of its weight on the fore limbs and 46-48% on the hind but the weight supported on the hind is higher at 90 and 105 kg body weight. In a study of gilts and sows in Denmark about 12% of gilts showed stiff locomotion but at some point 53% of gilts had at some time showed the same sign. Buck-kneed forelegs, upright pasterns, legs turned out wide, standing under position, and swinging hindquarters were associated with stiff locomotion or lameness. Weak pasterns on the hind feet were associated with stiff locomotion and lameness. Weak pasterns on hindlegs and splayed digits on forelegs were associated with brisk movement (freedom from locomotor problems). The following leg weakness signs at the gilt stage were found to have a significant effect on the longevity of the sows: buck-knee forelegs, swinging hindquarters, and standing under position on the hind legs.

Nutrition and rate of growth. The disease is associated with rapid early growth, but it does not appear to be related to protein, vitamins A and D or calcium and phosphorus imbalance in the ration. Maximal mineralization of bones is not necessary to prevent leg weakness. Only almost complete absence of calcium and phosphorus causes lameness. Disturbances of the Ca:P ratio below 0.5 or over 3.0 are necessary to produce lameness. Recently, it has been suggested that long-term acidosis may be associated, as bone is not formed as phosphorus is removed from the bone. In this context the acidification of pig diets has been suggested as a contributory cause. It has also been shown that the presence of deformed forelimbs is not associated with low levels of vitamin C in plasma. Rapid growth, especially during the early period, was thought to have a significant influence on the occurrence and there is also some breed variation in susceptibility. However, in some feeding trials of pigs from weaning to slaughter weight there was no direct effect of rapid growth rate on the incidence and severity of OC. In other feeding trials, average daily gain of gilts was an important factor in the severity of lesions of OC. Decreasing the rate of gain by restricting energy intake appeared to decrease the prevalence and severity of OC when gilts were slaughtered at 110 kg. However it was shown that when pigs were fed waste food, and grew more slowly, they had an increased prevalence and score for OC when compared with pigs fed a commercial feed concentrate. Decreasing the concentration of protein in the diet of gilts from 16 to 12% resulted in less longitudinal bone growth but did not decrease the incidence of OC. A simple association between growth rate and the incidence or severity of joint lesions has not been consistently demonstrated and a reduction in growth rate of pigs does not control the disease. A significant favourable association between leg action and daily gain has been noted. There has also been speculation that growth hormone could influence the development of lesions of OC by exerting a direct effect on differentiation and colonization of epiphyseal chondrocytes. There is no consistent relationship between the incidence of osteochondrosis and selection of pigs for lean tissue growth rate.

Genetic and breed predisposition. It has been proposed for many years that selection of pigs for increased growth rate resulted in a concomitant increase in the incidence and severity of musculoskeletal disease. Genetic studies indicate that the heritabilities of leg weakness are low to moderate (0.1–0.3). A more recent study suggested from 0.01 to 0.42 for leg weakness and OC and that both are associated with production traits (lean% and backfat thickness). Genetic analysis of the incidence of OC and leg weakness in the Swedish pig progeny testing scheme revealed a low to moderate heritability. Genetic control of leg weakness has been achieved by various researchers and thus inheritance is probably an important risk factor for this disease complex. The genetics of leg weakness have been described in Finnish Large White and Landrace populations. Meaty breeds are worst affected including the Duroc and the Dutch and Swedish Landrace.

Osteochondrosis also occurs in cross-bred Wild boar-Yorkshire pigs with a genetically decreased growth rate, raised under the same conditions as finishing pigs. The distribution and extent of OC was similar to that of purebred Swedish Yorkshire pigs. This suggests that it is not limited to rapidly growing pigs. Synovial bursae at the hock joints were higher in Large White pigs with straight or bowed hind legs and in Landrace with sickle shaped hind legs. There are significant breed differences in the peri-articular and meniscal ossifications seen on X-ray. Recently, the quantitative trait loci for locomotion and osteochondrosis-related traits have been identified in Large White x Meishan pigs. Correlations between breeding values for longevity and for OC were low but significant, and in a favourable direction. Higher OC scores were associated with a higher risk of being culled. It has been seen in wild boar in Slovenia.

Sex. The differences in the incidence and severity of OC between the sexes of different breeds has also been analyzed. The degree of leg weakness and OC of one sex in a breed can neither be translated to the other sex within that breed nor to the same sex of another breed.

Type of floor. Insecure footing because of unfavorable floor surfaces and the presence of foot lesions may change the posture of the animal and cause local overloading of certain joints. The effect of the quality of floor has been examined and there is no clear evidence that hardness of floor contributes to an increased incidence of leg weakness associated with joint disease. However, the incidence and severity of joint lesions may be related to the duration of confinement in pigs confined individually. Exercise will prevent abnormalities such as bow legs, flexion of the carpus and sickle-legs from impairing the mobility of boars, but does not influence the severity of joint lesion. The milder syndromes of poor movement and lameness associated with defects in leg conformation in the grower stage are not necessarily associated with bone or joint lesions and may regress spontaneously or improve if affected pigs are placed on pasture. However, severe lameness at this age, and that which occurs in replacement stock and young adults is frequently associated with severe bone and joint lesions which may be irreversible. A recent study has looked at type of floor (solid floor plus straw, solid floor no straw, and fully slatted). The slatted floors were worst for leg weakness and the floors with straw best. The different types of floor affected leg weakness and claw disorders differently.
Exercise and confinement. There is some limited evidence that high lean growth rate may predispose towards leg weakness under confinement rearing. Trauma during handling, penning, and transportation may be associated with a relatively high frequency of OC but the evidence is very limited. A high stocking density had an adverse effect on 4 of the leg weakness signs (knock knees, turned out front or hind limbs, standing with the legs under the body). A recent study of housing and treadmill training did not show any adverse effects on leg weakness.

Economic importance

In Scandinavia, breeding pigs culled because of lameness had a 100% frequency of OC or OA, and up to 40% of boars in a performance test station had osteochondrosis or osteoarthritis. A conservative estimate suggests that 3% of sows and 10% of boars are culled for unsoundness associated with OC and OA. The hidden costs include a reduced pool for selection of high-performance boars and gilts, the maintenance of pigs which cannot be used for breeding, increased mortality among pigs crushed by lane sows, reduced feed intake and growth rate in lame pigs, and transportation costs of replacement stock.

PATHOGENESIS

The condition has been seen as early as 1 day and with age the lesions develop. The essential lesion is the necrosis of cartilage canals and surrounding cartilage. They may be seen to be developing and healing at the same time. In growing animals, the superficial layer of joint cartilage is articular cartilage, and the deeper layer is epiphyseal cartilage which undergoes endochondral ossification as the animal matures. The articular cartilage persists in the mature animal while the epiphyseal cartilage becomes a layer of calcified cartilage and underlying subchondral bone. The cartilage on the Elbow joint is known as the growth plate and is involved in metaphyseal growth. The normal growth plate cartilage has a well-ordered structure with the chondrocytes of the proliferative and hypertrophic regions arranged into columns.

Osteochondrosis is a generalized disease in which there are focal areas of failure of endochondral ossification in the physeal (metaphyseal growth) and epiphyseal growth cartilages. The underlying defect may be an abnormality of the chondrocytes which do not undergo normal hypertrophic ossification. They accumulate rough endoplasmic reticulum, lipid droplets and mitochondria. The surrounding matrix contains deposits of electron-dense material which may prevent normal vascularization and therefore ossification. The hypertrophic region is disorganized and greatly extended compared to normal tissue. The matrix surrounding the clustered chondrocytes is altered compared to that in normal cartilage. The primary abnormality is an increased thickness of the joint cartilages combined with degenerative changes which result in infoldings and erosion of articular cartilages. Defects of the growth plates (physes) result in short deformed bones.

Pathologically, severe clinical cases are characterized by osteochondrosis and secondary degenerative joint disease especially involving the medial aspects of the larger joints, epiphyseolysis and lumbar intervertebral disc degeneration and spondylosis. Osteochondrosis has been used to encompass lesions involving the physes and the articular epiphyseal complexes. However, because of morphological changes that have been observed in growing pigs, dyschondroplasia is now the preferred term to be used generically and then qualified by the location and nature of the morphological description since the causes may be different.

Osteochondrosis occurs commonly in growing pigs at predilection sites of the medical condyle of the humerus and femur, the epiphyseal plates of the distal ulna and the femoral head and the intervertebral joints. The 6th–8th costochondral junctions may also be affected. It may heal spontaneously or it may progress to osteochondritis dissecans or OA. Its progression in either direction is influenced by local loading and by joint stability which depends upon joint shape and muscle and ligamentous support. The age-related changes and OC in the articular and epiphyseal cartilage have been described. The cartilage increases with age up to 5 weeks and then begins to decrease in thickness. Detrimental influences such as defects in conformation, heavy muscling with skeletal immaturity, muscular weakness resulting from myofibrillar hypoplasia, myopathies or lack of exercise, inadequate flooring or even simple trauma may adversely affect this progression and lead to severe skeletal change.

Purine synovial fluid contains both hyaluronic acid and chondroitin sulfate and the chondroitin sulfate-to-hyaluronic acid ratio is not influenced by relatively advanced stages of osteochondrosis. Treatment of lame boars with glycosaminoglycan polysulfate improves leg soundness score and results in an increase in the hyaluronic acid concentration of the cubital joint synovial fluid, and an increase in the proportion of aggregated proteoglycans in the articular cartilage of the medial femoral condyle. It is suggested that the hyaluronic acid accounts for most of the viscosity of synovial fluid and for efficient lubrication of the joint.

Well-established lesions typical of OC associated with the physes can be found in young pigs between 25 and 30 days of age. The earliest change associated with a dyschondroplasia of the physis is a focus of persistent hypertrophied chondrocytes which do progress but heal. Lesions associated with physes and articular epiphyseal complexes develop continuously and regress as pigs grow older. Changes in cartilage vessels appear to be important in the pathogenesis. There is no evidence that vascular damage is a factor in the pathogenesis of the lesions.

Because foci of dyschondroplastic lesions are associated with physes of pigs between birth and the stage of rapid growth, they could be regarded as part of the usual growth patterns in contemporary commercial swine. However, clinical signs of dyschondroplasias, or degenerative joint disease secondary to dyschondroplasias, usually do not appear until pigs are almost 6 months of age.

Radiological monitoring of lesions

Osteochondrosis can be diagnosed radiologically. Radiologically the lesions were similar in Yorkshire, and Landrace but more severe in the Landrace and similar to the Danish Landrace.

The development of epiphyseal osteochondrosis in pigs from 42 to 147 days of age has been followed radiologically. Osteochondrotic lesions were seen radiologically in the articular-epiphyseal (A-E) complexes of the humeral condyles of 42-day-old pigs and in the femoral condyles at 63 days of age in contrast to earlier reports which indicated that lesions were not visible radiologically until 100 days of age. The osteochondrosis lesions of the A-E complexes develop, become progressive, and subsequently become either stable, regressive, or even more progressive as the pigs grow. This supports the observations that the lesions develop and become progressive and regress as the pigs grow. The humeral medial condyles have more pronounced lesions and are more frequent than the lateral ones.

Radiological monitoring of the development and sequelae of epiphyseal osteochondrosis lesions of the growth plate cartilage and A-E complexes of the fore and hind limbs in young breeding swine found that the majority of distal ulna lesions healed by 18–20 months and some started fusing at 18–21 months. The distal ulna healed without complications in most animals and the most severe lesions healed faster than the mild or moderate ones.
The syndrome is one of particular importance in breeding animals where it may interfere with successful mating. Boars may show initial interest in mounting but subsequently slide off the sow or dummy before mating is complete, presumably due to the pain of the lesions. In Europe this problem has been called impotencia coeundi.

There may be no meaningful association between visual scores for physical soundness in the live animal and the degree of joint damage.41 Some pigs with severe lesions are not lame and conversely other pigs are severely lame with minor lesions. Epiphyseolysis of the femoral head produces severe unilateral lameness and if bilateral is usually manifest by marked reluctance to rise and severe locomotor disability. Initial signs are frequently deceptively mild and follow physical exertion such as mating, transport, farrowing, or fighting but they progress to severe lameness over a 7–10-day period.

Epiphyseolysis of the tuber ischii (Aphophysitis) may also occur following physical exertion but is more common in second or third parity sows and is manifest by 'paralysis' with the hindlimbs in lateral angulation of the foot and sickle hocks to more severe lameness and, in the extreme, inability to rise and pareseis. Nine leg weakness signs were described.42 The signs listed include buck kneeed forelegs, steep hock joints, fore and hind limbs turned out, upright parters on the hind legs, stiff locomotion, standing under on the hind limbs, swaying hindquarters, goose stepping hind legs, lameness and tendency to slip, and the four most common signs were buck knees, small inner claws on forefeet, small inner claws on hind feet, and upright parters on the hind legs.43

The clinical syndrome is a locomotor disorder usually involving the hindlimbs. Often the most rapidly growing pigs are lame. The lameness may be acute, intermitent, chronic, progressive, or a combination of these. An insidious onset is common, and pigs are unwilling to move, the stride is shortened, and the limbs are held in partial flexion. The carpal joints may be under extended, the metacarpopha langeal joints are overextended, giving the limb an abnormal S-shaped profile.36 The pelvic limbs are commonly held straight and the back is slightly arched. In some cases, affected animals will assume a kneeling position with flexed carpal joints and walk on those joints.

Mild cases show stiffness, especially immediately after a period of lying down and lameness. Slowness to rise and a tendency to walk with short steps on tiptoes frequently in association with a marked inward curve of hindlimb motion during forward progression and side-to-side motion of the buttocks is frequently seen. More severely affected pigs sit on their hindquarters and are reluctant to stand. They carry one or both hindlimbs more forward under the body and walk with a short goose-stepping gait. Wasting is not a feature except in severely affected animals and the locomotor disorder may be minor unless exacerbated by physical exertion.

ficacious and safe for the treatment of non-infectious locomotor disorders in pigs. Treatment with 2.5-D vitamin D had no effect on the incidence and severity of OC/OA lesions. Animals that are affected with clinical signs should be removed from the herd quickly and, if necessary, should be humanely destroyed as soon as possible.

**CONTROL**

Because the etiology is unknown, it is not possible to provide specific control measures. The hereditary nature of the disease suggests that the selection of breeding stock with sound legs and a low incidence of lesions would be an effective long-term control measure. Genetic control of leg weakness has been documented by various researchers. Selection of boars for leg soundness has dramatic effects on the structural soundness of their crossed progeny and therefore selection of structurally sound replacements must be maintained if leg weakness in market or breeding pigs is to be avoided. Divergent selection for leg soundness in Duroc pigs has been dramatic. Progeny of leg-soundness sires had significantly better measures for all leg traits at 104 kg than did progeny of leg-weakness sires. Differences between the two progeny groups indicated that the realized heritability for front leg soundness exceeded 0.50.

Selection of breeding stock will require careful genetic selection, examination of all pigs which are to be retained for breeding, necropsy of siblings of affected pigs and of the same gender, to identify genetic lines of pigs which have a low incidence of lesions. A recent study showed that the increase in wild boar alleles in crosses with Large White pigs exceeded that in Duroc and Landrace crosses. Genetic control, in concert with careful genetic selection, examination of all pigs which are to be retained for breeding stock with sound legs and a low incidence of lesions would be an effective long-term control measure. **SPORADIC LYMPHANGITIS (BIGLEG, WEED)**

This is a non-contagious disease of horses characterized by acute fever, lymphangitis and severe swelling of one or both hindlegs – forelimbs are rarely, if ever, affected. The disease commences abruptly with fever (40.5–41°C, 100.5–102°F), shivering and a rapid pulse rate and respiratory. Pain in the acute disease can be severe. There is severe pain on palpation of the affected leg and lameness may be so severe that the horse may refuse to put its foot to the ground. The limb is swollen and hot; the swelling extends from the top of the leg and down to the coronet. There is cording of the lymphatics on the medical aspect of the leg and palpable enlargement of the lymph nodes in some horses. The acute disease resolves into a chronic phase with persistent and variable swelling of the leg, intermittent fever, and variable lameness. Occasionally abscesses develop in the lymph nodes and vessels but usually there is no localization of the infection. There is a tendency for the disease to recur and cause chronic fibrotic thickening of the lower part of the limb extending to the level of the stifle in many horses. Swelling of the leg is often exacerbated by late pregnancy.

Sporadic lymphangitis can be associated with superficial wounds and ulcers on the lower parts of the limbs, but often there are no wounds detected. The disease is thought to develop as a lymphangitis and, potentially, lymphadenitis of the deep inguinal nodes as a result of these wounds. The affected lymph nodes and swelling of the limb obstruct lymphatic and venous drainage causing lymphatic obstruction, edema and, in some cases, cellulitis. Ultrasound guided aspiration of this fluid yields fluid with a low total protein concentration and mild neutrophilia (high proportion of the cells present in the fluid are neutrophils, although the absolute count is usually less than 1.0 x 10⁶ cells/L). Culture of the fluid is recommended, and Actinobacillus sp. have been obtained. The clinical significance of results of culture of the fluid is unknown, but results could be used to guide choice of antibiotics. Radiographic examination is usually unremarkable apart from demonstrating the soft tissue swelling. Affected horses, in both the acute and chronic stages, have a mild neutrophilia and hyperfibrinogenemia.

Acute affected horses should be treated aggressively. The principles of treatment are control of the presumed infection, reduction of inflammation, and reduction of swelling. Penicillin or other antimicrobials should be administered parenterally to control the infection. Non-steroidal antiinflammatory drugs (phenylbutazone, flunixin meglamine, carprofen, or similar) should be administered to...
control the inflammation and provide pain relief. The limb should be hosed with cold water once to twice daily to reduce heat and provided with gently massage therapy. Manual massage of the limb might be beneficial. Supportive, compressive bandaging of the limb can reduce the swelling. The horse should be exercised as much as is practical and humane.

Horses with chronic disease should be treated with prolonged courses of antimicrobials (penicillin, sulfonamide-trimethoprim combinations, enrofloxacin, or rifampin in combination with sulfonamides-trimethoprim), non-steroidal drugs, and local therapy. Acute exacerbations can be managed by administration of dexamethasone (40 μg/kg orally or parenterally, once daily for 5 days, and then gradually tapering). This dose is not abortifacient in pregnant mares. Exercise and supportive bandaging are important in minimizing the swelling. The chronic disease requires prolonged and intermittent therapy, often for the rest of the horse’s life.

Prevention of the disease necessitates prompt and careful treatment of all wounds of the lower limbs. Provision of daily exercise, restriction of the diet during prolonged rest periods and dry standing in the stable also help to prevent the disease.

**LAMINITIS OF HORSES**

<table>
<thead>
<tr>
<th>Synopsis</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>ETIOLOGY</strong> Laminitis is caused by acute degeneration of the sensitive primary and secondary laminae of the hoof. The cause of this degeneration is unknown although a number of theories have been propounded and are summarized under 'Pathogenesis'. Situations that are associated with increased risk of laminitis include access to lush pasture (suspected as the cause in 46% of field cases), grain overload (7%), retained placenta (2%), and colic or diarrhea (3%). Ingestion of large quantities of soluble carbohydrate, such as grain, bread, calf feed, or exposure to shavings of black walnut (juglans nigra) causes laminitis.</td>
</tr>
</tbody>
</table>

**EPIDEMIOLOGY**

**Occurrence**

Single sporadic cases are the rule for horses in which the disease is usually related to individual risk factors such as obesity, systemic illness, or lameness. An estimated 13% of horse operations in the United States have a horse with laminitis at any one time, and laminitis accounts for 7.5 to 15.7% of all lameness in horses. Laminitis accounts for up to 40% of hoof problems in horses, depending on the use of the horse. Approximately 5% of horses with laminitis die or are euthanized. Among cases occurring in the field (as opposed to veterinary hospitals) approximately 74% recover and become sound, with 8% improving but continuing to be lame, however, approximately 10% of horses that developed laminitis had a permanent change in their primary use as a result of having developed laminitis.

**Risk factors**

**Animal risk factors**

With the exception of overweight ponies and horses with systemic disease, there are only a few identified innate factors that predispose individual horses to the development of laminitis:

- Any association between the disease and age, sex, or breed is weak, again, with the exception of ponies. There is no difference in risk among horses used for pleasure riding, showing, breeding, racing, or farm and ranch work.
- The disease is more common in the United States during spring and summer (1.5% in spring and 0.4% in winter in the central US). The disease is very uncommon in foals and horses < 8 months of age, and then increases in frequency with increasing age such that horses > 20 years of age have an incidence of the disease roughly 3 times that of horses between 5 and 20 years of age.

**Overweight ponies** appear to be most susceptible and the disease occurs four times as commonly in them as in other classes of horse.

- Fat ponies at pasture and getting little exercise commonly develop the chronic form of the disease.

**Trauma and other physical factors**

such as excessive work on hard surfaces, increased weight bearing on one limb, and persistent pawing contribute to the development of the disease in horses. Standing for periods of days during transport may predispose to laminitis. For horses that are severely lame, and not bearing weight in the affected limb, the risk of developing laminitis in the contralateral limb is related solely to the duration of lameness and not to body weight.

Laminitis is associated with many systemic illnesses of horses. Horses with illness attributable to colic, diarrhea, pleuropneumonia, and metritis are prone to develop laminitis.

**Potomac horse fever** (equine neorickettsiosis) is frequently a cause of laminitis in horses and laminitis is the major cause of mortality from this disease. Approximately 28% of horses with **anterior enteritis** (duodenitis/proximal jejunitis) develop laminitis, usually within 2 days of developing enteritis. There are anecdotal reports that suggest that administration of corticosteroids (dexamethasone, triamcinolone) causes or exacerbates laminitis, but this association has not been proved.

Laminitis is common in horses that engage on grain or similar feeds containing a high concentration of soluble carbohydrates. Ingestion of large quantities of lush pasture has been anecdotally associated with increased risk of laminitis, especially amongst ponies. It is believed that the presence of a high concentration of soluble carbohydrates fructans in the grass is responsible for the increased risk of laminitis. Fructans are metabolized in the large colon and may mimic the situation after ingestion of a large quantity of soluble carbohydrate.

**Importance**

Death is unusual, but the severe lameness may cause a great deal of inconvenience and affected horses may develop permanent deformities of the feet. Many have to be euthanized.

**PATHOGENESIS**

The basic lesion of laminitis is the separation of the sensitive laminae of the third phalanx from the interdigitating laminae lining the internal surface of the hoof, so that the third phalanx drops through the hoof and comes to rest on the sole. Exactly
It is speculated that a **pain-hypertension-vasoconstriction** cycle develops in horses with acute laminitis. The pain associated with the laminar degeneration causes release of vasoconstrictor substances such as the catecholamines, angiotensin II, and vasopressin. These substances then cause peripheral vasoconstriction with a subsequent reduction in blood flow to the foot, and systemic hypertension.

The common thread is that degeneration of the sensitive laminae. Loss of the connection between the third phalanx and hoof allows the third phalanx to rotate within the hoof capsule, likely in response to the torque applied by the deep digital flexor tendon, and to displace ventrally (sink) within the hoof as a result of weight transmitted through the third phalanx; or there may be a combination of these changes. Rotation of the third phalanx causes the sole to be pushed downward or 'dropped', and the point of the toe of the third phalanx may actually penetrate the sole. Serum accumulates in the space created by degeneration of the laminae and displacement of the third phalanx and there is breakdown of the white line.

Many of the inciting causes of laminitis are diseases that may be associated with endotoxemia, and in experimental models endotoxin was detectable in the blood of horses that developed laminitis, suggesting that endotoxin may contribute to the development of the disease. However, infusions of endotoxin do not cause laminitis, although endotoxin does impair endothelium-dependent relaxation and augments adrenergic contraction of palmar digital arteries. The disease occurs in 3 distinct phases: (1) a developmental stage in which lesions are detectable in the sensitive laminae but during which there are no clinical signs; (2) the acute phase from the development of the first clinical signs through to rapid resolution or to rotation or ventral displacement of the third phalanx; and (3) the chronic stage evidenced by rotation of the third phalanx with or without ventral displacement and characterized by variable but persistent pain.

### CLINICAL FINDINGS

The disease presents as both an acute disease and as a chronic disease. The severity of the acute disease varies considerably from very mild with rapid (5–7 days) recovery, to severe with progression to the chronic, refractory stage.

**The acute disease** develops rapidly; apparently normal horses can founder within hours. Signs of the disease are entirely attributable to pain in the feet. All hooves may be affected, but more commonly the fore feet are affected and the hind feet are spared. The disease is rarely unilateral except in cases in which the disease develops because of severe lameness in the contralateral limb or repeated pawing. Mild, or early, disease is apparent as a resistance to movement and repetitive and frequent shifting of weight from one foot to the other. There is a characteristic shuffling gait.

**More severe disease** is apparent as refusal to move or to lift a hoof. At this stage the horse wears an expression of great anxiety, accompanied by muscle fasciculation, sweating, a marked increase in heart rate to as high as 75/min, rapid, shallow respiration, and a moderate elevation of temperature. There is a characteristic posture with all four feet being placed forward of their normal position, the head held low, and the back arched. There is usually a great deal of difficulty in getting the animal to move and when it does so the gait is shuffling and stumbling and the animal evidences great pain when the foot is put to the ground. The act of lying down is accomplished only with difficulty, often after a number of preliminary attempts. There is also difficulty in getting the animals to rise and some horses may be recumbent for long periods. It is not unusual for horses to lie flat on their sides. In occasional cases the separation of the wall from the laminae is acute and the hoof is shed. There may be exudation of serum at the coronet and this is considered a sign of impending sloughing of the hoof and a poor prognosis.

**The diagnostic signs** in laminitis include pain on palpation around the coronet and a marked withdrawal response when hoof testers are applied to the hoof. The **intensity of the pulse** in the palmar digital artery, palpable over the abaxial aspects of the proximal sesamoid, of affected feet is markedly increased over normal. In horses in which the third phalanx is displaced distally (sinks), a concavity may be palpable at the coronary band. Infiltration of the palmar digital nerves at the level of the proximal sesamoid with local anesthetic agents provides marked, but not complete, relief.

### In the chronic stages

In the chronic stages of the disease there is separation of the wall from the sensitive laminae and a consequent dropping of the sole. The hoof wall spreads and develops marked horizontal ridges, and the slope of the anterior surface of the wall becomes accentuated and concave. Horses with chronic or refractory laminitis may continue to feel much pain, lose weight, and develop **decubitus ulcers** over pressure points because of prolonged recumbency. Loss of integrity of the sole and disruption of the white line may
allow infection to develop in the degenerate laminae. The infection may spread to involve the pedal bone, causing a septic pedal osteomyelitis. The lameness may abate but the animal becomes lame easily with exercise and may suffer repeated, mild attacks of laminitis.

Radiographic examination of the feet may not reveal, initially and in mild cases, changes in the position of the pedal bone. Radiographs of more severe or advanced cases will demonstrate rotation of the pedal bone within the hoof, evident as a tilting of the most distal aspect of the third phalanx toward the sole. The space created by rotation of the pedal bone may fill with gas or serum and be evident as a radiolucent line between the pedal bone and the dorsal hoof wall. Displacement of the pedal bone toward the sole will be evident in approximately 25% of cases as a thickening of the dorsal hoof wall and reduction of the distance between the sole and solar aspect of the pedal bone. Chronic or refractory cases may have osteopenia of the pedal bone with proliferation of bone at the toe.

Prognosis. The radiographic examination provides information of prognostic value. Horses that return to their previous level of athletic function after a bout of laminitis have pedal bone rotation of less than 5.5°, whereas horses that can no longer perform as athletes usually have more than 11.5° of rotation. However, there is considerable overlap between groups and these values should only be used as rough guidelines. The general rule is that the greater the degree of rotation, the worse the prognosis for return to function and pain-free living.

Objective radiographic variables include the distance between the proximal aspect of the hoof wall (marked on the radiographic image by a piece of wire or strip of metal stuck to the dorsal hoof wall) and the proximal limit of the extensor process of the distal phalanx (the 'founder' distance), and the distance between the dorsal hoof wall and the dorsal cortex of the distal phalanx. While values for these measures vary among breeds and with the size of the horse, most normal horses will have a 'founder' distance of 4.1 ± 2.2 (standard deviation) mm and a wall thickness of 16.3 ± 2.4 mm.

CLINICAL PATHOLOGY
There are no changes that are characteristic of the disease.

NECROPSY FINDINGS
The disease is not usually fatal but if a necropsy examination is carried out on an acute case, the stomach usually contains excessive amounts of grain, which has a pasty, mealy consistency and an odor suggestive of putrefaction of protein. Retained placenta and metritis may be present in postpartum laminitis in mares. No other reliable gross findings are visible, although the vessels of the sensitive laminae of the digital cushion may appear engorged if the cut surface of the hoof is examined.

In subacute and chronic cases the diagnosis can easily be confirmed by gross examination of sagittal sections of the foot. This permits assessment of the horn, soft, and osseous components of the foot. In some cases the degree of rotation of P3 results in perforation of sole.

Histological examination is required only in acute cases and confirmation of the diagnosis in such instances demands that the foot be cut into slab sections and fixed shortly after the death of the animal, before even moderate autolysis can ensue. Microscopically, the sequence of acute changes in experimentally induced laminitis begins with the loss of some of the keratogenic structures of the epidermal laminae. This is followed by vascular engorgement, edema and some necrosis of laminar tissues.

Radiographic examination of the feet may not reveal, initially and in mild cases, changes in the position of the pedal bone. Radiographs of more severe or advanced cases will demonstrate rotation of the pedal bone within the hoof, evident as a tilting of the most distal aspect of the third phalanx toward the sole. The space created by rotation of the pedal bone may fill with gas or serum and be evident as a radiolucent line between the pedal bone and the dorsal hoof wall. Displacement of the pedal bone toward the sole will be evident in approximately 25% of cases as a thickening of the dorsal hoof wall and reduction of the distance between the sole and solar aspect of the pedal bone. Chronic or refractory cases may have osteopenia of the pedal bone with proliferation of bone at the toe.

Prognosis. The radiographic examination provides information of prognostic value. Horses that return to their previous level of athletic function after a bout of laminitis have pedal bone rotation of less than 5.5°, whereas horses that can no longer perform as athletes usually have more than 11.5° of rotation. However, there is considerable overlap between groups and these values should only be used as rough guidelines. The general rule is that the greater the degree of rotation, the worse the prognosis for return to function and pain-free living.

Objective radiographic variables include the distance between the proximal aspect of the hoof wall (marked on the radiographic image by a piece of wire or strip of metal stuck to the dorsal hoof wall) and the proximal limit of the extensor process of the distal phalanx (the 'founder' distance), and the distance between the dorsal hoof wall and the dorsal cortex of the distal phalanx. While values for these measures vary among breeds and with the size of the horse, most normal horses will have a 'founder' distance of 4.1 ± 2.2 (standard deviation) mm and a wall thickness of 16.3 ± 2.4 mm.

TREATMENT
Acute laminitis is an emergency and treatment should be started without delay, as early and aggressive therapy might enhance the chances of recovery.

The adage 'where facts are few experts are many' (Donald R. Gannon) applies well to the treatment of laminitis. There are no changes that are characteristic of the disease. The choice of treatment is based on personal experience, extrapolation from our imperfect understanding of the pathogenesis of the disease, the availability of certain drugs, and current fashion. In general, the treatments can be grouped into several classes, based on the intended intervention. These are:

- Removal of the causative agent or treatment of the inciting disease
- Pain relief and minimization of inflammation
- Vasodilation of blood vessels in the foot
- Prevention of formation of microthrombi in dermal capillaries
- Prevention of rotation or distal displacement of the pedal bone
- Promotion of keratinization and hoof growth.

The efficacy of administration of analgesic, anti-inflammatory, anticoagulant and vasodilatory drugs, local therapy such as ice baths of the hoof or having the horse stand in cold water, and mechanical support of the hoof has never been demonstrated in appropriate clinical trials.

Treatment of inciting disease
The inciting disease should be treated aggressively and every attempt made to remove any causative agent. Horses with traumatic laminitis should be rested and housed in stalls that are well bedded with sand or soft shavings. Horses suspected of having a tumor of the intermediate lobe of the pituitary gland should have the diagnosis confirmed and appropriate therapy instituted.

Analgesics and anti-inflammatory drugs
A mainstay of the treatment of both acute and chronic laminitis is the use of non-steroidal anti-inflammatory drugs (NSAIDs). Apart from the obvious humane requirement of providing pain relief, the use of NSAIDs is speculated to be beneficial by breaking the pain-hypertension-peripheral vasoconstriction cycle that may be important in the pathogenesis of laminitis. Furthermore, recent evidence suggesting that inflammation mediated by COX-2 plays a role in the developmental phase of laminitis supports the early and aggressive use of NSAIDs.

Phenylbutazone, at doses of 2.2–4.4 mg/kg intravenously or orally every 12–24 hours, is an effective analgesic in cases of mild to moderate laminitis. Higher doses (6.6 mg/kg every 12–24 hours) may be required in severe cases. However, the potential for phenylbutazone toxicity, evident as colic, gastrointestinal ulceration, nephrosis, hypoproteinemia, leukopenia, and hypothermia, is dose related and high doses of phenylbutazone should only be used for at most several days and only in severely painful horses.

Flunixin meglumine (1.1 mg/kg, IM or IV every 8–12 hours) and ketoprofen (2.2 mg/kg, IM every 12–24 hours) are also effective analgesics. Their concurrent use with phenylbutazone may enhance pain relief but also increases the risk of NSAID toxicosis. The use of aspirin is dealt with under Anticoagulants.

Dimethyl sulfoxide (DMSO), a putative anti-inflammatory drug that is also reputed to scavenge free radicals, has been used in the treatment of acute laminitis, again without clear demonstration of its efficacy. DMSO is administered at a rate of 1 g/kg, intravenously as a 10% solution in isotonic sodium chloride. The treatment can be repeated daily for several days.
VASOCONSTRICTION ASSOCIATED WITH THEIR USE.

Vasodilatory drugs are used on the premise that vasoconstriction is an important mechanism underlying the development or progression of acute laminitis. Several classes of drugs have been used including \(\alpha\)-adrenergic antagonists such as phenoxybenzamine and phentolamine, drugs with multiple mechanisms of action such as acetylpromazine and isoxuprine, and nitric oxide donors including glyceryl trinitrate (nitroglycerine) and L-arginine. None of the vasodilatory drugs should be used in horses with compromised cardiovascular function or dehydration.

Phenoxybenzamine and phentolamine are not readily available and have limited use. Phenoxybenzamine causes sedation. Acetylpromazine is a potent vasodilator, principally because of its \(\alpha\)-adrenergic antagonist activity, that is currently used frequently in the treatment of acute laminitis. Acetylpromazine increases blood flow to the digit, but its effect on nutritive flow to the laminae is unknown, as is the case for all the vasodilators. The effect of acetylpromazine persists for approximately 90 minutes after intravenous administration. Acetylpromazine can be administered at dose rates ranging from 0.01 to 0.05 mg/kg, IM, every 6–12 hours. Sedation may be considerable at the higher doses and/or with more frequent administration. Isoxuprine is a combined \(\alpha\)-antagonist and \(\beta\)-agonist that increases blood flow to the leg but not to the foot in normal horses. It has been used at doses of 1–1.5 mg/kg orally every 12 hours. Pentoxyfilline (44 mg/kg orally q8 hours) does not increase digital blood flow in normal horses. Application of glyceryl trinitrate, a nitric oxide donor, to the palmar digital arteries of affected horses has been reported to increase or not affect blood flow to the dorsal hoof wall. However, the effect of these substances on the course of the disease is unknown. In spontaneous cases of acute laminitis glyceryl trinitrate has been applied to the skin over both palmar digital arteries of affected feet at a dose of 15–30 mg per artery, once daily. However, because of lack of evidence of efficacy and the potential for systemic hypotension secondary to systemic absorption of the drug, its use is no longer recommended.

Anticoagulants
Anticoagulant drugs are administered to prevent the development of microthrombi within the hoof. Aspirin and heparin are commonly used. Aspirin is a very poor vasodilator in horses but is used because it reduces platelet aggregation in normal horses by blocking formation of thromboxane \(A_2\). However, thromboxane may not be an important cause of platelet aggregation in horses. Heparin is administered at a dose of 0.01 mg/kg orally every 48 hours. Heparin in sufficient doses prolongs blood clotting, provided that there is adequate antithrombin III in the patient's blood. Heparin has been reported to prevent or have no effect on the development of laminitis in horses with anterior enteritis or colic, respectively. Heparin can be administered at 40 to 80 \(\mu\)g/kg IV or subcutaneously every 8–12 hours for 3–5 days. Anemia may develop during heparin administration, but resolves rapidly when administration of the drug is stopped.

Mechanical support
Mechanical support to provide pain relief and in an attempt to prevent rotation or distal displacement of the pedal bone is an important part of the care of horses with acute laminitis.

Support of the frog and/or sole can be achieved using packing material such as dental acrylic or firm plastic that is molded to conform to the shape of the sole. Some clinicians prefer to use wedge pads to elevate the heel and reduce tension in the deep digital flexor tendon with the aim of preventing rotation of the pedal bone. Housing the horse on sand or similar soft bedding is important. The inciting disease should be treated aggressively.

After the acute phase has passed, likely in 5–7 days, attention should be given to trimming the hoof and corrective shoeing.

Promotion of healing

Methionine has been given to both acute and chronic laminitis cases on the known requirement for methionine in the chondroitin complex of collagen. There is some rationale for the treatment but it seems more appropriate as a supportive than as a principal treatment. The recommended oral dose rate is 10 g/day for 3 days followed by 5 g/day for 10 days.

Antibiotics may be indicated to prevent secondary infection of the degenerate laminae.

Rest is important in the convalescent phase. Horses with no rotation or sinking of the pedal bone should be given 21 days of rest after resolution of the clinical signs. Return to work should be gradual. Horses that develop rotation or sinking of the pedal bone should be monitored both by physical examination and radiographic examination. It will be many months before horses with even mild rotation can be returned to work. Horses with severe rotation will likely never resume active work, although they may become pasture sound.

Summary of treatment of acute laminitis

Depending on the cause, treatment of acute laminitis should include:

- The administration of non-steroidal anti-inflammatory drugs (preferably phenylbutazone)
- Vasodilators (acetylpromazine)
- Support of the frog and/or sole
- Housing on sand or similar soft bedding
- The inciting disease should be treated aggressively
- After the acute phase has passed, likely in 5–7 days, attention should be given to trimming the hoof and corrective shoeing.

Chronic, refractory laminitis

The prognosis for chronic or refractory laminitis (laminitis of more than 1 week's duration) is poor (see above for the use of radiography to determine prognosis). Treatment includes NSAIDs for pain relief, corrective shoeing (egg bar or heart bar shoes), and trimming of the hoof (shortening the toe or complete removal of the dorsal hoof wall). Tenotomy of the deep digital flexor may provide temporary relief but does not affect the long-term prognosis.

CONTROL

The disease is not readily subject to control because of its sporadic nature. Heavily fed or fat horses should be given some exercise when not working; if possible, horses in transit should be removed from the transport vehicle, given light exercise and rested for several hours at the end of each day; retained placenta in mares should...
be treated promptly. Heavy carbohydrate feeding should be avoided. Susceptible ponies should have limited access to pasture either by limiting the time that they spend at pasture or by application of a grazing muzzle.

**REVIEW LITERATURE**

**REFERENCES**

**LAMINITIS IN RUMINANTS AND PIGS**

**Synopsis**

**Etiology** Degeneration of the sensitive laminae of the hoof.

**Epidemiology**

**Cattle** An endemic disease of some herds of high producing dairy cattle, and in feedlots. Associated with ruminal acidosis, either clinical or subclinical.

**Clinical signs**

**Cattle.** Inapparent to severe lameness, most common in the hind feet. Predisposition to other infectious or traumatic diseases of the foot.

**Clinical pathology** None characteristic of the disease.

**Diagnostic confirmation** Physical examination. Radiography.

**Treatment**

**Cattle** Non-steroidal anti-inflammatory drugs. Corrective hoof care.

**Control**

**Cattle** Dietary control to prevent ruminal acidosis. Correction of housing and flooring problems.

**ETIOLOGY**

Laminitis is caused by acute degeneration of the sensitive primary and secondary laminae of the hoof. The cause of this degeneration is unknown. The disease is less well characterized than that of horses and several conditions are often classified as laminitis.

**EPIDEMIOLOGY**

**Occurrence**

In cattle the disease may occur as clusters in herds and on farms where a predisposition appears to be inherited or where access to large quantities of soluble carbohydrate are available such as for high producing dairy cows or feedlot cattle. On farms of high-producing dairy cattle the prevalence may be as high as 78%.1 The disease is also reported in calves and first calf heifers.

**Risk factors**

Cattle and sheep

**Subclinical laminitis** that predisposes to the development of other diseases of the hoof occurs in calves and first calf heifers and is common in intensively fed feedlot cattle.2 Laminitis, conditioned by the inheritance of an autosomal recessive gene, is recorded in Jersey heifers.3 There may be an association between the disease in feedlot ruminants and ruminal acidosis.

Beef cattle being prepared for shows are often grossly over fed on high grain rations and become affected with a chronic form of the disease which markedly affects their gait and may cause permanent foot deformity. The disease occurs in dairy cattle fed improper rations, and especially first calf heifers and cattle of herds attempting to increase milk production and is not uncommon for the disease to present as a herd problem.

Among dairy cattle the heifers are usually worst affected and the disease usually develops soon after calving, with more than 50% of cases occurring in the period 30 days before and 30 days after calving. There may be a relationship between being introduced to the herd, with the frequent harassment by dominant cows, when heavily pregnant and when the surface of the yards is rough. Housing may be important including standing in slurry or having to twist and turn in narrow passageways and races, and there is an association between the prevalence of the disease and rough concrete floors.3,5

Diet is an important risk factor for development of laminitis in heifers. Diets of wet, fermented grass silage are associated with a greater risk of laminitis than are diets rich in dry unfermented straw and a concentrate.7 Furthermore, transition from a low net energy diet to a high net energy diet immediately after calving increases the risk of subclinical mastitis in Holstein dairy cows.8

The disease is also reported to occur after metritis, retained placenta, mastitis, and mammary edema but the incidence is not usually very high.

**Pigs**

Laminitis has been recorded in pigs but the disease is difficult to diagnose in this species and many cases secondary to other diseases, e.g. postparturient fever, may be missed. The disease is also recorded when pigs are fed very heavy concentrate diets.

**Importance**

Subclinical laminitis of dairy cattle predisposes to other hoof diseases that may decrease milk production.

**PATHOGENESIS**

The pathogenesis of laminitis in cattle, sheep, and pigs is unclear, but likely has some similarity to that in horses (see Laminitis in horses). Subclinical laminitis can predispose to white line disease.

**CLINICAL FINDINGS**

Cattle and sheep

In these species the clinical picture is similar to but less marked than that observed in the horse.

In calves 4–6 months of age, and in heifers, an acute syndrome similar to that seen in the horse has been described. Affected animals lie down much of the time, and are reluctant to rise. When they attempt to rise they remain kneeling for long periods. Their standing posture is with all four feet bunched together and the back is arched; they shift their weight from foot to foot frequently and walk with a shuffling painful gait. The feet are painful when squeezed and later become flattened and enlarged and look as though slippers are being worn. There is severe ventral rotation of the third phalanx.

In adult cows some cases have acute signs, others show only local lesions. These include sole ulcers and patchy changes in the horn including softening, waxy yellow discoloration, and red-brown patches suggestive of previous hemorrhage. The cow is chronically lame.

Young bulls are very susceptible to laminitis and may develop abnormalities
of gait and posture, such as a stilted gait and frequent knuckling of the fetlocks, which may mislead the diagnostician.

**Chronic laminitis in adult cows** is characterized by a smaller anterior hoof wall-sole angle, down from 558 to 358, a concave anterior wall, and the appearance of horizontal grooves (growth arrest lines) around the entire claw. The sole is usually dropped a little and bluish, and sole ulcers may be present. Overgrowth of the sole of the lateral claw may reach the point of creating a false or double sole. The white line is greatly widened and disrupted and stones and other debris may be impacted in it.10

Chronic, traumatic laminitis is most common in heifers when they are first introduced into the milking or dry herds. Housing them on concrete and exposing them to frequent confrontations with bossy cows lead to the development of sole hemorrhages and inflammation of the laminae.

**Radiographic signs** in cattle include rarefaction of the pedal bone, particularly the claw, and the development of osteophytes at the heel and on the pyramidal process.

**Pigs**

In sows the clinical signs are similar and include arching of the back, bunching of the feet, awkwardness of movement, increased pulsation in the digital arteries and pain when pressure is applied to the feet.

**CLINICAL PATHOLOGY**

There are no changes that are characteristic of the disease.

**NECROPSY FINDINGS**

Histological findings in the feet of cows affected by laminitis are similar to those in horses.

### Differential Diagnosis

**Cattle**

White muscle disease, epiphysitis.

**TREATMENT**

Although similar principles to those used to determine treatment of laminitis in horses are likely to apply to cattle, treatment in cattle is usually limited to administration of NSAID (aspirin 0.3 grains/kg, orally every 12 hours, phenylbutazone 4.4 mg/kg orally every 48 hours or flunixin meglumine 1.0 mg/kg IV every 12 hours). The inciting cause (metritis, ruminal acidosis) should be treated aggressively.

**CONTROL**

Cattle and lambs which are brought into feedlots should be gradually introduced to grain feeds and a higher forage:grain ratio provided in the feed. Calves should not be fed intensively on grain until they are 14 months old because of the high frequency of internal hoof lesions at the earlier ages. Some protection against laminitis in dairy cattle in intensive units is gained by careful planning of housing units to make them more comfortable and less damaging to the feet, and by providing more straw in the cubicles. Exercise should be provided around calving time. Vaccination with a Gram-negative bacterin-endotoxoid combination vaccine has provided some protection against laminitis induced by grain overload. Dietary supplementation of biotin (20 mg per head per day) improves hoof health of primiparous dairy cows11 and may be beneficial in reducing the incidence or severity of lameness in a herd. This treatment might not improve objective indicators of hoof health, but it does improve production.12

### REFERENCES

susceptible to the abnormality ranges from 107 to 230 days. It is suggested that irreversible injury to the fetus occurs by day 180 of gestation.

Prenatal rickets was considered as a possibility in the early stages of the investigations. The overgrowth of chondrocytes and delayed mineralization of the growth plates of affected calves in previous years were similar to those described for neonatal rickets. In addition, the vitamin D concentration of silage may be low and the wavelengths of ultraviolet light necessary for transformation of the provitamin 7-hydroxycalciferol to vitamin D3 are almost entirely filtered out by the atmosphere during the winter months because of the acute angle of the sun in northern latitudes. In Canada, pregnant beef cows fed exclusively a diet of grass or clover silage during the winter months may have low levels of vitamin D. However, supplementation of pregnant cows with vitamin D3 during one winter season did not reduce the risk of abnormal calves.

The disease resembles ‘acorn calves’ which have occurred in California and Australia. One possible hypothesis suggests that the two conditions may share a common pathway.2 Certain unspecified seasonal and environmental conditions or stressors may convert forage into a teratogenic substance. In areas where acorn calves occur, supplementation feeding of the cows on pasture practically eliminates the problem.

CLINICAL AND PATHOLOGIC FINDINGS

The abnormalities are obvious at birth and characterized clinically by generalized joint laxity, disproportionate dwarfism and, occasionally, superior brachygnaethia.2 The anomaly has occurred in some beef herds for several consecutive years and has affected 2–46% of the calf crop.3 In a case reported from Ireland, the affected beef herd consisted of Hereford, Simmental, and Friesian cows bred to a Hereford or Charolais bull. The pregnant cattle were self-fed grass silage preserved with Kofasalt (calcium formate, sodium nitrite, and hexamethylene tetramine). Affected calves, were characterized clinically by disproportionate dwarfism, varying degrees of micromelia, limb rotation, joint laxity, and skull abnormalities.4 Inferior and superior brachygynaethia were present. Radiographically, the diaphyses were grossly shortened and thickened, the epiphyses were enlarged, misshapen and flared with increased opacity on some radiographs.5 Histologically, there was chondrodystrophic of the metaphysis of the dwarf long bones. Consistent changes in organ weights or in trace element status were not present, and there was no evidence of infectious agents. There was no evidence of an inherited basis for the abnormal calves.

The epiphyses of the long bones are abnormal with overgrowth of chondrocytes and delayed mineralization. The common defect is one of growth plate maturation. The secondary ossification centers are slow to develop. Perinatal mortality is higher in affected calves than for normal calves in the same herd. The joint laxity may cause problems with dystocia. Within a few weeks after birth, the joints in surviving calves become stable, and calves walk normally.

REFERENCES

SLIPPED CAPITAL FEMORAL EPIPHYSIS IN CALVES

This occurs in newborn calves of the well-muscled, rapidly growing European breeds, such as the Charolais, Maine-Anjou, and Simmental. It is characterized by varying degrees of lameness, palpable crepitus over the greater trochanter on passive manipulation of the affected limb, muscle atrophy in longstanding cases, and prolonged recumbency. Some calves carry the affected limb or drag the foot, whereas others tolerate slight weight-bearing during standing or walking. Most calves are lame at birth or within a few days after birth. About 75% of cases are associated with a dystocia and forced traction delivery.1

Laboratory stress testing of calf femurs found that mechanically induced fractures had configurations and locations similar to those found in clinical cases associated with forced extraction.2 The breaking strength of all femurs was within the magnitude of forces calculated to be generated when mechanical devices are used to assist delivery during dystocia. It is suggested that the femur is compressed during force extraction when the pelvis of the calf is wedged in the pelvis of the dam in anterior presentation. Every effort must be employed to avoid premature engagement of the calf’s stifle into the pelvic cavity to avoid or correct a ‘stifle lock’.2

Radiographically, there are varying degrees of displacement of the femoral neck from the head. In chronic cases there is partial resorption of the femoral head. Excision arthroplasty has been attempted with some encouraging results.

The disease must be differentiated from perinatal femoral nerve degeneration and neurogenic atrophy of the quadriceps femoris muscle which also occurs most commonly in the same breeds of cattle. The right hindleg is most commonly affected and affected calves are unable to bear weight on the leg; there is obvious neurogenic atrophy of the quadriceps muscle.3 The problem has been treated by stall rest, femoral head and neck excision, and open reduction by use of Knowles pins, multiple intramedullary pins, or interfragmentary compression screws.4

Slipped capital femoral epiphysis has also been reported in cattle 3–5 months and 1.5–2.3 years of age.3 Trauma is the suspected cause. If early diagnosis can be made, intramedullary pinning can provide a good long-term prognosis in cattle when function as a breeding animal is important to their future value.

REFERENCES

TAIL-TIP NECROSIS IN BEEF CATTLE

Tail-tip necrosis occurs in cattle housed in confinement on slatted floors. The disease has occurred in steers, heifers, and bulls being fed for beef production.1,2

The lesion is caused by a traumatic injury of the tail caused by trampling of the tail. The lesion begins at the tip of tail followed by varying degrees of extension proximally. Initially, the tip of the tail is swollen, followed by inflammation and suppuration. Histopathological changes are compatible with cutaneous ischemia as a pathogenetic mechanism.3 Extension of the infection can result in metastases to other parts of the body, resulting in abscesses and osteomyelitis. Affected cattle do not grow normally and deaths from pyemia may occur. The morbidity is about 5%. Approximately 10% of affected animals may be condemned for osteomyelitis and abscessation.

Risk factors

These include slatted concrete floors, close confinement, warm seasons, and a body weight above 200 kg. The risk increases as the space allotment, expressed as kg animal per m2 pen increases from approximately 165 kg/m2. Tail trampling is more frequent in slatted-floor pens with lower space allotment (1.5 m² per head) than in similar pens.
with higher space allotment (2.4 m² per pen head). In an Ontario study, no case of tail-tip necrosis was diagnosed in solid-floor barns, while 1.36% of cattle in slatted-floor barns were either treated or slaughtered for tail-tip necrosis. In a mail survey of feedlots in Ontario, 96% of 71 feedlots with slatted floors, but only 5% of 184 feedlots with solid floors, reported a problem with tail-tip necrosis from 1982 to 1986. Of 441 tails inspected at slaughter plants, 34.5% were affected, with 3.4% involving skin lacerations and infection, and 4.3% amputated before slaughter. Most cases occur from May to September when the temperature is above 18°C. This may be associated with increased contamination due to increased humidity and temperature under confinement conditions.

In slatted-floor barns, abnormal locomotor patterns occur from 20 to 25% of the times animals get up and lie down. When animals get up abnormally, they first rise in their front, and consequently assume a dog-like sitting posture. In order to obtain momentum to rise in the rear, they then start to sway back and forth. The tail may become pinched between the hock of the rocking animal and the floor, resulting in blunt trauma to the tip of the tail.

TREATMENT
Treatment consists of early amputation combined with intensive antimicrobial therapy. Early detection is important. During warm months, cattle confined on slatted floors and weighing more than 200 kg should be closely inspected at least 2 or 3 times weekly. This includes palpation of all tail tips because early lesions are difficult to see.

CONTROL
This is dependent on providing sufficient space for housed cattle on slatted floors.

REFERENCES

TOE ULCER AND NECROSIS OF THE APEX OF THE PEDAL BONE OF CATTLE

ETIOLOGY
A toe ulcer is a defect in the white line at the apex of the sole in adult cattle. Lameness does not occur in the early stages but discomfort gradually develops at which stage the animal carries the foot further forward than normal. The etiology is not well understood. In one series of cases, overtrimming using a grinding disc and/or perforation of the sole was considered a major cause (49%), laminitis in 30%, and traumatic injuries in 11%.

EPIDEMIOLOGY
In South America, where dairy herds are pastured and supplemented with concentrate and corn silage, toe ulcers are common lesions in heifers from 15 to 60 days after calving. Two types of toe lesions are usually presented. One is a single claw horn defect occurring in Zone 1 which after further examination, granulation tissue is often observed. This lesion responds well to local treatment and the application of an orthopedic block on the healthy claw. The second type of lesion is more severe and includes necrosis of the pedal bone, complicated by secondary infection.

CLINICAL SIGNS
Clinical signs of apical pedal bone necrosis vary widely depending on the severity of the lesions, the number of claws involved and the causative factors. A marked-to-severe lameness may occur in cows with one claw affected, and a severely stilted gait in cows with two or three affected claws. In some cases, the lameness is so severe that the initial impression from a distance was that of a neurological disease because of the severely stilted, convulsive limb movements at rest and walking. The involvement of the pedal bone can be determined by clinical examination, inserting a probe or by direct visualization of the discolored and exposed apex of the distal phalanx.

PATHOGENESIS
The gross pathological findings of affected claws vary from moderate topical inflammatory signs of the corium at the toe of the claw, to severe and extensive necrosis and osteomyelitis of the pedal bone. Histologically, there are different types of demarcation of the necrotic bone. Mixed infections are common.

Radiographically, the degree of involvement of the distal phalanx can be clearly identified, facilitating the choice of surgical therapy.

TREATMENT
Treatment options include excision of necrotic bone using a bone curette, resection of the necrotic apex of the distal phalanx, and digital amputation in severe cases.

DIFFERENTIAL DIAGNOSIS
Toe ulcers must be differentiated from toe abscesses which occur in yearling cattle and beef calves grazing irrigated pastures in the fall at which time they may be lame due to a toe abscess.

Diseases characterized by involvement of the skin

PITYRIASIS ROSEA
Pityriasis rosea is a condition of man. The condition is seen in pigs is not the same because of a prominent component of eosinophils and confluent zones of epidermal necrosis. Dermatopathological authorities have suggested that the condition be renamed postural psoriasiform dermatitis of pigs.

This skin disease of pigs resembles ringworm closely but skin scrapings do not reveal the presence of fungal hyphae or spores, and cultures for fungal growth are usually negative. Treatment with standard preparations used for pigs is usually ineffective, although spontaneous recovery may occur.

The disease occurs in sucking pigs and young pigs in the 10–14 weeks age group. Up to 50% of each litter and herd may be affected and in large groups of feeder pigs there may be only individual pigs or the majority of the group with lesions. The disease is usually innocuous, although digestive disturbances, particularly anorexia and, to a lesser extent, diarrhea and vomiting may accompany the appearance of lesions and affected pigs lose some body weight. There is no fever. Usually the condition resolves spontaneously after 2–4 months.

Lesions occur most commonly on the ventral abdomen but may spread to the rest of the body. They commence as small, red nodules which enlarge to flat plaques and become covered with thin, dry, brown scales. The lesions appear to enlarge centrifugally, leaving a center of normal appearance surrounded by a narrow zone of elevated, erythematous skin covered by typical scales. Individual lesions are generally circular except that they often coalesce to produce a large, irregular lesion. There is little irritation and the skin lesions, although obvious, are superficial. There is no loss of bristles. Histologically, the lesions show a progression from acute to chronic with a dense superficial and deep perivascular infiltrate of eosinophils, lymphocytes, and histiocytes.

The cause is unknown, although infectious, genetic and allergic causes have been suggested and there is strong evidence of familial susceptibility, either through inheritance or by vertical transmission of an infectious agent. Transmission experiments have been unsuccessful and the disease has been observed in SPF pigs.
produced by cesarean section.\(^5\) By analogy with a similar condition affecting man, it may be a viral infection. Treatment appears to be completely ineffective but in general consists of the local application of a salve containing 5% salicylic or iodized mineral oil. Affected pigs should be isolated from the group. Spontaneous recovery occurs in 6–8 weeks in most instances.

ANHIDROSIS (NON-SWEATING SYNDROME, PUFF DISEASE, DRY COAT)

Reduced ability to sweat affects horses in hot and humid climates. Affected horses are unable to maintain their body temperature within safe limits, especially during or after exercise, and suffer heat stress and a reduction in athletic performance. The only effective treatment is to move the horses to a cooler environment.

ETIOLOGY

The etiology of anhidrosis is unknown, but involves a reduction in the sensitivity of the sweat gland to \(\beta-2\) adrenergic stimulation, the normal stimulus for sweating in the horse.\(^1\) Hypothyroidism does not contribute to anhidrosis.\(^2\)

EPIDEMIOLOGY

The disease occurs in horses, and rarely in cattle, in countries with hot, humid climates including tropical and semitropical regions.\(^1\)

The overall prevalence is approximately 6% in Florida, with the highest prevalence (25%) in horses in training and the lowest prevalence (1%) in young horses.\(^2\) There is no reported sex or color predilection. Both native and imported horses are affected, apparently with similar prevalence.\(^3\) Among native horses the age of onset of the condition ranges from 1 year to 10 years.\(^3\) Foals, especially of draft breeds, can be affected. Horses imported to endemic areas usually do not develop the disease within 1 year.\(^3\) The incidence and severity of the disease are highest in the hotter season.

The disease is rarely fatal unless severely affected horses are exercised in the heat, in which case death from heat stroke can occur. The major importance of the disease is inability of affected horses to exercise and compete in athletic events.

PATHOGENESIS

Sweat is produced in horses by apocrine sweat glands that have a single type of secretory cell. The sweat glands are well innervated, and sweating is controlled by a combination of hormonal (\(\beta-2\) adrenergic) and neural factors.\(^4\) Sweat production increases with increasing concentrations of epinephrine in blood up to a peak value, after which sweating rates decline.\(^4\) Anhidrotic horses have lower initial and peak rates of sweat production, and lower overall sweat production, than do normal horses during intravenous infusion of epinephrine.\(^5\) Suggested, but unproved, mechanisms for decreased sweat production by anhidrotic horses include diminished glandular sensitivity to epinephrine, failure of secretory function, blocking of sweat gland ducts, fatigue of the gland, and gland atrophy.

Sweating is the predominant means by which horses dissipate heat. Reduction in the capacity to produce sweat results in an inability to effectively control body temperature during exercise and when temperature and humidity are high. The elevation in body temperature results in tachypnea in an attempt to dissipate heat through the respiratory tract. Hyperthermia impairs performance and, if severe, can result in heat shock, a systemic inflammatory response syndrome, and death.

CLINICAL FINDINGS

The most apparent clinical sign is lack of sweating in response to an appropriate stimulus, such as exercise. In severely affected horses, sweating may be limited to the perineum, brisket, and areas under the mane and saddle. Less severely affected horses have a diminished sweat response and may not lather during exercise. The skin becomes dry and scurfy and loses its elasticity, and there may be alopecia, especially of the face.

Affected animals become extremely tachypneic when heat stressed, leading to the colloquial term for the disease ‘dry puffer’. The animal’s appetite declines and it loses weight. Athletic performance is severely compromised. High body temperatures are observed after exercise, sometimes reaching 41.5–42°C (107–108°F) and persist for long periods.

The prognosis is poor for athletic function for affected animals that remain in hot and humid environments, but the condition may resolve if the horse is moved to a cooler climate.

CLINICAL PATHOLOGY

Plasma epinephrine concentrations are reported to be higher in affected horses than in unaffected horses,\(^6\) but this has not been a consistent finding among studies.\(^5\) Diagnostic confirmation is achieved by demonstrating reduced sweating in response to intradermal injection of epinephrine, or the \(\beta-2\) adrenergic agonists, terbutaline and salbutamol.\(^7\) A crude test involves the intradermal injection of 0.1 mL of a 1:1000 dilution of epinephrine. If the horse sweats then it is not considered to be completely anhidrotic. A semiquantitative test using epinephrine, terbutaline, or salbutamol may be useful in identifying partially anhidrotic horses.\(^6\)

Normal horses sweat when 0.1 mL of 1:1000 000 epinephrine is injected, while partially anhidrotic horses sweat only with higher concentrations (1:10 000 or 1:1000). Injections are usually made using small gauge needles (25 g) into the skin over the lateral aspects of the neck.

NECROPSY FINDINGS

There are no characteristic gross lesions at necropsy. Histologic examination of the skin of affected horses reveals abnormalities in sweat gland morphology including flattening of cells and loss of luminal microvilli and a reduction in the number of secretory vesicles. These findings are thought to be a consequence, rather than a cause, of the disease.

TREATMENT AND CONTROL

There is no specific treatment that restores the horse’s ability to sweat, other than movement to a cooler climate. Affected horses for which translocation to a cooler environment is not feasible benefit from housing in air conditioned stables so that exposure to high ambient temperatures is minimized. Exercise of affected horses during the coolest periods of the day is sensible. Affected horses are frequently administered electrolyte supplements, but without demonstrated benefit. However, as with all working horses, an adequate intake of sodium, potassium, and chloride should be insured.

Administration of thyroid hormone supplements is not warranted, and may be dangerous by increasing the metabolic rate, and therefore heat production, of affected horses. Vitamin E administration has no demonstrated efficacy.

Removal of affected animals to cooler climates is often necessary, although air conditioning of stables and maintenance of horses in higher country where they can be returned after a day’s racing may enable susceptible horses to be kept locally.

BOVINE OCULAR SQUAMOUS-CELL CARCINOMA

Ocular squamous-cell carcinoma, often referred to as 'cancer eye', is one of the most common neoplasms of cattle. The tumors are uncommon in cattle younger than 5 years and are rarely seen in cattle younger than 3 years. The condemnation rate of cattle with ocular squamous cell carcinoma in Canada is about 30% of cases. A squamous cell carcinoma of the anal and perianal area of a 15-year-old bull has been recorded.

Risk factors
The heritabilities, phenotypic, and genetic correlations of lid and corneoscleral pigment and eye lesions associated with eye cancer were investigated in 2831 Herefords from 34 herds in 21 states of the US and one Canadian province. The results indicated that lid and corneoscleral pigment were heritable and genetically correlated. These findings lead to the general conclusion that the genetic effect on pigment determines to a large extent the degree to which the eye is susceptible to some carcinogenic agent such as ultraviolet light.

In Zimbabwe, ocular squamous cell carcinoma was frequently observed in five breeding herds of Simmental cattle. In these herds, initial signs of the disease were evident in cattle about 3 years of age and gradually the prevalence increased to over 50% in animals older than 7 years of age. It is suggested that because most cattle in Zimbabwe are slaughtered by 10 years of age, that more than 67% of cattle without periorbital skin pigmentation would develop the tumor. The tumors were multiple and commonly bilateral. Simmental cattle have a complete or partly white face and the lack of facial pigmentation risks exposure to intense solar radiation when they are kept at a high altitude (1500 m) in a sunny and warm climate. The prevalence was much lower in white-faced Friesian cattle in the same environment which suggests a genetic predisposition for the tumors in Simmental cattle. In Zimbabwe, the tumor is not recorded in fully-pigmented cattle breeds.

The association between ocular squamous cell tumors and various measures of solar radiation indicate a significant association between increasing risks of developing eye cancer and increasing levels of radiation. Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge which receives the most sunlight. Cattle exposed to levels of radiation developing the disease at younger ages.

ETIOLOGY
A genetic-environmental interaction has been proposed as the cause. A relative lack of circumcircular and corneoscleral pigmentation, both of which are heritable, increases the probability of lesion development when the animal is exposed to a carcinogenic agent like the ultraviolet component of sunlight. The carcinoma has been regarded as a papilloma-associated tumor because papilloma virus can be found in the precursor lesions, and papillomavirus DNA in the carcinomas. However, advanced virological techniques have failed to reveal any association between the virus and the tumor.

The p53 gene product is highly expressed in bovine BOSCC, which provides support for its role in BOSCC tumorigenesis.

EPIDEMIOLOGY
Occurrence
Bovine ocular squamous cell carcinoma is a common neoplasm of the eyelids and the eyeball of cattle and one of the most common neoplasms of cattle. The disease is most common in beef cattle which are exposed to more sunlight than dairy cattle. The tumors are uncommon in cattle younger than 5 years and are hardly ever seen in cattle younger than 3 years. The condemnation rate of cattle with ocular squamous cell carcinoma in Canada is about 30% of cases. A squamous cell carcinoma of the anal and perianal area of a 15-year-old bull has been recorded.

Ocular squamous cell carcinoma is a disease that occurs in cattle exposed to high levels of radiation. Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge which receives the most sunlight. Cattle exposed to levels of radiation developing the disease at younger ages.

The association between ocular squamous cell tumors and various measures of solar radiation indicate a significant association between increasing risks of developing eye cancer and increasing levels of radiation. Ultraviolet light is generally regarded as an important risk factor. Most tumors are located only in the sun-exposed mucocutaneous areas not protected by hair. Tumors are predominantly localized in the third eyelid and the lateral limbus, and tumor growth usually starts at the outer edge which receives the most sunlight. Cattle exposed to levels of radiation developing the disease at younger ages.

Commercial cattle can be culled early without much loss, because only the head is condemned. Purebred cattle are more of a problem because of the difficulty of deciding when euthanasia must be humane, rather than another attempted extirpation of the eye.

PATHOGENESIS
The initial lesion may be on the eyelid or any structure in the conjunctival sac, except the avascular cornea or pigmented eyelid. Lesions can encroach on these tissues from others nearby, carrying a blood supply with them.

Lesions develop over three stages. The first stage is papilloma, which can be found in the precursor lesions, and the lack of facial pigmentation risks exposure to intense solar radiation. The tumor is located in the sclera adjacent to the lateral limbus, in the membrana nictitans (third eyelid), or in the lower eyelid. It is an invasive tumor, metastasizing along the draining lymphatics into cervical lymph nodes. Primary lesions of the lids are most likely to metastasize to these nodes.

Animals do not appear to develop resistance to the cancer; only a few cows with the disease develop measurable antibodies in their sera. It is one of the characteristics of this disease that the carcinomas appear to produce immunosuppressive substances, and removal of tumor mass reduces blood levels of them.

In countries and in herds where ocular carcinoma is common, it is not unusual to encounter lesions on the labia of the vulva, especially if there are patches of unpigmented skin.

CLINICAL FINDINGS
Typical precursor lesions are single or multiple plaques of gray-white, smooth or rough, hyperplastic to hyperkeratinized tissue anywhere in the conjunctiva. Plaques may develop into papillomas and acanthomas of the skin of the eyelids, also included as precursor lesions. Squamous-cell carcinomas may develop from any of these precursors which may also regress spontaneously. The proportion that regresses is of the order of 80%.

Classic BOSCC lesions resemble papillomas with a fleshy, sometimes crumbly, often necrotic and ulcerated mass attached to the lid or the orbit by a wide base. They are visible even when the eyelids are closed, and cause obvious irritation to the surrounding conjunctiva, resulting in increased lacrimation and sometimes in the discharge of pus. Invasion of surrounding tissues is common but metastases to nearby lymph nodes and to viscera occur in only a few cases and then only late in the course of the disease.
CLINICAL PATHOLOGY

Differentiation between carcinomas and precursor lesions is difficult clinically and cytological examination or biopsy is recommended for definitive diagnoses. The cytology of squamous cell carcinomas in domestic animals has been described.10

DIFFERENTIAL DIAGNOSIS

One of the difficulties encountered in the field is the clinical differentiation of benign precursor lesions from the malignant carcinomas; failure to do so may account for the high rates of spontaneous regression recorded, especially in Hereford cattle, where a spontaneous recovery rate of 88% is recorded. To avoid this inaccuracy, exfoliative cytology by the examination of smears of lesions is helpful. Combined with a clinical assessment this is the recommended method of confirming the diagnosis. Differentiation from similar lesions that are not BOSCC can only be achieved by proper laboratory examination of tissues.

BOSCC must be differentiated clinically from:
- Pink eye and its complications which results in excessive lacrimation and purulent material, and
- Lymphoma of the periorbital tissues which usually manifests as exophthalmos.

TREATMENT

Excision, sometimes by cryosurgery, is widely practiced in cattle. Results are good and treatment by the use of radioactive implants has also aroused favorable comment. Recurrence, or the development of new lesions at the same site, is a common sequel. Radical surgery, including removal of the local lymph nodes and parts of the salivary gland, may be desirable in some bovine cases. It is often combined with immunotherapy, e.g. with BCG vaccine injected systemically or into the lesion, or with vaccination with BOSCC tumor material. That there is a significant immune body response at the normal tissue-corneal interface has been demonstrated, but whether this plays any part in the rejection of the tumors is not known. One controlled trial in cattle showed that intralesional injection of BCG vaccine can interrupt neoplastic progression and prevent malignant disease. A permanent regression after BCG vaccination can be expected in 37% of cases, recurrence at the same site in 26%, and continued growth in 37%.10

A favorable response to a single injection of a saline phenol extract of fresh tumor tissue can induce a high rate of regression of ocular tumors with a higher recovery rate after the use of 200 mg of lyophilized tumor extract as compared with an injection of 100 mg. The injection may need to be repeated. Occasional tumors show enhancement of growth after vaccination, especially if it is repeated. The vaccine does not need to be autologous, and only one injection is required. A freeze-dried preparation of tumor antigen has been used successfully. In general, the use of a vaccine seems likely to provide a satisfactory method for controlling an esthetically distressing and financially important disease. Reports on the effect of vaccination with a tumor vaccine on the vulvar form of squamous-cell carcinoma vary.11

Other treatments which have received favorable comment, but need to be evaluated in the light of the known natural recovery rate of the benign precursor lesions, include electrothermal hyperthermia and combinations of the above procedures.

CONTROL

Because of the strong correlation between absence of pigmentation of the eyelids and the occurrence of the disease, and because of the high heritability of this pigmentation in Hereford cattle, it is suggested that a breeding program aimed at increasing the degree of pigmentation of eyelids could quickly reduce the incidence of the disease in this breed.10 A positive approach to the problem would be to crossbreed susceptible Bos taurus cattle with Bos indicus cattle which always have pigmented eyelids and have much less eye cancer. In Ayrshires there is a corresponding predilection for squamous-cell carcinoma of the vulva, but the neoplasm does not occur on both sites in the one cow. Selection on the basis of the occurrence of lesions alone results in only limited reduction in incidence.

EQUINE OCULAR SQUAMOUS-CELL CARCINOMA

Squamous cell carcinoma is one of the most common neoplasms of the horse and is the most common tumor of the eye and orbit but the rate of occurrence is low. The reported frequency has been highest in animals lacking periorcular pigmentation and is more common in Appaloosa, albino, and color dilute horses. An increased prevalence for ocular and adnexal SCC has been reported in draft horse breeds, Appaloosas, Paint Horses, Thoroughbreds, and Quarter Horses. A predisposition for the development of ocular and adnexal SCC has also been reported in geldings.1 The risk has been higher in draft breeds than in other pigmented breeds, probably related to the large expanses of white skin on the face and around the eye of the heavy draft breeds. The overall mean age range of affected animals is 8–10 years.2 In a series of limbal neoplasms in horses admitted to the Veterinary Teaching Hospital in the Netherlands, squamous cell carcinoma was the most predominant tumor type and Haflinger horses accounted for 69% whereas their occurrence in the hospital population was 5%.3

In a retrospective study of 50 cases submitted to the University of Florida Veterinary Medical Teaching Hospital, the Appaloosa accounted for the majority of cases4 which may be a reflection of the high level of solar radiation in southeastern US. The average age at which the tumor was diagnosed initially was 11.8 years; males accounted for 64% and females 36% of the cases. The rate of metastasis was 18%.

In the Florida study, higher cure rates were associated with surgical excision followed by radiation therapy for a cure rate of 75%; whereas with only surgical excision the cure rate was 55%.5 Best results with treatment are seen when surgical intervention is early.6 In horses, treatment is largely surgical but all of the immunological techniques developed for cattle have been used including local irradiation therapy with 85Sr or 222Rn.7

The most frequent site for ocular involvement is the nictitating membrane and conjunctiva but the eyelids and cornea are also involved. A case of limbal squamous cell carcinoma with invasion into the cornea and uvea of 12-year-old Haflinger gelding has been described.8 On initial presentation, a light-pink raised mass on the temporal limbus and conjunctiva of one eye was observed. Squamous cell carcinoma was confirmed histologically after keratectomy and cryotherapy. Seven months later, a smooth pink, progressively enlarging mass was observed within the cornea. Ultrasonographically, the mass was found infiltrating the corneal stroma and the anterior chamber. The globe was surgically removed. Histologically, a diagnosis of corneal ocular squamous cell carcinoma with deep stromal invasion, infiltration of the uveoscleral meshwork and iridocorneal angle and resulting intraocular extension was made.
A pigmented squamous cell carcinoma of the conjunctiva of a 17-year-old horse has been described.\(^7\)

Treatment of ocular and adnexal SCC has included various types of therapy, with and without adjuvant radiation therapy. Types of treatment without adjuvant radiation therapy include excision, cryotherapy, radiofrequency hyperthermia, immunotherapy, chemotherapy with cisplatin, and carbon dioxide laser ablation. Treatment with adjuvant radiation therapy includes use of strontium 90 (\(^{90}\)Sr) cobalt 60 (\(^{60}\)Co), gold 198, iridium 192 (\(^{192}\)Ir), cesium 137, iodine 125 (\(^{125}\)I), and radon 222 (\(^{222}\)Rn).\(^1\) In a series of 157 cases of ocular and adnexal squamous cell carcinoma, those treated with adjuvant radiation therapy had a significantly lower recurrence rate, compared with those treated without adjuvant radiation therapy, independent of anatomic location.\(^1\)

Superficial keratectomy followed by cryosurgery is a simple and effective procedure for the treatment of small-sized limbal tumors (less than 2 cm) in horses.\(^3\) Sophisticated equipment is not required and the legal restrictions associated with the use of radioactive substances in many countries are not a consideration.

Ocular pseudotumors have been described in horses. They are proliferative inflammatory lesions involving the eye, adnexa or orbit, which clinically mimics true neoplasms.\(^8\) Cases are characterized by a unilocular, pink proliferative limbal or perilimbal lesion. Affected horses may be from 5 to 9 years of age. Most cases occurred during the summer months and none of the affected animals had a history of trauma or recent deworming. The dorsal bulbar conjunctiva was most commonly affected, followed by the third eyelid. Lesions were relatively flat with indistinct margins or discrete and nodular. Histologically, the lesion is inflammatory characterized by predominantly lymphocytic infiltrates. The cause is unknown but an immune-mediated pathogenesis is suspected based on the preponderance of immunocytes consisting primarily of lymphocytes. Treatment consists of surgical excision alone, partial resection with anti-inflammatory therapy, or anti-inflammatory therapy alone.\(^8\)

**OCULAR SQUAMOUS CELL CARCINOMA IN GOATS**

A well-differentiated ocular squamous cell carcinoma has been described in two goats.\(^3\) The twin goats, one male and one female, were 3 years of age. Both animals had pigmented eyelids and had been reared at an altitude of 760 m above sea level in Italy. The lesions were very advanced when first examined. There was a history of bilateral ocular disease and impaired vision of 24 months duration. In the affected eyes, a firm mass with a fleshy appearance was evident, covering the entire cornea and protruding through the palpebral fissure. A bilateral ocular mucopurulent discharge, associated with corneal plaques, neovascularization and edema, was also present in both animals.

Histologically, cords and islands of squamous epithelial cells proliferated deeply throughout the cornea and invaded the basal layer, limbus, iris, and ciliary body, and other features, characteristic of a well-differentiated ocular squamous cell carcinoma.

Biomolecular studies to the identification of Papillomavirus-related DNA sequences within the neoplastic ocular parenchyma of both animals but immunohistochemical and ultrastructural examinations did not demonstrate viral particles.

**REFERENCE**

**COCKLE**

This is a superficial nodular dermatitis of sheep recorded only in New Zealand that results in nodules in the skin that are of economic importance to the leather industry. The presence of cockle downgrades the value of the pelt.

Cockle is not usually diagnosed clinically but examination by close inspection of the skin over the upper shoulder region after close shearing has high specificity for detection.\(^4\) The lesions are the result of an immune response in some sheep to infestation with the biting louse \(Bovicola avis\). The occurrence of cockle and its severity is positively correlated with the severity of the louse infestation\(^5\) and sheep that develop lesions have \(B. avis\)-specific homocytotropic antibody. Serum histamine concentrations are significantly higher in louse-infested lambs than louse-naive lambs.\(^6\)

Lesions commence on the neck and shoulders and may extend over the entire pelt. Widely distributed lesions, 'scatter cockle', are attributed to infestation with \(B. avis\), and this is the most common cause but 'rib cockle' may be a hypersensitivity to infestation with the sheep ked \(Melophagus ovinus\). Pelt lesions in the dorsal midline region are usually due to infection with \(Dermatophilus congolensis\).\(^6\)

**CONTROL**

This rests with the control of \(B. avis\). For cockle control sheep should be treated off-shears with pour-on or spray-on insecticide and, as soon as practical after shearing, treated by saturation dipping. Saturation dipping is required to significantly reduce louse populations.\(^7\) Prelambling dipping is also recommended to reduce the risk of lambs acquiring louse infestations.

**REFERENCES**

**WOOLSLIP, WOOL LOSS**

Woolslip is a condition in which housed ewes, shorn in winter, lose part of their fleece and develop bald patches over a large area of the rear half of the back.\(^6\) This commonly starts at the base of the tail and progresses to the rump and back and less commonly the neck. There is no systemic disease; the skin is normal. Histological examination of skin biopsies show that in affected sheep the wool follicles are in the active anogen stage rather than the inactive telogen phase of unaffected cohort sheep and the wool regrows immediately following loss.\(^7\) The loss of wool starts 2-3 weeks after shearing. All breeds are equally susceptible and there is no effect of age or whether the sheep are carrying single or twin lambs; up to 40% of a flock may be affected. The wool loss occurs because of a premature and synchronized shedding of wool fibers and not because of a pathological process which damages the wool fiber. Wool shedding can be induced experimentally by prolonged treatments with corticosteroids and the current explanation for the wool shedding that occurs with the woolslip syndrome is that blood corticosteroid levels rise after the stress of shearing and are maintained for a long period because of the trauma of being housed and shorn and kept in the cold. Blood zinc concentrations in woolslip affected sheep are within the normal range and there is no epidermal change as occurs in zinc deficiency.

The prevention of the condition is aimed at reducing the severity and length of the stress period by shearing the sheep at the time of entry to winter housing and insuring a good nutritional plane in the post-shearing period.\(^6\) This hypothesis as to cause may not be correct as the syndrome has also been seen in the
summer in Wiltshire shorn sheep which had little history of stress in the period immediately preceding the woolslip.\textsuperscript{2}

Woolslip should not be confused with the normal shedding of wool that occurs in breeds such as the Wiltshire or Shetland in the spring period. Loss of wool along the backbone also occurs in older longwool sheep and may be exacerbated by lambs playing or sleeping on the ewe.\textsuperscript{3}

**Impairment of wool growth** and a **thinning of fiber diameter** can occur during the course of any **severe disease** such as bluetongue, pregnancy toxemia, or foot rot temporarily affecting the growth of the fleece. This results in a segment of the wool fiber that has decreased tensile strength and the condition has the name **tender wool**. Following recovery from the inciting disease the wool growth is normal but there is a line of wool with poor tensile strength in the staple. This can be observed in the intact fleece as a line of decreased fibre diameter, often with a change in crimp character and discoloration due to entrapment of dust. The wool may break if the staple on either side of this break is sharply snapped between the fingers. The fleece may subsequently be shed in part or in whole at the level of the defect, a condition known as **wool break**. Tender wool downgrades the value of a fleece and has economic significance in wool-producing sheep.

Zinc deficiency can reduce keratinization, reduce wool growth and occasionally result in fleece loss in sheep.\textsuperscript{4,5} Wool loss associated with pruritus occurs in association with external parasite infestations (Ch. 27) and with scrapie and pseudorabies in ruminants.

**Pelodora dermatitis**, characterized by thickening of the skin and complete wool loss in affected skin areas is recorded in winter-housed sheep where there was poor bedding management. The condition affected the majority of the ewes at risk. The parasite, *Pelodora (Rhabditis) strongyloides* is a free living nematode commonly present in decaying organic material but can invade hair follicles to produce an inflammatory response. Histological examination of the skin showed the presence of the parasite in wool follicles and infiltration of eosinophils and mast cells in connective tissue. Affected skin areas were those that had contact with the bedding when the sheep were lying down and large numbers of the nematode were found in the bedding. Clinical signs regressed with the more frequent provision of new bedding and disinfection of the stable.\textsuperscript{6}

**WOOL EATING**

Wool eating can occur as a result pica associated with micronutrient deficiency. A condition called **shimao zheng**, occurring in a region of the Gansu province of China has wool eating as its primary manifestation. The disease has a seasonal occurrence with the peak incidence in January through April. Both goats and sheep are affected but the incidence and severity is much higher in goats where 90% may show signs. Affected animals bite the wool or hair off their own or other animals bodies particularly in the hip, belly, and shoulder areas. Histology on biopsies shows heavily keratinized epithelial cells, a decreased number of hair and aggregated foci of lymphocytes in the dermis. Controlled trials have shown the condition can be corrected by supplementation with sulphur, copper, and iron.\textsuperscript{7,8} Wool eating is also recorded in Israel possibly associated with trace element copper and zinc deficiency.\textsuperscript{9} Wool and hair loss in individual sheep and cattle in association with excessive licking is recorded and are postulated as psychogenic dermatoses.\textsuperscript{10}

### CONVERSIONS

- To convert grams per 100 mL into grains per US fluid ounce: multiply by 4.564
- To convert grams per 100 mL into grains per Imperial fluid ounce: multiply by 4.385
- To convert grams into ounces avoirdupois: multiply by 10 and divide by 283
- To convert liters into US pints: multiply by 2.114
- To convert liters into Imperial pints: multiply by 88 and divide by 50
- To convert kilograms into pounds: multiply by 1000 and divide by 454

REFERENCE LABORATORY VALUES

Reference values for some frequently measured variables in blood and serum are provided as a guide. Values of these variables from healthy animals vary depending on many factors including age, breed, sex, diet, geographical habitat and methods of sample collection and laboratory measurement. The values listed below are compiled from a variety of sources including the clinical laboratories of the Western College of Veterinary Medicine at the University of Saskatchewan, the College of Veterinary Medicine at The Ohio State University, and Kaneko JJ. Clinical biochemistry of domestic animals, 5th edn. New York: Academic Press, 1997.

Tables of reference values for newborn foals and calves are provided elsewhere.

## Appendix 3

### DRUG DOSES AND INTERVALS FOR HORSES AND RUMINANTS

Suggested drug doses and intervals for horses and ruminants. Dosages listed are general recommendations and might not be optimal or efficacious in all instances and might need to be adjusted depending on the disease, its severity, patient factors including but not limited to age or diet, and because of regulatory considerations regarding milk and meat withholding times in animals intended as human food. Manufacturer’s recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer’s recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that could be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses, such as intramammary preparations, are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), intrarticular (IA), intramammary (IMM), intraperitoneal (IP), inhalation (IH), per rectum (PR), topically (TO), or subconjunctivally (10). Drugs recommended not to be given to certain species are indicated by NR.

### Appendix 4

**DRUG DOSES AND INTERVALS FOR PIGS**

Suggested drug doses and intervals for pigs, and concentrations of medicaments in feed. Dosages listed are general recommendations and may not be optimal or efficacious in all instances and may need to be adjusted depending on the disease, its severity, patient factors such as age or diet, and because of regulatory considerations regarding milk and meat withholding times in food animals. Manufacturer's recommendations should be checked before administering any drug and the effect on withholding time of varying from the manufacturer's recommendation regarding dosing should be considered. Local regulations regarding use of drugs in animals that may be used for human food should be consulted.

Doses are given in milligrams per kilogram body weight (mg/kg) unless otherwise stated (g = gram, iu = international units). Drugs given as total doses are denoted by TD. Dosing interval is given in hours, unless otherwise stated, or unless given as a single dose (SD). The route of administration is indicated as: intravenous (IV), intramuscular (IM), oral (PO), subcutaneous (SC), or intraperitoneal (IP). One ton = 1016 kg.
